The complexity of the system, soil-water-air, is apparent from the many forms that water can assume. This complexity and the variety of forms, sizes, and types of soil particles explain why no theory is valid for all soils, and why a liberal engineering judgment is necessary to produce a successful and stable road design.

In all soil mixtures the maximum stability is obtained at the highest density. The free water acts like a lubricant for the individual particles. The density varies according to four moisture phases; that is: (*a*) Hydration,[38] (*b*) lubrication,[39] (*c*) excess water and air, and (*d*) total saturation.

The optimum moisture occurs in phase (*b*); in phase (*c*) the volumes of free water and free air exceed the volumes of the pores, and the density diminishes because the specific gravity of the water is less than the soil particles; and, in phase (*d*), the water begins to occupy the air space, thus completing the total saturation of the soil.

In soils with a great quantity of large particles, the maximum density is obtained easily; probably because the large particles form a structure that permits transmitting the exterior forces deeper into the subsoil. M. M. Filatoff[40] states that the optimum grading of materials to secure stability in a roadbed soil is obtained by studying their cohesive qualities. His experience indicates that stability is dependent on the clay fraction although it is evident that under different conditions this clay fraction can possess different properties. The maximum and minimum hygroscopicity for clay soils is sometimes very useful. When the maximum is greater than the plastic limit, the soil is not suitable for flexible pavements. Factors such as these, that affect the capacity of a soil to support external forces, are very numerous.

[40] "Principles of Pedology Applied to Road Construction," by M. M. Filatoff, Moscow, 1936.

The complexity of the system, soil-water-air, is the cause of the many failures in roadway design. The subject, so well presented by Mr. Mullis, deserves coordinated and widespread research by everyone interested in it.

K. B. Woods,[41] M. Am. Soc. C. E.—The idea used by the author in establishing a degree of compaction in roadbed materials sufficient to exclude water in detrimental amounts may be accepted generally as a satisfactory approach to the problem. This same thesis was developed independently by the writer and L. E. Gregg, Assoc. M. Am. Soc. C. E.[42]

The author proposes an arbitrary value of seven tenths of the plastic limit as the limiting value of moisture content for roadbeds. However, it is impractical, if not impossible, to achieve this value in plastic, low-weight (Proctor peak) soils. In contrast, soil-aggregate mixtures with high Proctor weights would be compacted inadequately under this requirement. This discussion is directed to a consideration of these two points.

Considering first the last line of Table 5, the soil with a Proctor maximum of 85.0 lb per cu ft has a saturation moisture content of 35.8% and a plastic limit of 30.7%. If the soil were to be compacted so that the saturation moisture content would be only seven tenths of the plastic limit or 21.5%, the soil would need be compacted to a weight of 105.3 lb per cu ft or to a percentage compaction of 123.9. This degree of compaction is impossible with present-day equipment. Therefore, if it is necessary to construct a roadbed upon such a subgrade, it is generally more economical to utilize base courses constructed of granular material (from local sources of supply).

Referring again to Table 5, if the first line is considered, it will be noted that, at 100% compaction, a soil with a Proctor maximum density of 131.1 lb per cu ft has a saturation moisture content of 9.9%, and a plastic limit of 15.4; however, if the degree of compaction is changed such that the saturation moisture content is seven tenths of the plastic limit or 10.8%, then the material would have a dry weight of 128.6 lb per cu ft and the degree of compaction would be only 98.1%. In other words, it is more advantageous, in this instance, to specify 100% of the Proctor dry-weight peak than to limit the saturation moisture content to seven tenths of the plastic limit. Furthermore, assuming that this material consists of 80% aggregate, that would be retained on a No. 200 sieve and 20% soil binder that would pass a No. 200 sieve, the saturation moisture content of 10.8% would be contained in the soil binder and in the voids of individual aggregate grains themselves. In the latter instance, the soil binder or material passing the No. 200 sieve is likewise contained in the voids between the aggregate grains, and, as a result, the moisture filling the voids is 100% effective in lubricating the soil fines. In other words, by using the foregoing illustration, it can be readily shown that the moisture content of these soil fines amounts to 34.0% (that is, $\frac{(128.5 \times 0.108) - (102.8 \times 0.05)}{(128.5 \times 0.2)} = 34.0$)

when the entire soil-aggregate mass has a moisture content of 10.8% and assuming that the absorption of moisture within the aggregate is 5.0%. In most instances, this moisture content will be several points above the liquid limit of the material passing the No. 200 mesh sieve. Thus, it can be seen that the limiting value for moisture content of seven tenths the plastic limit for semigranular mixes used in base courses is not necessarily adequate.

In conclusion, the writer feels that the over-all perspective of obtaining a degree of compaction sufficient to minimize the entrance of detrimental amounts of water is sound; however, it is often impractical to apply these principles to their ultimate with very plastic soils. In contrast, the use of the seven-tenths plastic limit as a limiting moisture content value for semigranular materials used as base courses may be entirely inadequate.

IRA B. MULLIS,[43] ESQ.—The science of roadbeds is being retarded by the use of too many empiricisms. Too many engineers have become engulfed in channels of procedure so deep as to obscure many of the simple laws of physics, thus beclouding the essentials of roadbed design. It was this situation that caused the writer to begin the paper with a review of the properties of gases, liquids, and solids which one discusser referred to as "academic." Therefore, for the sake of directing attention to these hidden causes of roadbed failure, the writer gladly accepts the criticism.

Attention is again directed to the effect of air at point A, and that of water at point B, in Fig. 1. The effect of these fluids on penetration resistance (load) is so apparent that no one familiar with stress-strain curves should overlook it. But they do! Common experience should tell one that for maximum resistance to weather and traffic the apex of the density-moisture curve should intersect the penetration resistance curve midway between points A and B.

Rock matter of which roadbeds are formed consists of minerals having usually a definite chemical composition and, if formed under favorable conditions, a certain characteristic atomic structure is expressed in its crystalline form and in other physical properties. Even clay, the most weathered and changed residue of the original minerals, consists largely of crystalline matter and hence has definite properties. Of these properties, specific gravity is an important one. The specific gravity of kaolin, according to E. S. Dana and W. E. Ford,[44] is from 2.60 to 2.63, a value not far removed from that of the feldspars. It should be stated, however, that certain of the less common members of the kaolin group may have a specific gravity as low as from 2.00 to 2.20, although the high silica content of most clays utilized in engineering work causes the value to range near 2.65. In the absence of definite information, one should remember that a ±0.05 change produces a difference in pore space in most cases less than 4%. Another important property, particularly involving fine sediments such as silt and clay, is the critical point at which they become plastic. Other critical points of crystalline materials need not be discussed because of their lack of application to roadbeds.

Critical Moisture.—A very important critical point of roadbed material is the one at which a definite quantity of water causes a rigid body to change to a plastic one. Apparently no discussers were willing to contradict the value of this critical point although two denied its practicability. This phase will be discussed in a subsequent paragraph.

The "stability index" as defined in the paper (see heading, "Change of State" and the discussion of Table 3) is the ratio of the lower plastic limit to the moisture content. Since the date of first publication (April, 1945) research has been continued and the writer now (1946) desires to invert the ratio to read: The stability index is the ratio of the moisture content to the lower plastic limit. The latter definition is the one originally set up, but it was revised before publication to avoid an inverse relationship between the stability index and the stability stress (Cols. 10 and 11, Table 3). With this revision it is possible to combine the ratio of the moisture capacity to the critical moisture (lower plastic limit) with the stability index by multiplying the one by the other to give the "voids-moisture function" (Cols. 6, 7, 8, Table 10). By this combination it will be seen that an inverse relationship is found to exist between the voids-moisture function and the compressive strength of the cylinders of earth tested (Cols. 8 and 9). This relationship is to be expected as it is apparent that the actual water content and the pore volume also should affect strength in an inverse measure. The values in Cols. 8 and 9, Table 10 (from basic data presented by Henry C. Porter, M. Am. Soc. C. E.[45]), are shown graphically in Fig. 5. The characteristic break in the curve is due, no doubt, to the effect of critical moisture that occurs between 0.90 and 1.00. Similar data are shown in Table 11 with like relationships shown between Cols. 12 and 13. In this table no stability index is shown. The explanation for this may be found in Col. 10 with values slightly higher than those in Col. 9 obtained at estimated sat-

uration. This shows that actual moisture content (Col. 10, Table 11) is also practical saturation; hence, the voids-moisture function is equal to Col. 11 squared. Again the voids-moisture function follows the compressive strength values in inverse order without exception. These values (from basic data

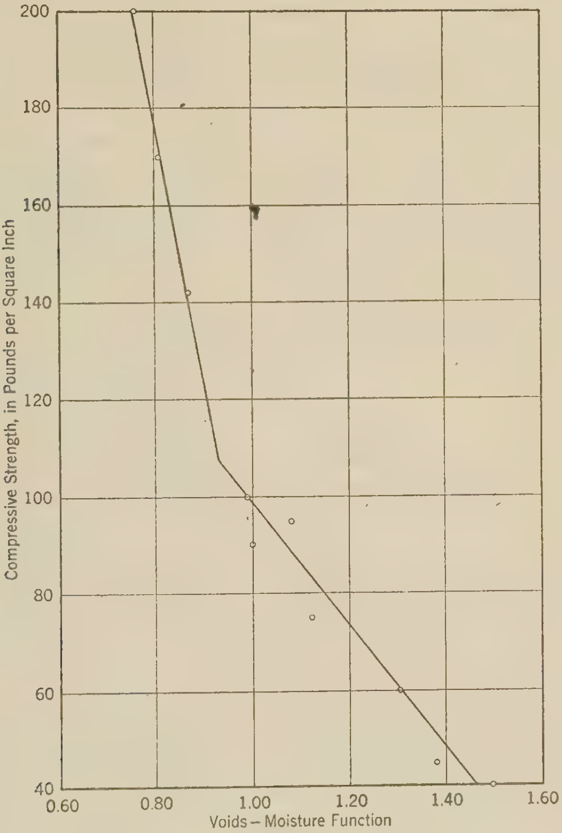

FIG. 5

presented by Mr. Porter[45]) are shown graphically in Fig. 6, the break in the curve being somewhat in excess of the voids-moisture function 1.00. The extent to which this deviation may occur is not known.

Values in Table 12 show certain physical conditions found in a survey of roadbed conditions in the State of Iowa. The table is considered as being representative of roadbeds in that state that did, and those that did not, have frost boils. Col. 11, Table 12, shows a mean ratio of pore capacity to the plastic limit of 1.49 in frost-boil roadbeds and of 1.23 in those that did not have frost boils. The mean thickness of gravel on frost-boil roadbeds was found to be 0.4 ft and in those without frost boils only 0.2 ft. At the time the writer computed the

data in Col. 9, he had not developed the term "voids-moisture function" although he has since computed the mean voids-moisture function of the frost-boil roadbeds in this survey and finds they have a value of 1.82. Those without frost boils have a value of 1.24. Therefore, by the use of the voids-moisture function, the relative strengths of the two conditions are probably more truly indicated.

Because of the lack of adequate experience in the use of the voids-moisture function, the writer hesitates to compare the values obtained from one material with those of another. He will suggest, however, that the frost-boil voids-moisture function of 1.82 be compared with specimen No. 8, Table 11, having a voids-moisture function of 1.77 and a strength of 5 lb per sq in. In a like manner, the non-frost-boil strength of 1.24 may be compared with specimen No. 2, Table 11, having a voids-moisture function of 1.19 and a strength of 19 lb per sq in. Again it may be compared with specimen No. 3 or specimen No. 4, Table 10, with a voids-moisture function of 1.31 and a strength of about 65 lb per sq in. This problem is one that seems to offer promise of success to the research engineer although additional research is needed.

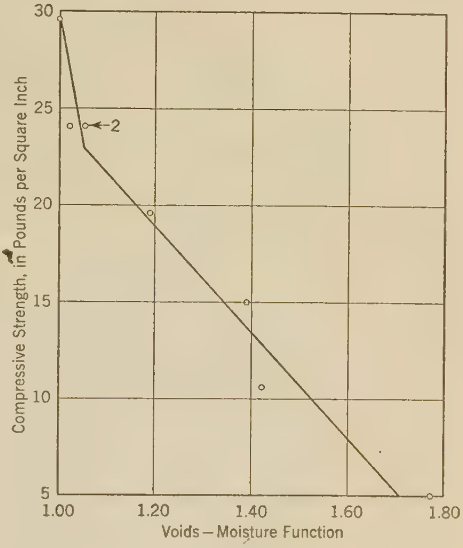

FIG. 6

Density.—The most striking manifestation of the density-strength relationship can best be shown by reference to Fig. 7, the rock cycle. This figure is a modification of one by Carey Croneis and William C. Krumbein[46] (see Richard M. Field,[47] and C. K. Leith and W. J. Mead,[48] Affiliate, Am. Soc. C.E.) but is modified by the insertion of the point at which the identity of the immediately preceding rock or sediment is lost. This loss of identity is the method used by the Committee on Sedimentation, Division of Geology and Geography, National Research Council,[49] as well as by William H. Twenhofel,[50] for differentiating the several forms of rock matter. Several states or phases of rock formation are shown in Fig. 7. Fig. 7 includes all the major stages of the cycle, including magmas, igneous rocks, unconsolidated sediments, consolidated sediments, and metamorphic rocks. In each stage certain types of rock representing important members belonging to it are shown. The several stages are connected by arrows showing the rock trend under given conditions of environment. Attention is directed to the term, "loss of identity," designated as the practical point at which one stage of the rock cycle passes into the next one.

Fig. 7.—Rock Cycle

The strongest and most weather-resistant rocks, such as granite, have very small pore spaces and hence absorb very little water (Fig. 7). Of course weathering, including temperature changes, eventually enlarges the pore spaces and at the same time causes them to lose part of their capacity to resist loads and weather. In the case of granites, for example, when weathering has caused the feldspar minerals to change to clay, the resultant material is a mixture of clay and sand (quartz). According to the authorities cited, the granite is said to have lost its identity and therefore becomes unconsolidated sediment, Fig. 7. If the parent granite is fine-grained, the resultant sediment will consist of fine sand, silt, mica, and clay. This unconsolidated sediment, whether wet or dry, will have much more pore space and hence can offer little resistance to loads and weather. The specific gravity of the parent granite was near 2.65 and that of the sediment is nearly identical. The outstanding change observed by the road engineer is the increase in pore space and attendant loss of resistance to loads and weather.

If a road is proposed across a belt of sediment derived from granite, the major problem of the engineer is the consolidation of the sediment to a measure that will not allow it to become plastic when fully saturated. The ideal toward which he should strive is to reduce the pore spaces to the measure of those in the parent rock, although the ideal is unattainable. Whether the proposed road is to be paved or used as an earth road, means must be found to seal the pores against the entrance of water in critical amounts or failure will follow sooner or later. How can this be accomplished? Returning to Fig. 7 one finds that nature converts unconsolidated sediments into more resistant consolidated sediments through cementation and compaction. Of course, the first step that should be made is to determine the plastic limit, the natural boundary between the rigid and plastic states. The second step should determine the possibility of consolidating the sediment to a measure that pore spaces will not receive water in critical amounts. To be successful, the engineer must determine the best method of converting certain unconsolidated sediments into consolidated equivalents. He must also know how nature converts gravel aggregate into gravel conglomerate, sand into sandstone, silt into siltstone, and clay particles into claystone. This is imperative if he is to build resistant roads. Moreover, this natural law applies to the making of Portland cement concrete, bituminous concrete, sheet asphalt, and sand-clay roads as well.

The application of data such as those shown in Table 10 is recommended as a means for analyzing roadbed problems and pointing the way to successful solution.

The values obtained on a homogeneous sample of clay in Table 10 computed from basic data by Mr. Porter[45] show the effect of density and water content on compressive strength. Table 10 also shows why the density-strength relationship is not always constant. For example, compare specimens Nos. 2 and 3, 5 and 6, also 7 and 8, in Table 10. Note the constancy of relationship between Cols. 8 and 9. Similar comments are also applicable to values in Table 11 computed from another series of tests by Mr. Porter and described in the same paper.

Table 12 shows the effect of density (Col. 3) and hence pore capacity (Col. 5) of roadbeds having frost boils and those without them. Although the mean percentage of pore saturation (Col. 6) in frost-boil roadbeds and the mean percentage of pore saturation in non-frost-boil roadbeds are nearly identical, one may observe the effect of low porosity (Col. 5) in the prevention of failure.

The part of Table 9 on this phase of the subject, in Mr. Lacey's discussion, shows striking contrasts between the modulus of deformation of like specimens of the higher densities (less wet) and that of those with the lower densities (wetter). In an effort to make the data as concise and conclusive as possible, the writer has recomputed the pore capacity in each case as a ratio of the lower plastic limit and presents it as Table 13. Without a single exception the reduction of the ratio (Cols. 2 and 4) causes a considerable increase in the modulus value (Cols. 3 and 5). In the case of sample No. 21 a reduction of about 70% of the modulus increases the strength about ten times. No doubt it would be very enlightening if one might have similar test data on identical samples compacted to produce pore capacities ranging from small to large values. Table 9 shows several cases in which an increase in density has produced a higher modulus even when the water content remains the same or is higher.

Messrs. McNew, Guerra, Feld, and Stuckey also support this method of approach in obtaining stability of roadbeds. Although Messrs. Britzius and Woods recognize the need of compaction, both seem to regard the standard proposed as impracticable although neither one offers any data in support of his belief. Apparently both base their opinions on the so-called Proctor density method (A.S.T.M. D698–42T and A.A.S.H.O. T99-38) as their standard of compaction used in conjunction with light rollers of comparable effectiveness.

[a] The four samples indicated in Col. 1 were remolded in the laboratory. The remaining sixteen were obtained in an undisturbed condition from the existing roadbed.

Mr. Britzius states that the writer's claim, that sediments compacted to low air voids are resistant to frost action, is misleading. Table 12 offers specific evidence in support of the value of low voids; and Tables 10 and 11 contain evidence showing that, since water content decreases with pore space, less damage through frost action should follow.

Mr. Woods states that it is impracticable, if not impossible, to compact certain clays to a water-capacity value equal to 70% of their plastic limit; he is no doubt thinking in terms of lightweight rollers and not of ones with weights suggested by the writer. Although the writer does not claim that certain clays, such as China clay and certain so-called pipe clays, can be compacted to prevent them from becoming plastic, he does insist that the use of excessive quantities of water, required to soften tough clays to bring them within the compaction range of light rollers, is a fallacy. This statement is proved when wide shrinkage cracks develop through drying after such light roller operation. Certainly one should expect roadbeds to be poor with pore spaces indicated in the last five tests in Table 5.

Through oversight, the writer failed to account for approximately 35% of coarse granular material in the first item in Table 5, referred to by Mr. Woods. This fact, of course, lowers the critical moisture in the mixture to perhaps 10%. On the basis proposed by the writer, the mixture should have a capacity of about 7%, although it is essential that the critical moisture point of mixtures be tested by the stress-strain method. Certain clays have been found with a density of 2.10 and experience teaches the writer that they are satisfactory when surfaced. It was this type of material the writer had in mind.

Compaction and Moisture Standards.—In 1933 R. R. Proctor[8] published a standard of compaction for earth dams which was intended to cause a body of earth to offer a needle resistance of not less than 300 lb per sq in. when saturated, and to restrict the percolation rate of water to 0.3 ft per yr. The quality of the work was measured by the capacity of the earth to support wheel loads and to resist the penetration of water. The weight of the roller and the number of its passes were such as to produce the required resistance to load and water. Density was intended only as a means for obtaining adequate resistance.

Some time after the introduction of this method, certain engineers undertook to improve on the Proctor method by applying a certain number of foot-pounds of energy to earth using the mold and rammer designed by Mr. Proctor. Whatever density this procedure produced was considered satisfactory by them. The method has been standardized by the American Association of State Highway Officials (T99-38). It has also been adopted by the American Society for Testing Materials as a tentative standard (D698-42T).

Like other materials, clays and other roadbed materials offer varying resistance to compaction or shaping. China clay or kaolin, being weak, offers little resistance, although gumbo and adobe offer much resistance to change of shape unless quite wet. Of course, all clays are brittle when dry but tend to become tough when the ideal proportion of water is absorbed. This being true, the tougher the clay the greater will be the quantity of water required to deform a clay under a small force. Since the deforming force in A.S.T.M. D698-42T is only 5½ ft-lb applied seventy-five times, it follows that the tougher the clay the greater will be the proportion of water required to soften it to the point where 5½ ft-lb will eliminate the maximum percentage of air space.

Table 14 substantiates this point.[51] Col. 3 shows that the material represented by curve No. 1 is the toughest as it requires the largest percentage of water to soften it within the range of the rammer. Optimum moisture, of course, decreases constantly throughout the series. The density value follows in inverse order; but the percentage of saturation of pore spaces remains near 90% in every test, with a maximum deviation of 8.2%.

According to the facts presented and the experience cited in the paper, roadbeds constructed with densities such as those in the upper third of Table 14 should be expected to offer little resistance to loads or the penetration of water.

With adequate means for compacting the upper third of the table, it probably could have been compacted to densities and moisture contents shown in the lower third of the table.

To expect to produce adequate consolidation in a mass of an unknown clay by means of applying a given amount of energy is like supplying a given quantity of fuel to an unknown steam engine or gas motor and assuming the delivery of a definite amount of power from the shaft. Of course, this is a grave fallacy that cannot be condoned. The effectiveness of consolidation can be measured only in terms of the resistance it offers to loads and weather.

In an effort to uncover as much fact as possible from Table 8, the writer has recomputed the data with results as shown in Table 15. For these computations the specific gravity of the sediment is 2.62 and the lower plastic limit is 19. With a density of 1.51 the water capacity is nearly 1.5 times the critical moisture (19%) and hence is of low bearing capacity. The pore space is so great that little swell occurred when compacted with only 12% moisture (42.8% saturation). Obviously, air content would be displaced if water entered and little swell followed. With a density of 1.85 and a moisture content of 14% (88% saturation) swell amounted to only 1.5% because the pore spaces were already so nearly saturated that little additional moisture was absorbed. The writer's interpretation of these and other similar data seems to indicate that for minimum volume change pore spaces should be reduced to a minimum, should be from 85% to 90% filled with moisture, and evaporation should be restricted by means of an adequate surface.

[a] For computing moisture capacity a specific gravity of 2.65 is assumed.

Economy of Consolidation.—Objections to raising the standard of consolidation seem to be based on the belief that it will be impracticable or too expensive, although no cost estimate has been submitted by the discussers. The writer found that prior to 1940 many materials could be consolidated to adequate densities at a cost of from 4¢ to 5¢ per cu yd. Cost data published under the auspices of the Tennessee Valley Authority[52] show a cost usually less than 5¢ per cu yd for sheepsfoot rollers exerting from 300 to 400 lb per sq in.; 4¢ per cu yd is equivalent to a cost of $1\frac{1}{3}$¢ for rolling 1 sq yd 1 ft thick. A cost of 10¢ per cu yd is only $3\frac{1}{3}$¢ per sq yd 1 ft thick.

In lieu of high consolidation two discussers would stabilize with aggregates; but it should be remembered that aggregates must be placed on firm roadbeds to avoid potholes or other types of failure. Moreover, it is not economical to import selected material until local roadbed material has been rendered as efficient as may be economically possible. For example, it would not be economical to haul pit-run gravel costing 60¢ per cu yd to be placed 4 in. thick at 4.4¢ per sq yd when a square yard could be rendered stable for surfacing by rolling it 1 ft thick at a cost of $1\frac{1}{3}$¢ per sq yd. Also, if one consolidated a road to a thickness of 1 ft at a cost of $1\frac{1}{3}$¢ and then placed only 2 in. of gravel on it at a cost of 2.2¢, the total cost would be only $3\frac{1}{2}$¢ and this of course would be much more valuable than the entire 4 in. of gravel placed on a less compact roadbed.

TABLE 15.—Effect, on the Total Swell, of Density and the Percentage of Saturation at the Beginning of the Swell Test (Recomputation of Table 8; "Sat." Denotes "Saturation" and "Sw." Denotes "Swell")

Compacted density (g per cm³)	Water capacity (%)	Percentage Moisture When Compacted									
		10		12		14		16		18	
		Sat.	Sw.	Sat.	Sw.	Sat.	Sw.	Sat.	Sw.	Sat.	Sw.
1.51	28.0	35.7	1.0	42.8	3.2	50.0	2.6	57.1	1.6	64.2	....
1.60	24.3	41.1	5.5	49.3	3.6	57.6	2.6	65.8	1.8	74.0	1.2
1.70	20.6	48.5	5.7	58.2	4.4	67.9	2.6	77.6	1.6	87.2	0.7
1.80	17.4	57.5	5.6	68.8	4.1	80.4	2.5	91.9	1.4	....	0.0
1.85	15.9	62.8	5.5	75.5	3.6	88.0	1.5	....	0.8	....	....

When aggregates cost considerably more than a dollar per ton (as they usually do), the economy of roadbed consolidation produces a striking contrast to usual procedure.

The reader is again directed to Table 12 showing the effect of roadbed compaction on the possible reduction of gravel thickness. Col. 5 shows a mean pore capacity of 29.7% in the frost-boil roadbeds with a mean gravel thickness of 0.4 ft (Col. 10). In contrast, the pore capacity in non-frost-boil roadbeds was 22.4% and did not fail with only 0.2 ft of gravel surface. As far as could be determined, no difference other than porosity existed. This survey seems to indicate that non-frost-boil roadbeds with a mean pore capacity of about 75% of that of frost-boil roadbeds remained stable with only one-half the gravel thickness, whereas frost-boil roadbeds failed. It is apparent, therefore, that a 25% reduction in pore capacity was of greater value than a 0.2-ft increase in thickness of gravel surfacing. Indeed if the cost of rolling should be as much as 15¢ per cu yd (5¢ per sq yd 1 ft thick) and the cost of crushed stone $1.40 per cu yd (7.8¢ per sq yd 4 in. thick)—a total of 12.8¢ per sq yd—this procedure would be more economical than spending the entire 12.8¢ for $6\frac{1}{2}$-in. stone alone. On the basis of past experience, including the survey shown by Table 12, if the writer had only 8.9¢ per sq yd available, he would appropriate 5¢ for consolidation and the remaining 3.9¢ for a 2-in. crushed stone surface.

Summary.—As a summary the following conclusions are offered:

1. The change from the plastic to the rigid state is indicated by rupture.

2. The point of rupture in fine sediments, as determined by the Atterberg and stress-strain methods, are nearly identical (Cols. 5 and 6, Table 1).

3. The point of rupture is affected more by moisture than by load (Cols. 1, 2, 3, and 4, Table 1).

4. The apex of the ideal density curve of a roadbed should intersect the penetration resistance curve midway between points A and B, Fig. 1.

5. Masses of earth compacted, as described in the paper under the heading, "Change of State: Consolidated Roadbeds," and in Table 6, absorb little additional water; hence, they remain stable.

6. The plasticity index is of very limited use in predicting resistance to impact or weather (Figs. 3 and 4).

7. The "voids-moisture function" appears to offer splendid possibility in predicting the capability of roadbeds to resist load and weather (Tables 10 and 11).

8. Since the most resistant rocks have little pore space and the least resistant rocks (unconsolidated sediments) have much pore space, it is evident that the least resistant ones can be made resistant only by the process of consolidation (Fig. 7 and Tables 10, 11, 12, and 14).

9. The two outstanding characteristics of the data in Table 14 are the constancy of saturation (Col. 5) at the time of compaction and the lack of uniformity of density (Cols. 1 and 2) upon completion of the compaction effort.

10. Obviously, sediments of the highest density and least capacity for moisture are the most resistant to traffic and water. It is also obvious that those having the least density and greatest capacity for water are the least resistant (Table 14). By increasing the compactive effort to a magnitude that would reduce optimum moisture to a nearly constant value, the density and moisture capacity in most cases, if not all cases, could have been reduced to a nearly constant value. However, micaceous and one-size sediments would continue to have large capacity for moisture.

11. To render sediments—especially clays—the most resistant to swell, they must be made very compact with pore spaces from 80% to 90% saturated (Tables 14 and 15).

12. To prevent sediments, especially clays, from losing moisture by evaporation, they must be surfaced with a covering that prevents undue evaporation.

13. Excessive evaporation losses from clay roadbeds can be prevented by the application of a thin blanket of loose sand, although a rigid surface (sand-clay, sand-asphalt, etc.) is superior.

14. Money spent in adequate roadbed compaction becomes an asset to the future road surface or pavement. Indeed, it may warrant the use of a less thick pavement at a considerable reduction in cost (Table 12).

In July, 1945, the U. S. Waterways Experiment Station,[53] Vicksburg, Miss., reported certain stress-strain data to which the present writer compared the voids-moisture function as in Figs. 5 and 6 and Table 11. The Vicksburg data, plotted as in Figs. 5 and 6, showed a similar relationship. As in Figs. 5 and 6, the data conform more closely to the curve when the voids-moisture or strength function is low. Also it should be stated that, since the Vicksburg materials were tested at moisture contents drier than that of the lower plastic limit, no break occurred in the straight-line curve as in Figs. 5 and 6. It is now obvious that only identical materials produce like voids-moisture functions, because each material may not possess a strength identical to that of another.

In conclusion, the writer expresses his deep appreciation for the several discussions submitted.

DETERIORATION OF CONCRETE DAMS DUE TO ALKALI-AGGREGATE REACTION

BY R. F. BLANKS [1] AND H. S. MEISSNER,[2] MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. RALPH R. PROCTOR, MILTON D. BURRIS, H. A. KAMMER, THOMAS E. STANTON, R. W. SPENCER, W. L. CHADWICK, J. C. WITT, DUFF A. ABRAMS, AND R. F. BLANKS AND H. S. MEISSNER.

SYNOPSIS

For many years engineers have been concerned over a peculiar and characteristic type of concrete deterioration, manifested by large-scale, random-pattern cracking. Such cracking is not unusual or new; in fact it is difficult to find massive concrete structures that do not display random cracking in some degree. Most instances of pronounced pattern or map cracking, as distinguished from ordinary small-scale crazing, have been attributed to excessive internal expansion, aggravated by varying degrees of surface drying shrinkage. The mechanisms producing internal expansion have been explained in the past on the basis of unsound aggregate or unsound cement, the latter resulting from high magnesia content or underburning and high free-lime content. Although some instances of expansive deterioration appear to be explained adequately by unsoundness, most cases, until recently, have remained enigmas and subjects for speculation only. Many concrete dams in all sections of the United States have developed evidence of this type of degeneration. Several of these cases have been caused by adverse chemical reactions between the alkalies in Portland cement and certain siliceous mineral constituents in the aggregates.

Identification of alkali-aggregate reactions as the cause of many cases of concrete deterioration has been recorded in contemporary technical literature. A brief selected bibliography is included as an Appendix of this paper. The destructive effects of the chemical instability of some aggregate constituents in the presence of alkalies contained in Portland cements have been definitely established. The problem is extremely complicated, however, and many questions, practical and technical, remain to be answered satisfactorily.

NOTE.—Published in January, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams

The random-pattern cracking is very conspicuous, as may be observed from the photograph of a typical affected surface reproduced in Fig. 1. However, positive association of such surface manifestations with adverse alkali-aggregate reactions usually requires detailed investigation. Although crack openings of as much as 1.5 in. have been observed, they extend into the concrete only a comparatively short distance. The superficial nature of cracks caused by alkali-aggregate expansion has been established by drill cores, as illustrated in Fig. 2. The shallow depth to which such cracks penetrate has also been indicated by attempts to fill the openings by grouting. In one instance a hole was drilled parallel to a concrete face at a distance of 2 ft to intercept large, open cracks in evidence at the surface. Water under a pressure of 50 lb per sq in. failed to develop any connection between the surface cracks and the drill hole 2 ft inside the mass. Water tests from one surface to another, both displaying large, open cracks which from superficial evidence appeared to be connected, have been similarly unsuccessful.

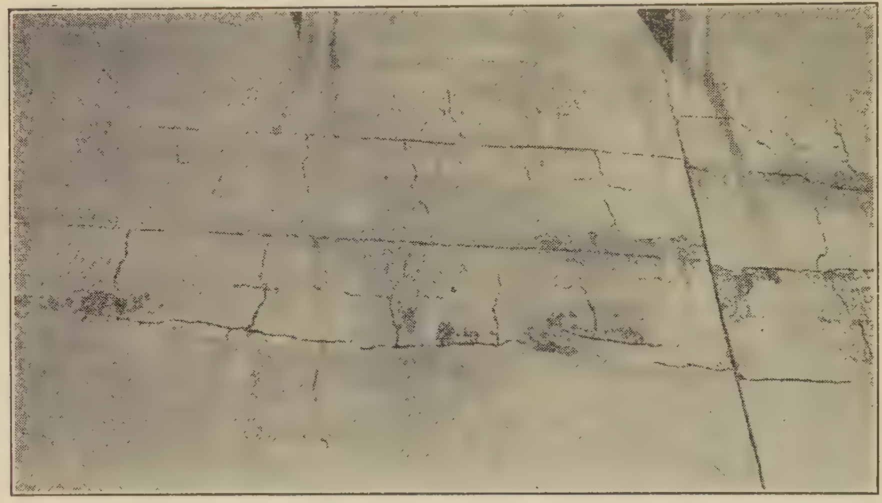

Fig. 1.—Expansive Reaction Between Aggregate and High-Alkali Cement Produces Typical Pattern Cracking on a Dam

Outward evidences of excessive internal expansion in concrete dams affected by adverse combinations of high-alkali cement and reactive aggregates are usually obscured by the massive proportions of the structure and the difficulty of establishing reference points for observing expansive movements. It is suspected that, under some conditions, restraint is sufficient to prevent most of the expansion that would normally occur if the concrete was not restrained. It is also suspected that such restraint of expansion tendencies in no way lessens the destructive action, except to reduce the surface crack openings.

In fact, deterioration may even be aggravated by internal stresses set up by the expansion forces. Some indication of the latter concept is given by the extremely low modulus of elasticity obtained in tests of cores drilled from affected structures.

Excessive expansion in massive concrete structures can sometimes be detected by the abnormal closing of expansion joints, particularly joints in a superstructure on a massive concrete foundation. Misalinement or displacement of hydraulic machinery such as the binding of gates, the cracking, bending, or buckling of penstocks, pit-liner plates, guide vanes, and speed rings, and the shifting or tilting of turbine-generator shafts are other signs of abnormal expansive movements in concrete which accompany alkali-aggregate reactions. Offsets at cracks, particularly in tunnels and galleries, frequently occur in affected concrete. Precise surveys and other forms of accurate measurements will sometimes indicate both the extent and direction of movement.

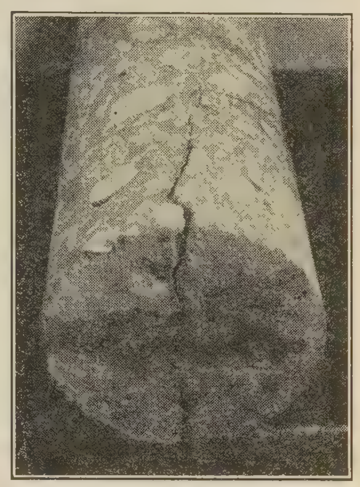

Fig. 2.—Cores Reveal That Wide Cracks Are of Shallow Depth

Positive identification of the alkali-aggregate disease in concrete dams usually requires laboratory study and tests of cores drilled from the structure, and of specimens made with the particular aggregate used in the dam. Invariably, cores from affected concrete, when stored in the presence of moisture, will develop gelatinous exudations and whitish amorphous deposits on their surfaces. These gel deposits are also found in pores in the concrete mass, particularly adjacent to pieces of reactive aggregate. Chemical analyses of the gels show them to be composed essentially of sodium and potassium silicates. The gels may be transparent, closely resembling ordinary water glass as illustrated in Fig. 3, or they may be white or gray with a porcelaneous luster as shown in Fig. 4. Table 1 shows the results of chemical analyses of typical gel deposits from alkali-aggregate reactive concrete.

TABLE 1.—Analyses of Gel Deposits Show Them To Be Composed Essentially of Alkali Silicates (Values Are Percentages)

Type of gel sample	Loss at ignition	Silica SiO_2	R_2O_3	Lime CaO	Magnesia MgO	Sulfate SO_3	Soda Na_2O	Potassa K_2O
Bead	....	51.2	...	...	...	0	16.8	
Fig. 4	10.5	81.9	0.7	1.1	...	...	4.0	2.0
Fig. 3	20.5	53.4	1.5	4.7	0	0	12.7	4.5

Hand specimen and microscopic study of core samples from affected concrete also invariably reveal what appear to be zones of chemical reactivity, alteration, or infiltration around certain aggregate particles, as shown in Fig. 5. Aggregate pebbles which appear to have experienced reaction in concrete are

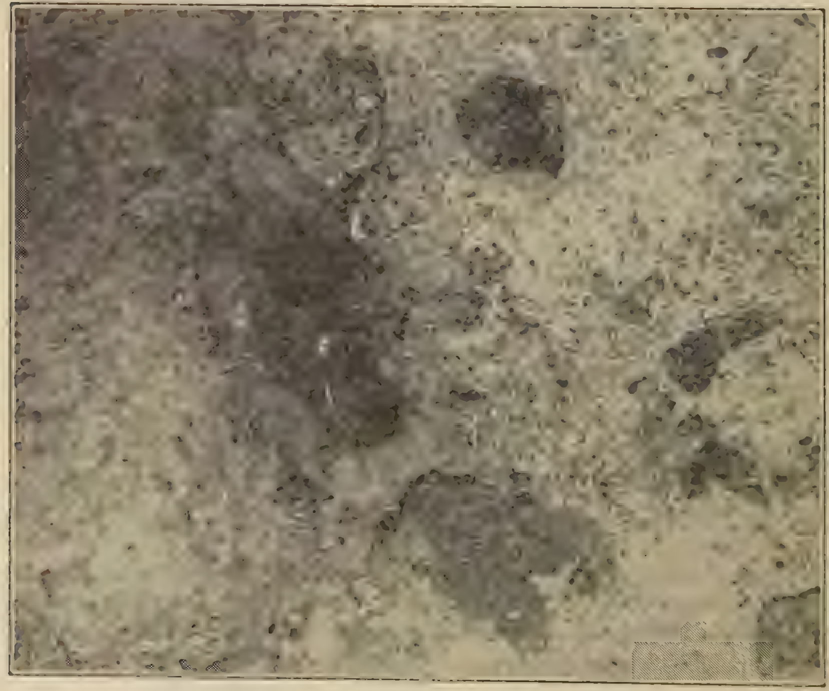

FIG. 3.—TRANSLUCENT GEL ON THE INTERIOR FRACTURED SURFACE OF A CORE

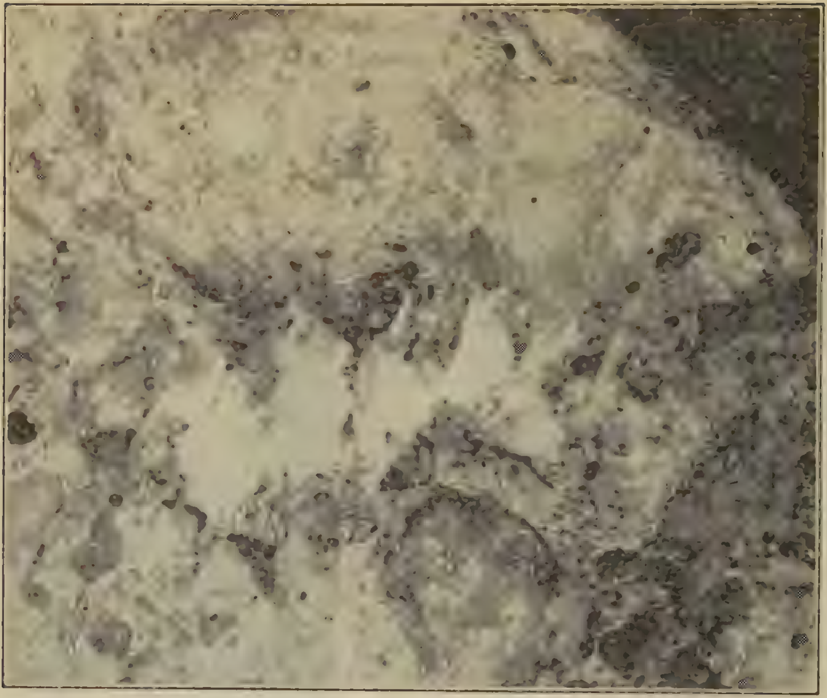

FIG. 4.—CARBONATED OPAQUE GEL ON A CONCRETE CORE

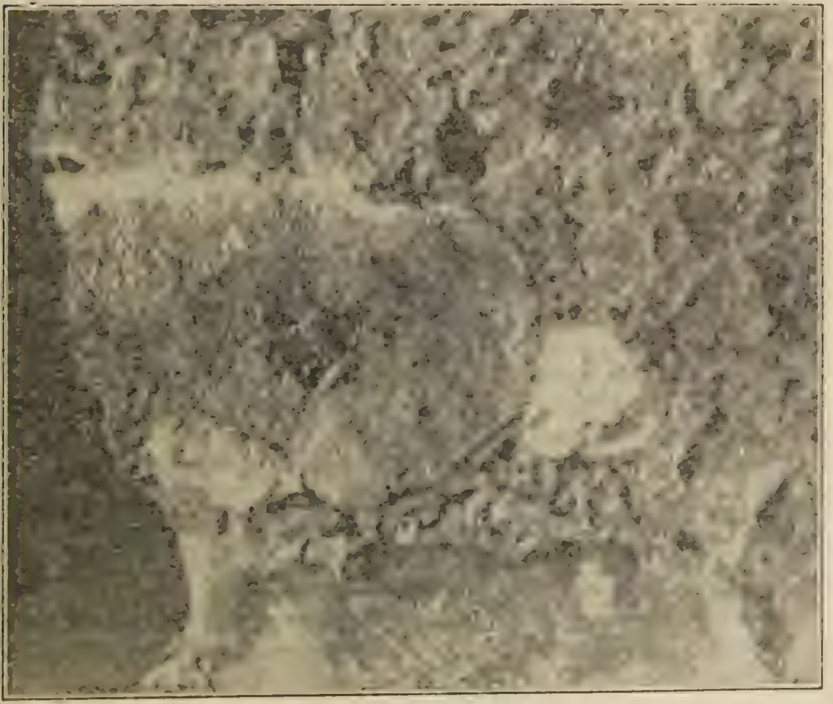

FIG. 5.—RIMS AND GEL POCKETS OFTEN SHOW ON REACTIVE AGGREGATE PARTICLES IN FRACTURED SECTIONS OF EXPANDING CONCRETE

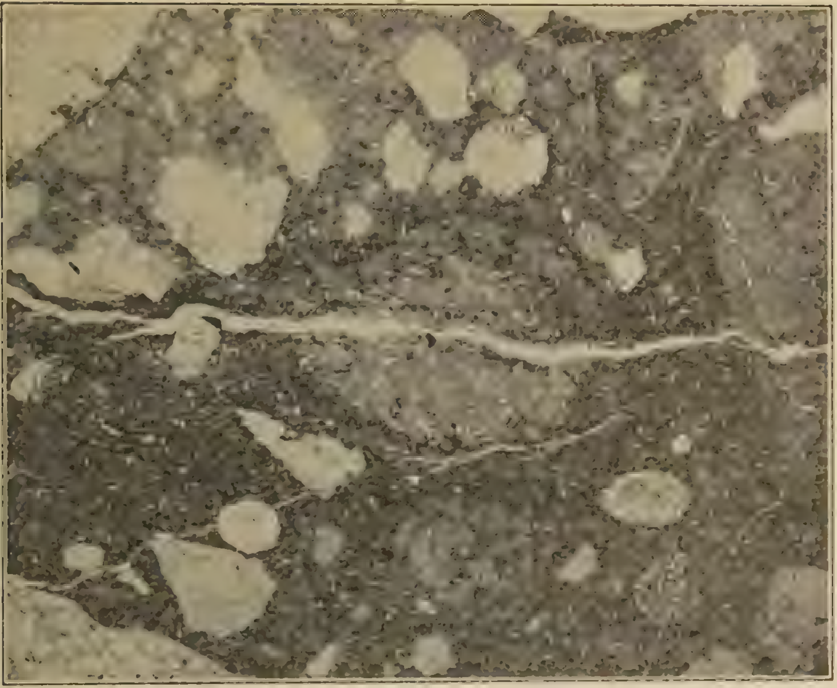

FIG. 6.—CRACKS IN AFFECTED AGGREGATE PARTICLES EXTEND INTO THE PASTE AND ARE FILLED WITH GEL DEPOSITS

frequently softened and fractured. The cracks extend outward into the surrounding matrix and are usually wholly or partly filled with gel substances as illustrated in Fig. 6. The zones around reactive particles are characterized by discolored borders and loose sockets filled with gel material or other abnormal products.

Far too little is known about the specific mineral constituents of various rock types which contain silica in forms susceptible to reactivity with alkalies in cement to permit positive predetermination of troublesome combinations by petrographic analyses. Some of the more conspicuously reactive aggregate materials include: Opaline and other siliceous rocks such as some cherts, some siliceous limestones, some chalcedonies and intimate opal-chalcedony admixtures; certain acid to intermediate volcanic rocks such as some andesites and rhyolites, including tuffs and glasses of similar composition; and miscellaneous rock types such as phyllite. Eminent authorities have stated that all rocks, with the possible exception of pure limestone, are potentially reactive in concrete. Small amounts of adversely reactive substances are known to occur in a large number of aggregate materials; but it is not known, as yet, what is a tolerable limit below which amount such substances can be ignored and above which they must be considered as dangerous in combination with high-alkali cements.

In studying the various dams that are deteriorating because of alkali-aggregate reactions, it has been impossible in most cases to establish the exact alkali content of the cements used, because determinations for Na_2O and K_2O were normally not included in routine chemical analyses of Portland cements until quite recently. However, from information disclosed by occasional analyses made by the manufacturers, it has been proved with reasonable certainty that high alkali ($1.0 \pm \%$ $Na_2O + K_2O$) cements were used in all structures that have exhibited serious deterioration because of alkali-aggregate reaction. It has been possible to obtain samples of the aggregate materials actually used in constructing the various dams, which have been subjected to accelerated expansion tests in mortar or concrete bars. Again invariably, these aggregate materials have developed high expansions in comparatively short periods of time in combination with high-alkali cements and no abnormal expansion when used with low-alkali cements.

When correctly interpreted, results from laboratory expansion tests are in agreement with the service histories of a number of cases where reactive aggregates from a given source have been used in construction, with both high-alkali and low-alkali cements. The experiences from such cases have repeatedly demonstrated that concrete made with reactive aggregates and high-alkali cements develops expansive deterioration but the same aggregates in combination with cement of less than 0.6% alkali content cause little or no trouble. Typical examples of such service records are provided by the Parker, Gene Wash, and Copper Basin dams in comparison with the Gene and Intake pumping plants, all in southeastern California.

Parker, Gene Wash, and Copper Basin dams were completed late in 1937 or early in 1938. These structures were all built with the same aggregates (a natural gravel deposit at the confluence of the Bill Williams and Colorado rivers in Arizona), and cement from the same mill containing 1.44% total alkalies. All three of these structures evidence profuse random-pattern cracking and expansive deterioration, which started from two to three years after completion. The Gene and Intake pumping plants were built almost coincidentally with the dams using aggregates from Colorado River deposits a few miles below the mouth of the Bill Williams River. Investigations have shown that the two aggregate sources (1) are of the same geologic age, (2) that they contain the same mineral elements in about the same proportions, and (3) that they show about the same degree of reactivity in the mortar-bar expansion test. The cement used in the pumping plants contained 0.51% total alkalies. After five or six years of service the concrete in these plants

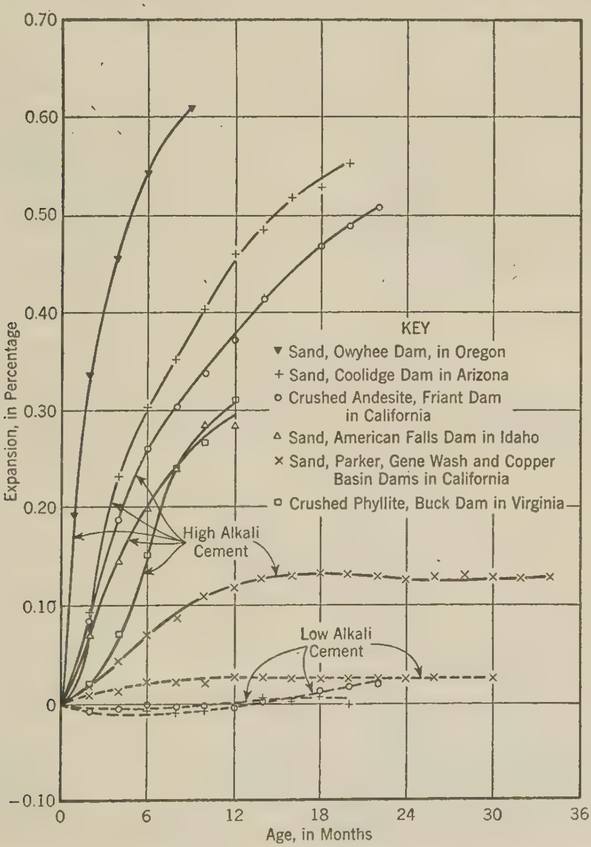

FIG. 7.—AGGREGATES USED IN SEVERAL DAMS EXPAND WHEN COMBINED WITH HIGH-ALKALI CEMENT

is as nearly perfect as any concrete could be. The same mill that supplied cement for the dams also later furnished cement for the Parker powerhouse but with a specification provision which limited the alkali content to 0.60% of ($Na_2O + 0.658\ K_2O$). The concrete in this latter structure, some of which was poured the latter part of 1940, was still in excellent shape at the end of 1944, although the aggregate is known to give expansion with a high-alkali cement. Expansion-test data obtained with aggregates from various dams in combination with high-alkali and low-alkali cements are shown in Fig. 7. The mortar bars tested were first stored with moisture at 100° F, and sealed.

Although excellent correlations have been obtained between laboratory results and service performance, the mortar-bar expansion test has not been developed so that it can be relied upon as an infallible indication of troublesome combinations of cements and aggregates. Neither can it be considered as a satisfactory acceptance test for either cements or aggregates. The test is useful only as an indication of possible troublesome combinations of reactive aggregates and high-alkali cements. If high expansions are obtained in mortar bars within a period of three or four months, it may be concluded safely that the materials contained in the bars are reactive. However, slowly reactive aggregates may require much longer periods of time to develop excessive expansions in the bar test. In such cases it is not always easy to determine whether the expansion is due to inherent alkali-aggregate reaction tendencies or to extraneous causes. Furthermore, because of the highly accelerated nature of the test, excessive expansions may ultimately be indicated with a highly reactive aggregate and relatively low-alkali cements, although field records do not indicate that such combinations will necessarily cause trouble in actual service.

Progressive Development of Alkali-Aggregate Deterioration in Concrete Dams

The rate at which expansive reaction develops does not appear to follow any predictable schedule. Perhaps the variable nature of the progression is due to the fact that the action is influenced by so many factors, including the alkali content of the cement, the thickness of section, the quality of the concrete, and the conditions of exposure, particularly with respect to moisture conditions within and surrounding the concrete.

At Parker, Gene Wash, and Copper Basin dams, severe open-surface cracking developed with the appearance of warm weather two years after the structures were completed. The cracking extended rapidly until all exposed surfaces were covered by the random pattern. Measurements across typical cracks in these structures indicate that the cracks are increasing in width very slowly, if at all. Embedded instruments appear to record some slight expansive growth.

At Buck Dam in Virginia excessive expansion was apparently not observed until ten to fifteen years after construction. Surface cracking and expansion progressed until extensive repairs of the dam and power plant were required after some thirty years of service, as reported (1)[3] by Philip Sporn, M. Am. Soc. C. E., and H. A. Kammer, Assoc. M. Am. Soc. C. E.

Although the natural aggregate used in building Owyhee Dam in Oregon is very reactive according to expansion-bar tests, only two or three small isolated areas of random-pattern cracking were in evidence in 1937, five years after its completion. The deterioration in these areas had progressed noticeably after another six years (1943), as shown in Fig. 8, and several other affected areas had appeared.

[3] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).

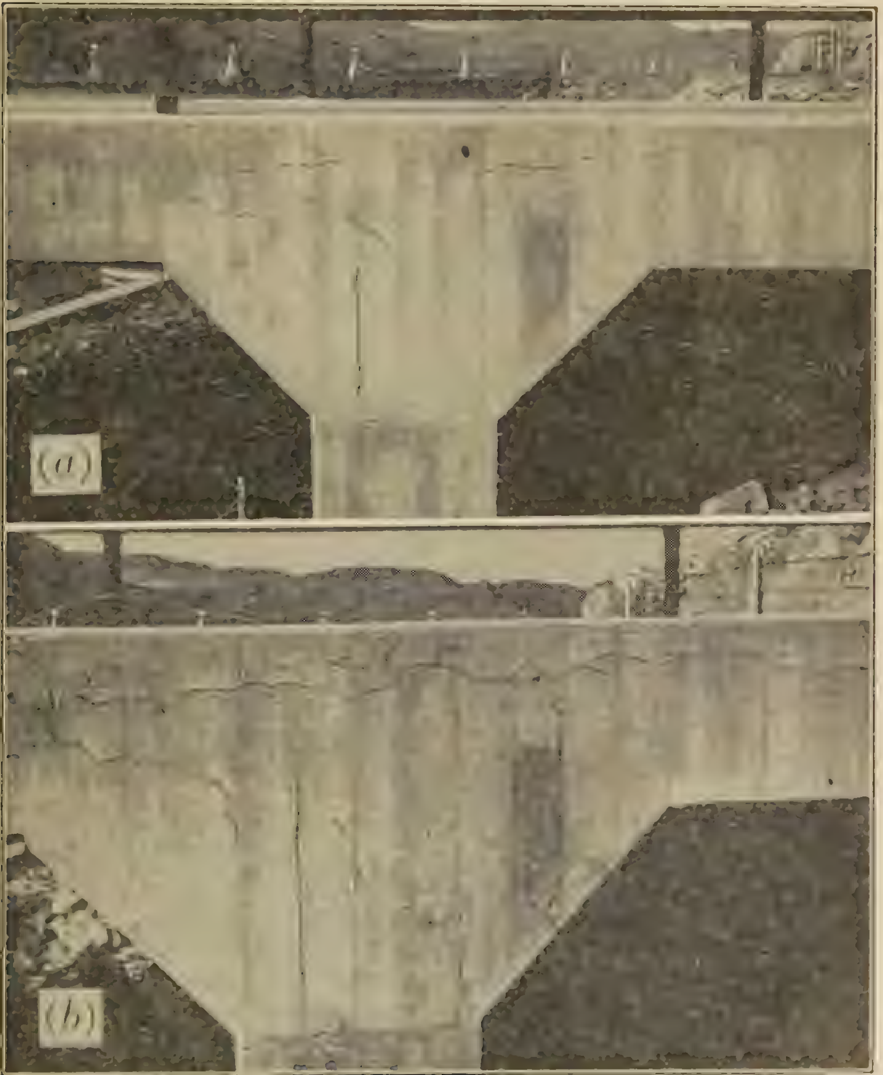

FIG. 8.—EXPANSIVE CRACKING HAS DEVELOPED PROGRESSIVELY IN THIS CONCRETE MEMBER, BUILT IN 1932

At Coolidge Dam in Arizona expansive deterioration has developed only in the parts where high-alkali cement was used, the greatest part of the structure (where low-alkali cement was used) being unaffected. During the period of fifteen years since its completion, severe cracking has necessitated minor repairs to the parapets and maintenance work to correct binding of the reinforced concrete spillway gates.

American Falls Dam in Idaho was completed in 1925. In 1929 there was no evidence of random-pattern cracking. There was noted at that time an efflorescence of sodium carbonate on the walls of the gate-operating gallery. By 1940 all of the previously described symptoms of alkali-aggregate deterioration were in sharp evidence. From information available, it can only be concluded that there has been a marked progression of cracking, spalling, and disintegration since that time.

Although some constituents in the Boulder Dam (Arizona-Nevada) aggregate have been found to be reactive, there is only minor development of random-pattern cracking in the structure, some of which must be ascribed to extreme drying exposure in the hot, arid location. The only place where alkali-aggregate reaction had been definitely identified at Boulder Dam, after eight years of service, was in the lining of a drainage tunnel through some wet rock.

From information collected on various types of structures, it appears that, in those cases where early, rapid expansion occurs, the action generally seems to slow down or even stop after a few years. The slower cases seem to be more insidious and deterioration progresses, comparatively slowly, for thirty years or longer, or until rehabilitation is required. Apparently almost any combination of conditions may be anticipated.

Significant Effects of Alkali-Aggregate Deterioration on the Service Life of Concrete Dams and Appurtenant Works

The preceding evidence has been given in considerable detail in order to present as clearly as practicable the symptoms by which alkali-aggregate degeneration is recognized, how it may be diagnosed positively, and a brief review of some known case histories. The next question of more immediate concern to engineers is the manner in which the "disease" affects structures in service.

Since the cracking that accompanies alkali-aggregate reaction is only a superficial surface condition, its effect on the structural stability of massive concrete structures would appear to be of minor importance. The esthetic and psychological effects of such cracking may require particular attention. Concrete dams subjected to severe conditions of exposure, such as freezing and thawing, corrosive waters, extreme temperature ranges, and extreme drying shrinkage, of course, will be weakened materially in their resistance to the disintegrating elements by the surface cracking which accompanies alkali-aggregate reaction.

Concrete cores drilled from affected structures show that the interior concrete is characterized by a chalky, lifeless appearance. Cores break easily during drilling and it is difficult to obtain representative samples sufficiently intact for strength and elasticity tests. Therefore, strength tests with cores from alkali-aggregate concrete must be considered as representing the best of such concrete. In general, such tests reflect some retrogression in strength as compared with that which might be expected from sound concrete under comparable conditions. In most cases, however, core samples have developed higher strengths than might be expected from their dead appearance.

Cores taken from Parker Dam, three years after construction, averaged 3,480 lb per sq. in. in compressive strength, with an average modulus of elasticity of 2,200,000. Previous cores, six months old, gave an average strength of 4,180 lb per sq in. and an elastic modulus of 3,800,000. In contrast to these results, 28-day control cylinders made during construction had an average strength of 4,180 lb per sq in., and 1-yr laboratory tests on Parker Dam concrete yielded 4,620 lb per sq in. strength and showed an elastic modulus of 4,200,000.

Similarly, although 28-day control cylinders showed the concrete in Gene Wash and Copper Basin dams to produce 3,450 lb per sq in. compressive strength, cores taken two years later showed the strength of this concrete to be 3,295 lb per sq. in., and the elastic modulus to be 2,420,000. Two-year-old cores, taken from pumping-plant structures which were built with the same aggregate as that used on Gene Wash and Copper Basin dams, but with low-alkali cement, were found to give 5,775 lb per sq in. compressive strength and to have a modulus of 4,800,000.

Mr. Kammer, with R. W. Carlson, Assoc. M. Am. Soc. C. E., reports (2) the strength of cores from the 26-yr-old concrete in Buck Dam as 2,100 lb per sq in.; and cores from the 15-yr-old affected concrete in American Falls Dam gave 2,840 lb per sq in. The latter concrete showed a low elastic modulus of 1,880,000 which, as may be observed from the other moduli listed in the foregoing paragraphs, appears to be a characteristic of concrete afflicted with expansive reaction between aggregate and high-alkali cement. The change or decline in elastic modulus has been used by many investigators as a measure of durability, or of the effect produced by some treatment of the concrete and may be considered as reflecting some deterioration. A marked reduction in modulus of elasticity, therefore, is interpreted as a sign of disintegration. Such changes in elasticity will also affect the distribution of stresses in a structure and will result in deflections or strains differing from those assumed in the design.

Measurements of the crown deflections of Copper Basin Dam, made regularly since completion of the structure, by the Metropolitan Water District of Southern California, show a progressive and steady upstream movement of 0.5 in. per year, amounting to 3.75 in. of total displacement in the latter part of 1944 (see Fig. 9). Superimposed upon the record are seasonal fluctuations due to temperature variations and load changes resulting from filling and drawdown of the reservoir; however, the data are positive in regard to a continuous movement of the structure. These deflection measurements have been corroborated by several independent observations from undisturbed control points on the solid-rock abutments and by plumb lines on the downstream face of the dam. Accurate measurements of several chord lengths across the top of the dam likewise reveal enlargement of the concrete, amounting to

0.018% linearly during the period of one full year. Other substantiating evidence of growth in the concrete exists in precise level measurements over points on the top of the dam, which show the crest of the dam to be rising over a 2-yr period. The increase in elevation at various points is roughly proportional to the height of the dam and with reference to this distance indicates a rate of expansion of 0.018% per year, corresponding to the data gathered from the chord measurements. Although these movements are indicative of the general enlargement of the concrete mass, the upstream deflection, which is already large for a thin arch structure, is significant because of the effect that it may have in changing the stress distribution from that originally contemplated.

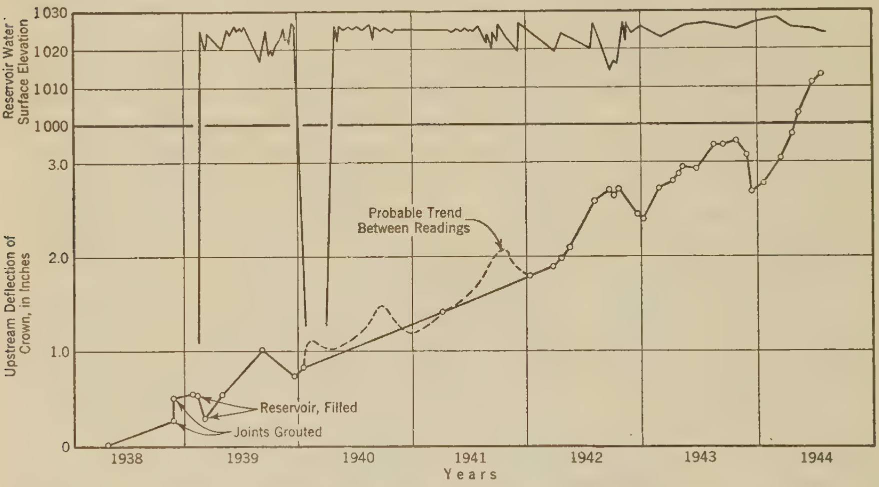

Fig. 9.—The Crown of Copper Basin Dam Has Shown Progressive Upstream Movement

Positive evidence of expansion in the concrete of Parker Dam exists in the record of measurements obtained from Invar rods mounted in holes drilled in the concrete. The rods are anchored in the bottom of four adjacent vertical holes (12, 30, 60, and 120 in. deep) and have dial gages attached to their upper ends so that any expansion or contraction over the span of the instruments is registered. As may be seen in Fig. 10, a general progressive expansion is recorded with seasonal temperature variation impressed upon the data from each hole. It is further indicated that expansion of Parker Dam concrete is greater within the interior than near the surface, the shallow holes showing the least expansion.

Aside from surface cracking and general deterioration, reactive expansion in concrete has been most significantly felt through its effect on embedded machinery. The alinement of generator and turbine shafts has been disturbed to the extent that further adjustments required extensive resetting and repairs. The strain in speed rings has been great enough to break the guide vanes, necessitating costly shutdowns and difficult repairs.

CORRECTIVE AND PREVENTIVE MEASURES

In mild climates expansive cracking may not present the serious aspect that it does in northern regions where it will be aggravated by exposure to the elements. In the latter cases, surface cracks, although superficial, serve as points of entrance for precipitation and assist the destructive processes of freezing and thawing, necessitating repairs much earlier than concrete in more moderate temperatures would require. Such repairs generally would comprise chipping away the affected concrete and incasing the new, taking pains to secure good bond and to provide the new work with joints which would allow additional growth in the underlying mass without producing random cracks in the new work. The paper by Messrs. Sporn and Kammer (1) describes restorations of this nature.

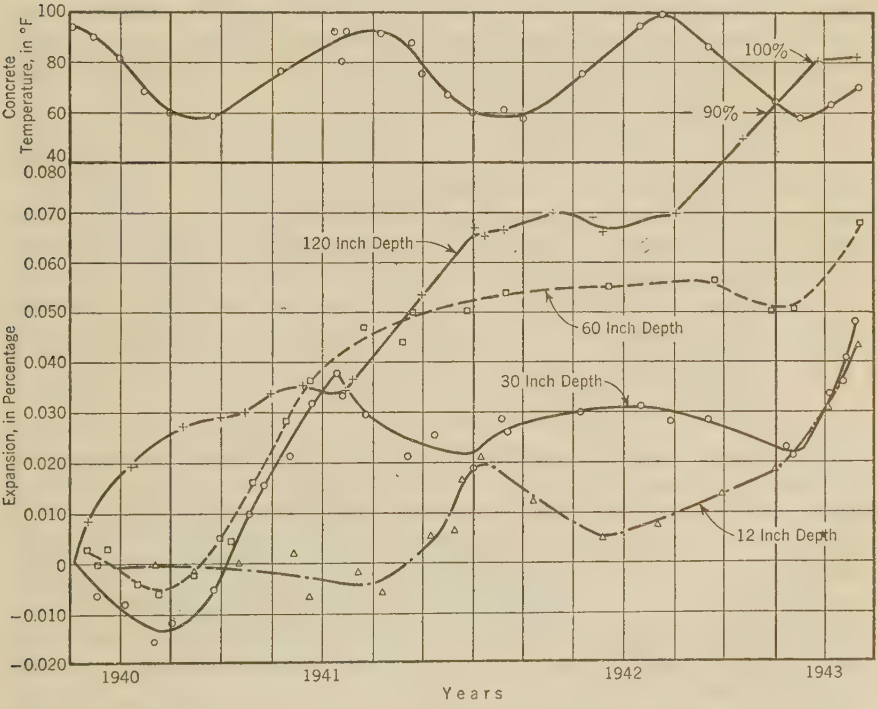

FIG. 10.—INVAR ROD METERS, MOUNTED IN DRILL HOLES, INDICATE PROGRESSIVE EXPANSION IN THE CONCRETE OF PARKER DAM

Where expansion has affected the alinement of embedded machinery to the extent that its operation can no longer be continued, satisfactory repairs can be effected only by removing the defective concrete in immediate contact with the parts and resetting the machinery in new, sound concrete. Precaution requires that the new concrete be free of the old, with joints or articulations that will insure no disturbance by further movement in the old concrete. Where watertightness in the entire structure must be preserved, the joints should be provided with flexible metal seals or plastic filler, or both. Continued frequent maintenance, alteration, and adjustment of the embedded machinery itself is the only alternate to any such major restoration work.

New concrete construction in areas where expansive reaction may occur dictates that precautionary measures be taken. The quantities of aggregates required in dam building usually necessitate the utilization of near-by sources for economic reasons. Such sources may have established service records from previous use but more than likely they have not. Therefore, it is usually not feasible to avoid the use of aggregates that may be known to be, or are suspected of being, reactive in combination with high-alkali cements. Furthermore, in most cases, reactive aggregates have been found to possess excellent physical and structural qualities, making them first-class materials for use in concrete in all respects, except in their tendency toward adverse chemical activity in the presence of inordinately high-alkali cements. Experience to date indicates that reactive aggregates can be used without danger of destructive reaction, provided that low-alkali cement (less than 0.60% $Na_2O + K_2O$) is employed (see Fig. 7).

Specification of low-alkali cement for all important hydraulic structures is strongly recommended regardless of what may or may not be known about the reactive tendencies of the aggregates to be used. Such a precautionary measure not only provides insurance against possible eventual deterioration due to alkali-aggregate reactions, but limits undesirable constituents of Portland cements and usually improves the quality in several other ways.

The Bureau of Reclamation, U. S. Department of the Interior, has purchased several million barrels of cement under specifications limiting the alkali content. This cement has been produced by a number of mills, and there is unanimous agreement that the result has been a much improved product, based on presently accepted criteria for judging the quality of Portland cements. In most cases the reduction in alkali content has been accompanied by marked reductions in C_4AF (tetracalcium alumino-ferrite), which is a fluxing material having little cementing value in itself, and lower C_3A (tricalcium aluminate), which is generally considered to be an undesirable compound. Coincidentally the principal cementing compounds, C_3S (tricalcium silicate) and C_2S (dicalcium silicate), have been increased as much as 9%. It seems evident that the additional cost of low-alkali cement, which may range from nothing to about 20¢ per bbl, is more than repaid by the improvement in quality alone.

Tests have indicated that some Portland pozzolanic cements may be safely used with reactive aggregate. It has also been demonstrated that additions of fine pozzolanic materials to reactive aggregate and high-alkali cement combinations or a replacement of some of the high-alkali cement by the pozzolanic material will reduce the expansion. In the construction of Friant Dam, on the San Joaquin River in California, 20% of naturally fine pumicite (by weight of the cement) was used as one of the concrete ingredients. Both high-alkali and low-alkali cements were used in the concrete since wartime production conditions made it impossible to secure low-alkali cement for all the work. The aggregate used in this dam was found to be reactive with high-alkali cement and it is therefore felt that pumicite has furnished some protection against expansion where the low-alkali cement was not provided.

No specific preventive for alkali-aggregate reaction has as yet been discovered although the problem is under intensive investigation. Specification of low-alkali cement, while admittedly inadequate, is the only recourse available to engineers at the present time.

SUMMARY

Expansive reaction between aggregate and high-alkali cement has been found responsible for the random cracking and deterioration of the concrete of a large number of dams. The binding of gates and of generator rotors, the misalinement of generator and turbine shafts, and the straining and breakage of guide vanes and other machinery embedded in concrete have been traced to the excessive expansion which accompanies such reaction. Aggregates that have been found to react with high-alkali cement include opaline silica, highly siliceous rocks (such as siliceous limestones, chalcedony, and some cherts), and acid to intermediate volcanic rocks. These same materials have caused no trouble in service when combined with cement low in alkali content.

Aggregate which will give this trouble in concrete may be recognized if it produces expansion within a short time in test specimens made with high-alkali cement. Absence of such expansion in a short period is no guarantee, however, against a latent type of reaction, for which no reliable accelerated test has appeared. Prudence dictates that aggregates known or suspected of adverse activity be used only with cement of low-alkali content or not at all. Low-alkali cement is recommended generally for all concrete in hydraulic structures as its use provides security against the uncertainty of encountering expansive reaction, and otherwise improves the general quality of the concrete.

DISCUSSION

Ralph R. Proctor,[4] M. Am. Soc. C. E.—The cracking of concrete from internal expansion has been under investigation by the writer since about 1930, together with the general subject of expansion and shrinkage of concrete in connection with various structures that should be watertight. There seems to have been much more of this type of deterioration in the concrete used in construction since 1930 or 1935 than in older structures. As concrete aggregate probably has not changed much, it would appear that the first place to look for the trouble would be in all the new types of cement that have been produced during recent years; particularly as a considerable part of this trouble has occurred where new types of cement have been used.

Effect of Carbon Dioxide on Various Cements and Its Relationship to Alkali Aggregate Reaction.—During the driving of a long tunnel, large amounts of carbon dioxide were encountered. Tests were made to determine what the effect of this carbon dioxide would be on the concrete tunnel lining and what types of cement should be used to resist this action. As the contract for the cement to line the tunnel had already been entered into, five separate types of cement produced by the manufacturer who was to supply the cement were secured for testing. Small test beams for use in a miniature modulus-of-rupture test were made from sand mixed with each of the five types of cement, two of which were new type cements, and subjected to immersion in water under one atmosphere of carbon-dioxide pressure for eighteen months. At the end of that time it was found that all of the small beams, 1 in. wide, $\frac{1}{4}$ in. deep, and 3 in. long, had expanded and broken into bits, except those made from one type of cement not considered suitable for use in dam construction. The latter beams were unaffected, having the same strength when tested as similar beams that had been kept immersed in water in the concrete curing room of the laboratory. Thin sections from beams made from each type of cement were prepared and examined under the petrographic microscope. All those that had failed exhibited a white chalky substance between most of the sand grains, but the specimens that had resisted carbon dioxide showed a glassy substance, light amber in color, between the sand grains with only an occasional small speck of chalky substance embedded in the glassy material. Unfortunately, the sample of cement from which these carbon-dioxide resistant beams were made was lost so it could not be tested further.

The conclusion to be drawn from this experiment, in connection with this discussion, appears to be that, if a cement could be manufactured that, when set, would exhibit this glassy carbon-dioxide proof structure, there would need to be no worry about any kind of reaction between aggregate and cement. There would be no travel of chemical compounds, with resulting contact and crystallization, through such a glassy material, as it must have been completely watertight or the carbon dioxide would have broken down the structure as it did in all of the other specimens. Therefore, it appears to the writer that the afore-mentioned carbon-dioxide test of cement should be investigated as a possible means for preventing the kind of concrete deterioration under discussion.

---

[4] Field Engr., Water System, Dept. of Water and Power, City of Los Angeles, Los Angeles, Calif.

Relationship of Carbon-Dioxide Test to Merriman Cement Test.—Further testing of various cements (about eighty separate samples being tested) for resistance to carbon dioxide disclosed a wide variety of test results which could not be correlated with chemical compounds in the cement or any other cement designations such as sulfate resistant, low alkali, low heat, high early strength, etc.; and only two samples from the group showed reasonable resistance to carbon dioxide. All attempts to correlate test results with any means of testing or designating cement failed, except the comparisons made with the tests proposed by the late Thaddeus Merriman, M. Am. Soc. C. E. (9). The two cements that resisted carbon dioxide to a reasonable extent were not proposed by any one as carbon-dioxide resistant cements, but had simply been added to the test group because they were cements actually available even though made supposedly for other purposes.

When thin sections of these two best specimens were examined under the petrographic microscope, they exhibited similar glassy characteristics between the sand grains as has been described previously, although there were more small areas of chalky material visible. As far as can be determined, the main difference between the cements that resisted carbon dioxide and those that did not was in the temperature at which they had been burned during manufacture, as indicated by the Merriman sugar solubility index, rather than in chemical compounds. It is of special interest to note that the writer visited a cement mill that was producing a "low-alkali" cement for one large organization which does extensive research in cement; a "sulfate-resistant" cement for another large organization equipped similarly; and a "Merriman" type cement for a third large organization; and the exact same clinker was burned and subsequently ground and sold to each of the three separate organizations under their own separate specifications for cement. Furthermore, the cement thus manufactured met exactly all three specifications, according to statements of the manufacturer's chemist.

As far as could be determined, the essential characteristic of this clinker was the temperature in the kilns during manufacture, which appeared exactly in accord with several conversations that the writer had with Mr. Merriman on this subject at the time the tests were being made.

Evidence of Excessive Shrinkage in Expanding Concrete.—Fig. 1 is apparently the upstream or downstream face of a dam. It will be noted that over the distance shown in the picture (possibly 25 ft) there are at least eight vertical cracks that might be $\frac{1}{4}$ in. wide each. If the concrete in the dam had expanded enough to cause such cracking, it would mean that a 25-ft length of the dam had expanded as much as 2 in. (certainly not less than 1 in.) which raises the question of what happened to the dam when it elongated to this extent. Such expansion could occur vertically, of course, but it is difficult to visualize how it could occur horizontally, except in the case of a thin arch dam. Therefore, it would appear that the concrete must have excessive shrinkage properties when dried. This is further evidenced by referring to Fig. 5 to describe a condition noted by the writer on a specimen of concrete from the Parker Dam which had been freshly broken. To illustrate this point, it will be assumed that the piece of aggregate shown in the upper center of Fig. 5 represents the surface of a piece of nonreactive aggregate and that the white spots shown in the picture represent crystal growth on the surface of the nonreactive aggregate and between the aggregate and the remainder of the concrete.

The question arises then as to what circumstances permitted the formation of these crystals between the piece of nonreactive aggregate and the remainder of the concrete, for if the aggregate had been coated originally with cement paste there would be no reason for large quantities of these crystals to form next to the nonreactive aggregate rather than at any other location in the mass of the concrete. Therefore, it appears reasonable to assume that the aggregate probably had a higher coefficient of shrinkage when dried than did the concrete mass, with the result that it pulled away from the surrounding concrete and left a thin void that became filled with solutions that, upon subsequent drying caused the crystallization. Then, upon subsequent wetting, the aggregate expanded, crushing the crystals against the concrete and producing pressure. The formation and shape of the crystals bore out this conclusion. There has been other evidence found by the writer that this type of expansion in concrete can be associated with aggregate having a high shrinkage rate, or, to express it differently, an aggregate which expands considerably if immersed in water when in a dried condition. Therefore, it appears that the shrinkage or expansion properties of aggregates should also be investigated in connection with important structures.

Effect of Adding Admixtures to Concrete.—The free-alkali content of admixtures should also be investigated. It came to the attention of the writer in connection with one large dam where great care was being used in the selection of low-alkali cement, and where the aggregate was being scrutinized by all known methods, that the admixture used contained enough of the same free alkalies customarily found in cements to more than overcome the benefits secured from using low-alkali cement.

Tests for Reactive Cements.—Test bars similar to those used in autoclave tests were made in an attempt to determine the reactive properties of several types of Portland cement. These were immersed in water and dried through several cycles and the net result secured from the tests was shrinkage rather than expansion, even though the specimens were made with at least 50% of the aggregate and sand comprising supposedly reactive aggregate; however, the cements were not high in the Merriman sugar solubility index.

Conclusion.—It would be most interesting to secure test results similar to those shown in Fig. 7 wherein the expansion of concrete made from the various aggregates would be expressed in terms of the Merriman sugar solubility index of the cements used.

MILTON D. BURRIS,[5] ESQ.—For several years the writer has used petrographic methods to determine the reactive properties of aggregates with the alkalies contained in Portland cements. Thin sections of proposed aggregates are prepared in the usual manner: A small piece of rock is selected and polished on one side, after which it is cemented with Canada balsam to a glass microscope slide; and the other side of the rock is ground and polished until a thickness of 0.03 mm is secured. The rock section is then nearly transparent and the various minerals contained therein may be identified by polarized or plain light transmitted through the specimen and by the use of other standard petrographic methods for mineral determination.

---

[5] Petrographer, Los Angeles, Calif. (formerly with Los Angeles Dept. of Water and Power).

In the section on "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams," the authors state that

> "Far too little is known about the specific mineral constituents of various rock types which contain silica in forms susceptible to reactivity with alkalies in cement to permit positive predetermination of troublesome combinations by petrographic analyses."

The structure of the thin section of rock and the texture of the individual minerals contained therein are usually among the first of the many properties determined by the petrographer. The texture of each specific mineral readily reveals the state of weathering undergone. Since practically all rock specimens show alteration or weathering to some extent, a perfect, unweathered or unaltered thin section of rock is seldom encountered.

This is well illustrated in samples of "andesite" aggregate from the Parker Dam analyzed by the writer. Under the microscope the ground mass (a glassy material filling the space between the larger crystals) in thin sections of these rocks proved to be quite dense and virtually unaltered; however, the andesine crystals (soda-lime-alumina silicates) were almost invariably affected. Numerous andesine crystals were poorly formed; others had been altered in varying degrees by chemical action. Many of these crystals showed replacement of portions of the andesine crystals by calcium carbonate to a considerable extent. This is not unusual and is quite common in many rocks where hydrothermal and other forms of metamorphism have taken place. Furthermore, the partial weathering of the aggregate renders it more susceptible to attack by the free alkalies in cement, particularly as some of the silica (SiO_2) had been released in the form of hydrated or opaline silica SiO_2 (n) H_2O—the amount of hydration expressed by n in the chemical formula varying from 1% to 21% and averaging between 9% and 13%.

Reactive Minerals Found in Parker Dam Aggregate.—Although the reactive aggregate in the Parker Dam is generally referred to as an andesite rock, this is partly disproved by the presence in some thin sections of albite and in others of oligoclase as the prevailing feldspar. Albite and oligoclase were also found more or less altered, and when combined with andesine they form the three feldspars that chemically contain the most sodium in the group of six soda-lime feldspars. Thus, it is logical to assume that the further release of sodium from the feldspars as well as from the cement would tend—through chemical reaction with the silica in feldspars and cements—to promote expansion even in a low-alkali cement but at a slower rate than in the case of a high-alkali cement.

Types of Siliceous Rocks that May Be Reactive with Cements.—In the "Summary," the authors state that

> "Aggregates that have been found to react with high-alkali cement include opaline silica, highly siliceous rocks (such as siliceous limestones, chalcedony, and some cherts), and acid to intermediate volcanic rocks."

Wollastonite ($CaSiO_3$) is formed only from a limestone deposit by contact or metamorphism; it is highly siliceous (51.7%) and has a calcium content of 48.3%. This rock has a specific gravity of 2.85 and a hardness of 5, and has been used, when available, with much success as a concrete aggregate. The siliceous limestones to be avoided are those that contain nodules of silica derived from organic matter such as Radiolaria and diatoms. They are readily distinguishable under the petrographic microscope because of the different optical properties of this type of silica. Opaline silica becomes dark under crossed "nicols" (the light passing through the thin section being passed through polarizers placed below and above the thin section and set at right angles to each other), and remains dark as the stage is rotated whereas pure silica, SiO_2, alternates between dark and white for every 90° the stage is rotated.

Additional Precautions To Be Taken in Cement Manufacture.—The authors state (see heading, "Corrective and Preventive Measures") that

> "In most cases the reduction in alkali content has been accompanied by marked reductions in C_4AF (tetracalcium alumino-ferrite), which is a fluxing material having little cementing value in itself, and lower C_3A (tricalcium aluminate), which is generally considered to be an undesirable compound."

These two compounds are dependent wholly upon the clay (alumina) and iron content of the materials used in the manufacture of cement. Most of these two compounds are derived from the waste material found in fault zones and from fractures that are always present to some degree in practically all quarries of consequence. These two compounds constitute 20% and more of most cements and range in value from "practically useless" to "quite detrimental." Furthermore, rather than depend upon a coincidence for a reduction of these compounds in the finished product, it is suggested that closer attention be paid to the elimination of waste material from the quarry.

Aggregate Reaction Shown by "Popouts."—Fig. 11 is a view of the underside of a "popout" from the surface of a concrete slab showing a piece of aggregate of unknown composition that became gelatinous through chemical reactions of alkalies and silicates. This chemical change increases the volume of the aggregate particle; and, when the compressive stress thus formed within the aggregate exceeds the tensile strength of the concrete, "popouts" are the result. Popouts occur but an inch or two below the surface of the concrete and over a 3-in. or 4-in. diameter, but the chemical reactions are identical with those which occur at greater depths in mass concrete structures. The shrinkage cracks shown in the aggregate particle near the center of the photograph are the result of dehydration of the gel after exposure to the sun for three or four hours. The dehydrated piece of aggregate shown in Fig. 11 is one of a number of mineral substances that do not yield definite chemical formulas and furthermore show no signs of crystallinity. These substances have been called "gel minerals" or "mineraloids." The power of these minerals to absorb other substances accounts for their often wide variation in chemical composition although silica predominates greatly in all analyses.

Fig. 1 shows a typical view of concrete where expansion within the mass has occurred. However, if the reaction was entirely between coarse aggregate and cement, there should be evidence of this by popouts caused by pieces of aggregate lying close to the surface. The writer has observed considerable expanded concrete where there were no popouts visible, leading to the conclusion that at least the coarse aggregate was not involved. Accordingly, two thin sections were prepared from a small piece of Parker Dam concrete available from an area adjacent to some expansion cracks having pronounced expansion cracks within one section and slight expansion cracks in the other. There was no positive evidence of reaction between cement and coarse aggregate or between cement and sand, leading to the conclusion that the expansion possibly might be caused by reaction within the cement. It is suggested that the possibility of opaline silica from the limestone remaining in the cement, because of too low kiln temperatures, and uniting with free alkalies remaining in the cement for the same reason, should be investigated thoroughly as a possible source of this expansion.

(Approximate Magnification, 3 X)

Conclusions.—All rocks, with the possible exception of pure limestone, are potentially reactive in concrete. This is especially true of any aggregate that shows the least sign of weathering. Incipient alteration in any aggregate chosen should be observed and studied with a polarizing microscope.

Radiolaria and diatoms are microscopic animals and plants, respectively, whose tests or shells are composed of hydrated silica which contains from 1% to 21% of H_2O. Hydrated silicas react with the sodium and potassium hydroxides referred to as free alkalies in Portland cement to form sodium and potassium silicates, thus causing expansion by the formation of a gel.

Far too few data have been made available to engineers concerning reactive aggregates, such as the mineral and chemical composition and the state of weathering, whether incipient or otherwise. For instance, during the process of weathering, an albite feldspar produces a sodium silicate gel and free lime which eventually carbonates causing further expansion. Secondary crystal growth and carbonation of freed calcium, as well as the formation of a highly siliceous ooze or gel, have been observed under the microscope, by the writer, in all expanded concretes examined.

The large amount of concrete manufactured without trouble from expansion appears to indicate that ordinarily both cement and aggregate must contain an excess of available free alkalies to cause expansion and that when either cement or aggregate is practically free of alkalies no serious difficulty has been encountered. However, for an important permanent structure, a full investigation of the free-alkali properties of both cement and aggregate should be made, with special emphasis on the analysis of the aggregate by petrographic methods as outlined herein in order that all known precautions may be taken to prevent concrete expansion.

H. A. Kammer,[6] Assoc. M. Am. Soc. C. E.—The deterioration that develops in concrete structures as a result of the reaction that sometimes occurs between certain concrete aggregates and the alkalies in some Portland cements has been well described in this paper. The authors also have recommended certain corrective and preventive measures that might be used to limit, or possibly to eliminate, the destructive effects of this phenomenon.

In 1941 it was established definitely that the serious deterioration of the concrete structures at the Buck Hydroelectric Plant in Virginia was caused by a reaction that was taking place between the alkalies in the cement and the phyllite aggregate used in the concrete. The basis for this conclusion was reported by R. W. Carlson, Assoc. M. Am. Soc. C. E. (2), and the writer at that time.

In the summer of 1942 work was started on rebuilding and rehabilitating some sections of the substructure of the powerhouse and the exposed surfaces of the dam. In the powerhouse the old concrete structure supporting the turbine and generator was removed to a level a few feet below the bottom of the scroll case and the foundations were rebuilt using cement with an alkali content of approximately 0.5% and an aggregate which the engineers were reasonably certain was not reactive with the cement. The details of this work were reported by Philip Sporn, M. Am. Soc. C. E., and the writer in 1944 (1). Reference points were established in pairs, one of each pair being established in the old concrete which was left in place and the other in the new concrete. The joint between the old and new concrete was treated to break bond.

---

[6] Constr. Engr., Am. Gas & Elec. Co., New York, N. Y.

Rebuilding of the first unit was completed early in 1943 and periodic measurements made since that time definitely indicate that the old concrete adjacent to the machine foundations is still growing. The measurements, made at the four corners of the foundation, indicate some difference in the amount of movement at the several corners which may be due to the variation in the depth of the old concrete still in place below the reference points. Inaccuracies in measurement may also be a contributing factor in these variations. In May, 1945, the surfaces of the old concrete structures were an average of 0.05 in. higher than the new.

The replacement of the foundations for the second and third units has been completed but, although a trend in the same direction as unit No. 1 is noticeable, sufficient time has not elapsed to permit accurate and conclusive information to be obtained relative to the behavior of the structures at these locations. Further growth of the old concrete was expected and allowed for in the reconstruction of the machine foundations. Therefore, no trouble is expected to develop as a result of the continued growth of the old structure.

The downstream face of the north abutment section of the dam was repaired by cutting off the affected face and replacing it with new concrete provided with regularly spaced control joints which were expected to open as the underlying mass continued to grow and expand. After two years this section of the work was behaving as expected and cracks developed in all of the joints. No random map cracking of the type previously experienced had developed by May, 1945.

Messrs. Blanks and Meissner point out that experience thus far demonstrates that reactive aggregates can be used without danger of developing destructive reactions in the concrete mass if the alkali content of the cement is less than 0.6% $Na_2O + K_2O$.

At one of the hydroelectric developments erected on the American Gas and Electric System in 1938 a dolomitic limestone was used for the manufacture of both the coarse and fine concrete aggregates. At that time nothing was known about any destructive reactions developing between some aggregates and the alkalies in some Portland cements. The cement was purchased under rather rigid specifications but no limit was placed on the alkali content.

When the cause of the trouble at the Buck Hydroelectric Plant was discovered, tests were made to ascertain if the dolomitic aggregate used in the new development was reactive. These tests showed that the particular dolomitic limestone that was used was more reactive than the phyllite aggregate used at the Buck development.

Fortunately, samples had been taken of all cements used in the new structure and they had been carefully stored. Tests were made to determine the alkali content ($Na_2O + K_2O$) which was found to be:

Cement No.	Alkali content (%)
1	0.75
2	0.62
3	0.46
4	0.36

Reference points were established at a number of locations on the concrete structures at the new plant and periodic measurements and observations have been made since 1942. Thus far (1945), no unusual expansions have been measured nor has any random-pattern cracking, which is so typical of alkali-aggregate deterioration, been observed.

THOMAS E. STANTON,[7] M. AM. SOC. C. E.—The material presented by Messrs. Blanks and Meissner is a valuable and interesting contribution to the exceedingly important topic of the "Deterioration of Concrete Dams Due to Alkali-Aggregate Reaction."

Reactive Minerals.—The authors have well stated:

> "Far too little is known about the specific mineral constituents of various rock types which contain silica in forms susceptible to reactivity with alkalies in cement * * *."

This is a fertile field for research.

Opal, Chalcedony, Limonite, Glauconite, Dolomite, and Calcite.—In the early reported California experience, it was definitely determined that opal was the reactive ingredient (4). Test data with 1:2 mortar and high-alkali cement (that is, 1.14% Na_2O), covering four years of observation, are given in Table 2. Because of the high lime-magnesia content, rock No. 28039 (Col. 2, Table 2) was classified as a siliceous magnesian limestone (4*a*). The expansion results in Col. 4, Table 2, however, indicate that opal is undoubtedly the reactive constituent of this rock. The long-time (forty-eight-month) tests confirm the original conclusions based on tests of specimens less than one year old, thereby indicating conclusively that pure chalcedony, limonite, glauconite, dolomite, and calcite have no abnormal reactive properties—at least in the percentages used in this test series.

TABLE 2.—REACTION CHARACTERISTICS OF MINERALS SIMILAR TO THE CONSTITUENTS OF SILICEOUS MAGNESIAN LIMESTONE (ROCK NO. 28039)

Mineral (1)	PERCENTAGE DISTRIBUTION: In rock No. 28039 (2)	PERCENTAGE DISTRIBUTION: In each test specimen[a] (3)	Percentage expansion after 48 months (4)
Chalcedony	15.0	10.0	0.019
Opal No. 1	12.0	2.5	1.574
Opaline chert	1.0	10.0	2.837
Limonite	1.0	5.0	0.012
Glauconite	1.0	5.0	0.010
Dolomite	10.0	10.0	0.007
Calcite	60.0	10.0	0.046
Combined	100.0	10.0	0.776

[a] These are the values substituted for equivalent percentages of the nonreactive sand used in each sand-mortar specimen. Separate bars were fabricated for each of the minerals in Col. 1.

Other tests have been made with higher percentages of chalcedony without the development of an expansive reaction, whereas tests on opal-bearing chalcedonic cherts and other cherts have developed expansive results proportional to the percentage of opal. An excellent discussion on this phase was contributed by Roger Rhoades in 1942 (10). Mr. Rhoades stresses the fact that:

---

[7] Materials and Research Engr., State Div. of Highways, Sacramento, Calif.

> "* * * authoritative conjecture surrounds the possibility that some chalcedony verges toward an opaline character in becoming hydrous, and the question naturally arises as to the possibility of such types also assuming other similarities to opaline silica, perhaps becoming potentially reactive in alkaline environments."

He cites the possibility that:

> "* * * opaline material minutely disseminated in chalcedonic aggregates may escape observation and yet impart opaline properties which appear to pertain to the enclosing chalcedony."

The studies of the rocks found in the coastal region of California, where the opal-bearing chalcedonic cherts have caused so much trouble, check Mr. Rhoades' observations.

Andesites, Rhyolites, Tuffs, and Volcanic Glasses.—The Bureau of Reclamation has definitely traced the cause of the trouble at Parker, Gene Wash, and Copper Basin dams to an andesitic rock. As a result, all andesitic rocks have justly been under suspicion as potentially reactive. This rock type has been observed in the Cowlitz (Washington) gravels and is present in the aggregates from the Friant and other Fresno County (California) areas along the San Joaquin River. The andesites from these areas have been examined petrographically; and, although there are wide variations as to type, texture, and other characteristics, they all have one feature in common—a glassy groundmass. Specimens of concrete from Friant Dam, the Belmont Traffic Circle in Fresno, Calif., the Summers Creek and Courtright Creek bridges in Washington, and the Parker Dam have been examined to observe which aggregates were reacting. Numerous thin sections were made of various particles that appeared to be participating in gel formation. The phenocrysts of plagioclase, hypersthene, hornblende, olivine, augite, rutile, and a few other less common minerals were, in most cases, unaffected by contact with the cement mortar. In various instances, however, the glassy groundmass showed signs of reaction.

It was decided, therefore, to study the glassy groundmass of various basic or intermediate volcanic rocks further. To insure sufficient uniform material for study, and for fabrication into expansion bars, it became necessary to synthesize a quantity of glass having a chemical composition equivalent to that of an average andesite (11)(12). A small furnace was constructed of firebrick. The finely pulverized charge was first moistened with sufficient water to mold it, and thus to prevent the flame from blowing the powder away. The charge was made of the straight oxides of aluminum, iron, silicon, and magnesium with equivalent amounts of the carbonates, calcium, sodium, and potassium. (Compounds of the rarer elements that are usually found in andesites, such as titanium, zirconium, phosphorus, manganese, etc., were omitted from the charge.) Chemical analyses were made of the charge before fusion, and of the fused glass. These analyses are shown in Table 3. Reaction characteristics of this glass are given in Table 4.

As soon as melted, the glass was ladled from the furnace; and, after cooling at room temperature, it was crushed and sieved into various sizes for fabrication into expansion bars with both low-alkali and high-alkali cements. The percentage of silica dissolved after twenty-one days in 10% NaOH (using the Bureau of Reclamation method) was 0.9%. Solubility in NaOH by the foregoing method does not appear to be significant, however, except possibly in the case of the highly soluble rocks, in which case the high solubility may be indicative of opal.

TABLE 3.—PERCENTAGE COMPOSITION OF SYNTHETIC ANDESITIC GLASS

Constituents	Unfused (original mixture)	Fused glass
Silica as SiO_2	54.3	61.8
Alumina as Al_2O_3	17.4	18.8
Iron as Fe_2O_3	3.3	2.5
Lime as CaO	12.8	7.6
Magnesia as MgO	3.9	4.0
Sodium as Na_2O	6.3	3.0
Potassium as K_2O	2.0	1.2
Undetermined	0.0	1.1
Total	100.0	100.0

TABLE 4.—PERCENTAGE EXPANSION OF 1:2 MORTARS OF A HIGH-ALKALI CEMENT (1.07%) AND NEUTRAL RUSSIAN RIVER SAND COMBINED WITH CRUSHED SYNTHETIC ANDESITIC GLASS

Age (month)	PERCENTAGE OF ANDESITIC GLASS							
	At 70° F				At 110° F			
	5	10	20	30	5	10	20	30

24	0.026	0.218	0.470	0.391	0.049	0.299	0.549	0.627
27	0.025	0.218	0.472	0.549	0.061	0.334	0.616	0.726

Chemical Alteration as an Activator.—Observations of many andesite specimens known to be reactive indicated that the specimens were moderately or partly altered and weathered. This condition was existent prior to fabrication into concrete. Work done by R. D. Evans and Howel Williams (13) in Lassen Volcanic National Park (California) shows a few rocks (with opal as a principal constituent) in the vicinity of hot springs to be highly altered. To simulate the Lassen Park condition, some of the synthetic glass was altered in the presence of SO_2 and water, for comparison of expansive reaction with the fresh glass.

A portion of the untreated synthetic andesite glass, crushed to $-20+50$ size was placed in a long glass tube, moistened with water and subjected to daily evolution of SO_2 from a cylinder. A petrographic study of the (SO_2-H_2O)-treated glass indicated a definite change not only in the appearance of the material, but also in its composition and refractive index. Tests at various ages on the unweathered and weathered material (Table 4) indicate a definite increase in reactivity following weathering. This work should be checked against, or compared with, glasses of other composition. A fertile field is indicated for the investigator who has the time.

Experience with the San Joaquin River aggregates from the vicinity of the Friant Dam and several miles lower down at Herndon, Calif., indicated that some of the andesitic rocks in these deposits are highly reactive and some only slightly so (Table 5).

[a] A mineralogical description of each type of rock is listed in the text.

The test data from which Fig. 7 was compiled indicate a definitely reactive andesite. California highway experience at the Belmont Traffic Circle, and on the concrete pavement between Fresno and Herndon is a further demonstration of the fact that at least portions of the San Joaquin River aggregates are highly reactive on occasion. However, because experience indicated that aggregates from this source are not consistently reactive and in some cases not reactive at all, a special series of laboratory tests on samples of rock from the San Joaquin River, which, on superficial inspection appeared to be andesitic in character, was begun several years ago with the results shown in Table 5.

The expansion observations in Table 5 indicate that only one (type No. 2) of the five andesites tested is highly reactive at 70° F but that one other (type No. 5), although not excessively reactive at 70° F, is materially activated at 110° F—thereby indicating potential ultimate excessive reactivity at 70° F. Type No. 2 is reactive at 110° even with the low-alkali cement. That the high results with type No. 2 are not accidental is indicated by the trend of all specimens containing this material in combination with a high-alkali cement at either 70° F or 110° F.

The rock samples in Table 5 were selected from stock piles of coarse aggregate at a commercial plant near Friant. There were no marked visible distinctions between the different samples; and it is difficult, therefore, to estimate the probable percentage of each in the combined product of the plant. That these relative percentages are not constant, however, can be inferred by the difference in performance in different projects using the same cement or cements of similar composition. Obviously, the only safe procedure with such variable quality aggregates is the use of a low-alkali cement as was done as far as practicable by the Bureau of Reclamation in the construction of Friant Dam.

In an effort to determine the reactive ingredients in the San Joaquin River aggregates, a petrographic analysis was made of each of the five rock types tested. The results of these analyses are as follows:

1. *Megascopically, a Dense, Dark-Colored Andesite with a Few Relatively Large Scattered Crystals (Phenocrysts) of Feldspar.*—The rounded pebbles of this type show little or no weathering on the outside surfaces. Under a microscope, the dense groundmass is found to be a fine felt of little rods of plagioclase feldspar arranged in more or less flowing lines with their long dimensions parallel with one another (trachytic texture). Included in the felty groundmass are ferro-magnesium minerals (principally augite), magnetite, and amorphous basic glass.

2. *A Dense, Mottled, Grayish-Green Andesite Which Shows Flow Structure.*—Along numerous fine cracks and planes of weakness parallel to the flow lines the rock has been altered to a reddish-brown material. Microscopic examination shows a felty, locally trachytic groundmass composed of plagioclase microlites (embryonic crystals) with interstitial pyroxene, finely divided magnetite, and basic glass. Portions of the groundmass (from 10% to 20%), particularly along seams and fracture planes, have been altered to a brownish, amorphous, hydrated glass which is probably the mineraloid palagonite.

3. *A Dark-Colored, Dense, Porphyritic Rock Which Shows Flow Structure and Is Streaked with Fine Light-Colored Veinlets.*—This rock consists of large phenocrysts of feldspar, quartz, and hornblende in a once glassy-flowing groundmass which has devitrified, or broken up into aggregates of quartz and feldspar in excessively minute crystals. Numerous quartz veinlets are scattered throughout the rock. This metamorphosed volcanic rock may be classified as an aporhyolite.

4. *A Weathered Andesite Whose Light, Grayish-Brown, Rounded Pebbles Have Fresh Dense Unweathered Cores.*—The amount of this weathering varies; some of the pebbles are completely altered, whereas others have only a rim of altered material on the outside. The unaltered central core of the rock consists of lathlike phenocrysts of plagioclase feldspar (andesine) in a felty, occasionally trachytic groundmass of plagioclase microlites set in a random mesh, the interstices of which are filled with augite grains, magnetite, and amorphous glass. The altered portion of the rock consists of corroded phenocrysts of plagioclase in a groundmass which has been almost completely altered to palagonite.

5. *A Grayish Andesitic Rock with Prominent Flow Lines and Embedded Eruptive Breccia.*—Microscopic examination shows that the embedded fragmental breccia and the matrix are very similar. Both are composed of a finely crystalline net of plagioclase feldspar needles with interstitial pyroxene, magnetite, and glass. Well-developed flow banding is common and alteration to palagonite has occurred along seams in some sections.

Although the cause of the high reactivity of type No. 2 can be traced to the glassy groundmass, the analyses indicate that type No. 4 should have been equally if not more reactive—judging by the petrographic analysis, which classifies it as a weathered andesite in which the weathered or altered portions consist of corroded phenocrysts of plagioclase in a groundmass that has been almost completely altered to palagonite. Since palagonite has been determined to be highly reactive, it was felt that type No. 4 should have shown high, instead of apparently negligible, reactive properties.

Because of the possibility that this was another case in which too great a percentage of a highly reactive ingredient had resulted in no measurable reaction, a new series of tests was begun in which only 2½% and 5% of type No. 4 were incorporated with a neutral sand instead of 10% and 25% as in the original series. Although preliminary 28-day test results indicate some greater reactions than do the original tests, they are not sufficient to justify any definite conclusions.

Phyllite.—The phyllite referred to by the authors, the reactivity of which is well illustrated in Fig. 7, was discussed by H. A. Kammer and R. W. Carlson, Assoc. Members, Am. Soc. C. E., in 1941 in connection with a report on the Buck Hydroelectric Plant in Virginia (2). The reaction at the Buck Plant was slow, and the expansion did not become sufficiently extensive to be noticeable until 1922. However, the expansion continued until, by 1941, the dimensions were reported to have increased about 0.5% and to be still growing. A possible explanation of this slow development of the reaction, if the phyllite is at fault, is the fact that this rock was used only in the coarse aggregate portion of the concrete mix. Crushed to sand size, reactivity becomes apparent at a much earlier period, as demonstrated by the Bureau of Reclamation tests which are checked by some work done by the California Division of Highways.

The authors declare (see heading, "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams") that "Eminent authorities have stated that all rocks, with the possible exception of pure limestone, are potentially reactive in concrete." This conclusion might, with accuracy, have been expanded to state that any such potential reactivity increases with temperature and that most tests indicate a higher expansion at 110° F and 130° F than at 70° F, thereby indicating the effect of temperature as an accelerator and, even on occasion, as an activator. Concrete temperatures exceeding 100° F are not unusual, particularly in pavements and thin walls subject to the direct rays of the sun in the hot summer temperatures that prevail in many areas in California as well as elsewhere throughout the United States. The effect of temperature has been demonstrated by the writer elsewhere (14).

The authors contend (see paragraph preceding the heading, "Progressive Development of Alkali-Aggregate Deterioration in Concrete Dams") that

> "* * * the mortar-bar expansion test has not been developed so that it can be relied upon as an infallible indication of troublesome combinations of cements and aggregates."

This may be true as far as mildly reactive combinations are concerned. However, the mass of evidence accumulated since 1939 has convinced the writer that not only is the mortar-bar test an excellent indication of reactivity but that it is the only dependable test developed to date.

If the authors had qualified this conclusion by a time limit clause such as "within 28, 60, or 90 days when no excessive expansion develops at earlier ages," the conclusion would have greater validity, as undoubtedly in certain slowly reacting combinations, such as the Buck Dam phyllite, a somewhat longer than normal time is required. However, any excessive expansion at early periods can be considered as a definite indication of reactivity, roughly proportional to the magnitude of the expansion.

It is conceded, however, that absence of early expansion cannot be considered as proof of the nonreactivity of the aggregate from a given source when used with a high-alkali cement. The aggregate, if reactive, reacts very slowly; or, if no reaction is observed, the particular sample under test just happens to contain none of the reactive mineral or minerals normally present. The truth of this last statement is well illustrated by experience in California where the mineral causing the reaction (opal) was sometimes present in such small percentages (less than 1.0% of the aggregate) that reactive particles might be entirely missing from a small-sized test sample secured from a commercial supply.

If (as the authors state) the mortar-bar test cannot be considered a satisfactory acceptance test for either cements or aggregates, the only alternative in the absence of any more suitable test is to limit the alkali content of all cements as a standard requirement if engineers are to insure against destructive combinations.

The writer agrees with most, if not all, of the authors' comments on the deficiencies in the mortar-bar test but would have no hesitation in being guided by the results thereof in the absence of evidence to the contrary. On the other hand, the authors are certainly justified in their conclusion that

> "* * * because of the highly accelerated nature of the test, excessive expansions may ultimately be indicated with a highly reactive aggregate and relatively low-alkali cements, although field records do not indicate that such combinations will necessarily cause trouble in actual service."

An illustration of the validity of this conclusion is the California low-alkali cement AS (Table 5) which apparently never develops excessive reaction at normal temperatures but is peculiarly sensitive and frequently becomes highly reactive even at temperatures as low as 110° F. It would appear logical, however, to follow the lead of the mortar-bar tests in the absence of any contrary and reliable job experience.

The authors cite the case of the Owyhee Dam aggregate which, although highly reactive in the mortar-bar tests, failed to show much reaction in service during the first five years. Neither the alkali content of the cement nor the amount of cement per cubic yard used in the Owyhee Dam construction is given. Is it not possible that an intermediate alkali cement, slow in developing sufficient reaction to be objectionable, was used at Owyhee Dam? The accelerated laboratory tests were made with a high-alkali cement and, therefore, are truly indicative of the ultimate potential reactivity of the aggregate. They constitute a warning that a low-alkali cement should be used under similar conditions.

Furthermore, the nature of exposure is undoubtedly an important factor in the development and progress of the reaction. Many structures in which reactive combinations are used show early distress in portions exposed to adverse weathering conditions, whereas protected portions of the same structure fail to develop appreciable distress, if any. Therefore, although the structural stability may not be seriously lowered, the evidences of the reaction occur where they are most readily observed or where there is the greatest likelihood of subsequent failure through either alterations of freezing and thawing or attack by alkalies from soils or sea water.

Corrective and Preventative Measures.—The authors' comments and suggestions with regard to the necessity for, and desirable procedure to be followed in, making repairs to damaged structures are excellent, as are their comments regarding precautions to be taken in the original construction in so far as the use of low-alkali cement (0.60% or less) is concerned. In addition, the authors state:

> "Tests have indicated that some Portland pozzolanic cements may be safely used with reactive aggregate. It has also been demonstrated that additions of fine pozzolanic materials to reactive aggregate and high-alkali cement combinations or a replacement of some of the high-alkali cement by the pozzolanic material will reduce the expansion."

With regard to the Fresno pumicite, however, there is some evidence indicating possible objectionable rather than beneficial qualities.

The California Division of Highways has tested a number of finely divided minerals for use as correctives but so far has found only two types of materials which appear to be always truly corrective when ground to −200 mesh and used in practicable amounts. These two materials are the opaline cherts and the calcined Monterey shale of the type used in the pozzolanic type of cement (HP) (4*b*)(4*c*). Cement HP had a relatively high-alkali content (0.78%) but has been entirely nonreactive over a period of six years although the standard cement of the same brand and alkali content is decidedly reactive. Checks have been made by adding this same pozzolana (calcined Monterey shale) to the high-alkali cement GS with uniformly successful results. All other local siliceous powders with the exception of the ground opaline rocks, however, have been found relatively ineffective.

TABLE 6.—EFFECT OF TWO TYPES OF POZZOLANIC ADMIXTURES ON SEVERAL REACTIVE CEMENT-AGGREGATE COMBINATIONS

Cement No.	Alkali (%)	PERCENTAGE EXPANSION IN FORTY WEEKS AT 70° F		
		No Admix-	Fresno pumicite	Calcined Monterey shale
1	0.47	0.067	0.162	0.014
2	0.47	0.168	0.183	0.015
3	0.51	0.118	0.108	0.016
4	0.62	0.255	0.123	0.011
5	1.17	0.230	0.221	0.086

Table 6 shows the relative effect of two pozzolanic admixtures, ground to pass a 200-mesh screen. The admixtures were Friant pumicite and calcined Monterey shale. Pozzolanic admixtures equal to about 20% by weight of the cement were substituted for an equivalent quantity of the neutral sand portion of the fine aggregate combination. The mortar mix—cement by weight to fine aggregate combination—was 1:2.25; and the fine aggregate was Perkins sand plus 10% of rock No. 28039. Specimens were cured in sealed containers at 70° F. The cements were from lots reported to have been used in the Friant Dam.

The answer to the erratic effect of the Friant pumicite may lie in the alkali content of this material. Chemical analyses show the following percentages of alkali in the Perkins sand, reactive rock No. 28039, Friant pumicite, and calcined Monterey shale:

Material	$Na_2O + K_2O$
Perkins sand	3.53%
Reactive rock No. 28039	0.19%
Friant pumicite	7.04%
Calcined Monterey shale	1.94%

R. W. Spencer,[8] Assoc. M. Am. Soc. C. E.—Damaging expansion of the concrete is known with certainty to occur at only a few points in major structures of the Southern California Edison system although expansion effects may exist, masked by surface deterioration from weathering. One of the examples of excessive expansion occurs in the drainage gallery in the base of a dam where a pit-run tunnel muck was used in placing a small section of concrete. The expansion is made evident by the cracking along exposed corners of the concrete. The concrete was placed in 1926 and the cracking first appeared in 1940. As of June, 1945, however, tests had not shown the presence of silica gel deposits typical of alkali-aggregate reaction. The remainder of the dam was constructed of quarried crushed granodiorite and shows no signs of excessive expansion.

A second instance of damaging expansion has appeared in the mass concrete footings of one of several flumes serving one of the Company's Kern River hydro plants. This concrete was placed in 1920 and surface cracking was noted in 1942, although it is probable that it began several years earlier. The footing concrete was made with crushed phyllite obtained from a near-by tunnel dump. The concrete flume box was made from a portion of the tunnel dump which is low in phyllite and high in granitic material, and no excessive expansion has occurred. Tests by the Bureau of Reclamation on a sample of the cracked footings showed the presence of silica gel typical of alkali-aggregate reaction.

A third case of excessive concrete expansion is known to occur in the walls of a gallery through a heavy tunnel plug at the Company's Big Creek No. 3 plant. The concrete was placed in 1923 and surface cracking appeared in 1940. The aggregate was chiefly granodiorite obtained from a near-by tunnel dump. The concrete where the expansion occurred was badly segregated and the expansion is confined to portions of the structure that are high in mortar and low in coarse aggregate.

In none of the three aforementioned cases has the quantity of concrete involved been large enough nor the effects of the expansion been important enough to require repair, but the fact that the expansion did occur made it desirable to test as many aggregates as possible in the region for reactive tendencies. The results of tests on thirty-one aggregates taken from various sources on the Edison system, including the three discussed herein, are given in Table 7.

M	Crushed marble	120	90	30
	Kern River, Adit No. 3; Tunnel Dump:			
KP	Freshly crushed phyllite	790	190	600
	Standards for Comparison:			
R	Known reactive aggregate[d]	8,450	170	8,280
RX	100% siliceous magnesian limestone	327	27	300

[a] Three 1 in. by 1 in. by 6 in. aggregate-cement mortar bars (mix, 2 : 1 by weight) for each condition tested; sealed and stored over water at 100° F, water-cement ratio, 0.57 by weight. [b] Specially manufactured, containing 0.89% sodium oxide and 0.43% potassium oxide. [c] Commercial cement containing 0.18% total alkali as Na_2O. [d] 20% siliceous magnesian limestone and 80% Bureau of Reclamation quartz.

In no case was the expansion measured in the mortar-bar test high in comparison with the expansion caused by a known reactive aggregate such as the siliceous magnesian limestone supplied by T. E. Stanton, M. Am. Soc. C. E., of the California State Highway Department. However, the Kern River phyllite (KP) used in the footings previously mentioned and the crushed andesite from Italian Creek (IL) showed expansion much greater than normal for non-reactive aggregate. The Italian Creek andesite has never been used in concrete but, because its geological age and vicinity are similar, its action in concrete probably resembles the reactive Friant andesite for which the authors show an expansion curve in Fig. 7.

The expansion of the Kern River phyllite test bars checked the field expansion observed in concrete made with this same material.

The test bars made with the crushed granodiorite (3N) used in the tunnel No. 3 plug, although showing greater than average expansion, did not show enough to put the aggregate definitely in the dangerous class if used with a high-alkali cement. Cored samples of the tunnel plug concrete when examined by the Bureau of Reclamation and the Portland Cement Association did not show deposits of silica gel characteristic of the alkali-aggregate reaction.

Test bars made from a tunnel dump aggregate similar to that used in the expanding block of the dam noted have shown an expansion greater than the average, but not enough to indicate that the aggregate would be dangerous if used with a high-alkali cement. It is possible that the test bars made with the granodiorite aggregates used for this work and that used for the tunnel plug fail to show excessive expansion because the action differs from the typical alkali-aggregate reaction. On the other hand, it may well be, as the authors suggest in the section on "Symptoms and Diagnosis," that the present accepted test procedure for alkali-aggregate reaction is not sensitive enough to predict expansions that may take place in structures twenty years or more after they are completed.

W. L. Chadwick,[9] M. Am. Soc. C. E.—Engineers concerned with the use of concrete are indebted to Messrs. Blanks and Meissner and to others in the Bureau of Reclamation for their straightforward presentation of troubles with concrete as a result of alkali-aggregate reaction. Because the activities of the Bureau cover many projects scattered over the entire western part of the United States, the experience gained is particularly valuable in determining the relatively few undesirable or dangerous cement-aggregate combinations.

The Southern California Edison Company has a number of dams and major concrete structures in the granitic region of the middle Sierra Nevada where natural sand and gravel for concrete aggregates are scarce. Consequently, it has been necessary for most of the concrete in these structures to be made from crushed granodiorite taken either from quarries or from tunnel excavation dumps. Some concrete in these Sierra structures has stood up well but some shows troublesome surface deterioration. Over a period of twenty years continuing efforts have been made to determine the reason for the differences. These efforts have included many tests and petrographic examinations of aggregates and concretes without positive results. When the alkali-aggregate reaction first became known, these structures were re-examined for evidences of such action and a few probable examples were found. The possibility that some particular mineral in the granodiorite was responsible for such trouble and also for other deterioration in the presence of high alkali was considered, as a result of which a fellowship was established at the California Institute of Technology, at Pasadena, in 1942 to test the susceptibility of these individual minerals to reaction with cement-borne alkalies.

---

[9] Mgr., Eng. Dept., Southern California Edison Co., Ltd., Los Angeles, Calif.

Under the direction of John P. Buwalda and Ian Campbell of the Institute, Lloyd Pray undertook the research including the difficult task of separating enough pure minerals from a 500-lb sample of granodiorite to permit the manufacture of a number of 1 in. by 1 in. by 6 in. mortar bars with various concentrations of each mineral. The average composition of the fresh granodiorite was:

Mineral	Percentage
Plagioclase (andesine)	38
Quartz	24
Potash feldspar (chiefly microcline)	18
Biotite	10
Hornblende	8
Magnetite	1
Sphene	0.5
Zircon	Trace
Apatite	Trace

Mr. Pray was able to obtain all the minerals listed with the exception of the plagioclase feldspar, zircon, and apatite in purities of 96% or better. The plagioclase was obtained as a concentrate containing 43% plagioclase and 53% quartz with the remainder largely potash feldspar. The minerals tested were used as aggregates in different percentages ranging from 2% to 100%. The remainder of the aggregate consisted of a crushed crystalline quartz furnished by the Bureau of Reclamation. The selected percentages were based on consideration of the natural proportion of the minerals in the rock and also of the amount of mineral concentrate readily available. The test bars were made up in triplicate, using a 1 : 2 mix by weight and high-alkali and low-alkali cements of known analyses. The low-alkali cement contained 0.18% of total alkali measured as Na_2O. The high-alkali cement contained 0.87% Na_2O and 0.47% K_2O. After curing for seven days at 70° F and 100% humidity, the bars were placed in a cabinet, over water, with a controlled temperature of 100° F, and length measurements were made periodically over a period of two years.

The volume changes for the principal series of test bars at an average age of 750 days are compared in Table 8, including the results from the use of the same cements with an aggregate made from altered or weathered granodiorite and also with siliceous magnesium limestone of proved reactivity obtained from T. E. Stanton, M. Am. Soc. C. E., of the California Highway Commission.

While making the mineral separations it was found that occasional pieces of slightly altered granodiorite contained a zeolitic mineral known as stellerite. Since a zeolite reacts with the ordinary tap water used in washing and may be eliminated by the washing operations, specimens were hand picked for high stellerite content and crushed and concentrated in the dry to obtain a sand containing 33% stellerite. Two series of test bars were made, one containing

2% stellerite and the other 33% stellerite, each mixed with the required complement of crushed granodiorite or quartz (see item 10, Table 8).

To date (1945) the test results are largely negative but they are of value nevertheless. These results may be summarized as follows:

(1) None of the bars showed clearly harmful expansion and presumably, therefore, the aggregate minerals are nonreactive with high-alkali cement;

(2) All the mortars made with high-alkali cement expanded more than those made with low-alkali cement; and

(3) Specimens containing large percentages of biotite mica show rather large expansions for mortar bars, but the rate of change over the last year has been so slow that these specimens cannot be placed definitely in the dangerous class.

TABLE 8.—EFFECT OF HIGH-ALKALI CEMENT (H) AND LOW-ALKALI CEMENT (L) ON THE VARIOUS MINERALS IN FLORENCE LAKE GRANODIORITE

(Expansion[a] in Millionths of an Inch Per Inch)

[a] Volume-change observations were made, after two years, on three cement-aggregate test bars for each condition. The mortar bars (1 in. by 1 in. by 6 in.; mix, 1 : 2 by weight; and water-cement ratio, 0.57 by weight) were sealed and stored over water at 100° F. [b] The abbreviations H and L denote, respectively, high-alkali cement, specially manufactured, containing 0.89% sodium oxide and 0.43% potassium oxide; and a commercial, low-alkali cement containing 0.15% total alkali as Na_2O. [c] Average of six bars. [d] Average of two bars only. [e] 20% of siliceous magnesian limestone in each case. [f] Age 270 days. [g] 33% stellerite.

The authors have assisted the writer materially in the work done under the fellowship and in searching for the causes of other concrete troubles, and this opportunity is taken to express appreciation for material assistance, advice, and free exchange of progress information.

J. C. WITT,[10] M. AM. SOC. C. E.—For convenience in discussion, the writer has divided the title of this paper into three sections, each of which refers to a section of the paper:

$$\overbrace{\text{"Deterioration of Concrete Dams}}^{1}\quad\overbrace{\text{Due to}}^{2}\quad\overbrace{\text{Alkali-Aggregate Reaction."}}^{3}$$

---

[10] Tech. Director, Marquette Cement Mfg. Co., Chicago, Ill.

The first section of the paper consists largely of a rather general account of deteriorated concrete, together with descriptions and illustrations of some examples. Many papers have appeared in which the deterioration of various types of building materials has been discussed, and examples almost without limit could be listed. In the third section, chemical reactions between compounds of alkalies and compounds of silicon are mentioned. These reactions have been known for a long time.

The tying together of the two groups of phenomena by the second section of the title suggests that the relation of the two is to be demonstrated in the paper. This relation is not demonstrated. In fact, if, by the reading of previous papers, one had been convinced that an increase of a few tenths of one per cent of alkali compounds in a cement would cause concrete to deteriorate, some statements in this paper might weaken his belief materially. Some of the statements that suggest this conclusion are:

(*a*) "The problem is extremely complicated, however, and many questions, practical and technical, remain to be answered satisfactorily" (see heading, "Synopsis").

(*b*) "It is suspected that, under some conditions, restraint is sufficient to prevent most of the expansion that would normally occur if the concrete was not restrained" (see heading, "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams"). Statement (*b*) implies that even in concrete free from cracks reactions tending to cause deterioration may be in progress.

(*c*) "Chemical analyses of the gels show them to be composed essentially of sodium and potassium silicates" (see paragraph that introduces Table 1). The analyses in Table 1 indicate that the gels contain sodium, potassium, and silicon; but they do not indicate how these elements are combined.

(*d*) "Hand specimen and microscopic study of core samples from affected concrete also invariably reveal what appear to be zones of chemical reactivity, alteration, or infiltration around certain aggregate particles, as shown in Fig. 5."

The authors have cited a number of references in support of their statements, and they could have cited additional ones. Many statements in opposition could also be made. For example, in discussing the expansion of mortar bars made with 106 cements varying in alkali content, W. C. Hanna (15) states:

> "At the age of 2 months the expansions of these bars, with few exceptions, were observed to be definitely related to the alkali content of the cements. At 6 months many exceptions were observed in this relation, and at the age of 18 months nearly all of the bars had expanded excessively. In many instances bars of low alkali content expanded to a greater extent than those of higher alkali content. * * * Some bars to which a deliberate addition of sodium hydroxide was made showed lower expansions than companion bars made without addition."

No one should accept the relation between the deterioration of concrete and the alkali content of cement expressed, and implied, in the paper without familiarizing himself with the great mass of information on this subject that is available in literature.

Under the heading, "Corrective and Preventive Measures," the following statements are made:

(*e*) "Experience to date indicates that reactive aggregates can be used without danger of destructive reaction, provided that low-alkali cement (less than 0.60% $Na_2O + K_2O$) is employed (see Fig. 7)."

(*f*) "Specification of low-alkali cement for all important hydraulic structures is strongly recommended regardless of what may or may not be known about the reactive tendencies of the aggregates to be used." If the deterioration of concrete may be caused by internal alkali compounds, and if there is a preventive measure, surely this preventive measure (statements (*e*) and (*f*)) is not so simple as to be merely a matter of reducing the percentage of alkali compounds in the cement. Many factors are involved, some of which are the total sodium and potassium in the concrete (not in the cement only), and the nature of their compounds.

(*g*) "Such a precautionary measure [reduction in alkali content] not only provides insurance against possible eventual deterioration due to alkali-aggregate reactions, but limits undesirable constituents of Portland cements and usually improves the quality in several other ways." Some examples are mentioned in which, "the reduction in alkali content has been accompanied by marked reductions in C_4AF (tetracalcium alumino-ferrite), which is a fluxing material having little cementing value in itself, and lower C_3A (tricalcium aluminate), which is generally considered to be an undesirable compound. Coincidentally the principal cementing compounds, C_3S (tricalcium silicate) and C_2S (dicalcium silicate), have been increased as much as 9%." There is no fixed relation between the alkali content of a cement and the percentages of the principal clinker minerals. This applies to the succeeding paragraph also.

(*h*) "It seems evident that the additional cost of low-alkali cement, which may range from nothing to about 20¢ per bbl, is more than repaid by the improvement in quality alone." If the authors mean the manufacturing cost, such a general statement is not warranted.

The lag between research accomplishments and their application is one of the most serious retarders of industry. Also serious, although far less common, is the lag between application and research accomplishments.

DUFF A. ABRAMS,[11] M. AM. SOC. C. E.—A notable feature of the paper by Messrs. Blanks and Meissner is its many contradictory statements. A few of the more obvious contradictions are listed here as an introduction to the arguments to follow:

Cracks in Boulder Dam (see heading, "Progressive Development of Alkali-Aggregate Deterioration in Concrete Dams") "must be ascribed to extreme drying exposure in the hot, arid location," but in Parker Dam, made of the same cements, a similar concrete mix, built by the same contractor, using the same equipment, in a hotter and more arid location, the cracks were ascribed (see heading, "Significant Effects of Alkali-Aggregate Deterioration on the Service Life of Concrete Dams and Appurtenant Works") to alkali-aggregate reaction. Surface cracks in concrete dams are attributed to internal expansion due to alkali-aggregate reaction, but the photographs that illustrate this phenomenon clearly show contraction cracks.

---

[11] Cons. Engr., New York, N. Y.

The mortar-bar expansion test on sand from Owyhee Dam shows the highest expansion of any sand reported. Photographs of "affected areas" (Fig. 8) do not show Owyhee Dam, but only part of a small viaduct.

Nearly every positive assertion by the authors is modified or nullified by contrary statements elsewhere in the paper.

Failure of Parker Dam.—A number of concrete dams were mentioned; but, to the writer, the paper seems primarily an attempt to explain the failure of Parker Dam on the Colorado River 155 miles south of Boulder Dam. This is an arch dam, 322 ft high, 100 ft thick at the base, and 39 ft thick at the roadway level, containing 276,000 cu yd of concrete. It was completed in 1938 by the U.S. Bureau of Reclamation (U.S.B.R.) for the Metropolitan Water District of Southern California, at a cost of $9,000,000. Two years later it was found to be in an advanced stage of disintegration.

It may be thought that "failure" is not the correct term, since, at last report, the dam was still in service. The following statements were made by the chief engineer, U.S.B.R., early in 1941 (16):

> "In the construction of Parker Dam full advantage was taken of every known advancement and modern improvement in the selection and utilization of materials, production control, construction methods and equipment; the concrete was cooled and no precaution was overlooked to insure the very highest quality of construction in that dam. Nevertheless, we have a dam there whose permanence must be very seriously questioned.***
>
> "Of course, Parker Dam is not going to fall down next year or the year after, but it is going to require a lot of maintenance work, and there is the possibility that at some time in the distant future it may have to be largely replaced."

When the chief engineer, two and one-quarter years after completion, sees a large concrete dam "whose premanence must be seriously questioned," and a dam that "may have to be largely replaced," the only accurate term is "failure." After five years of "intensive investigation," the authors attributed the failure to reactions between the alkalies in the cement and the aggregates.

This discussion examines the authors' evidences of alkali-aggregate reaction in concrete. It will be shown that the failure of Parker Dam was due to an entirely different cause, and that it was exactly what should have been expected from properties and behavior of concrete that had long been well known to the profession.

High-Alkali Cements.—It has been known for nearly a century that Portland cements contain alkalies. The first complete analysis of Portland cement was reported, in 1849, by A. Hopfgartner (17), an Austrian chemist, from tests made on English cement that gave 2.7% alkalies. Every subsequent complete analysis of Portland cement has shown alkalies. It is doubtful whether a commercial cement was ever made that did not contain alkalies.

Prior to the construction of Boulder Dam, the U.S.B.R. spent a large sum of money in studies of cement and concrete (18)(19). As a result of these studies they prepared a specification for what is now known as a low-heat cement. The principal characteristic of this cement is the high ratio of dicalcium silicate. The most direct method of producing such a cement is to reduce kiln temperature. It has long been known that low kiln temperatures increase the alkalies in the cement. This was brought to the attention of American engineers by W. F. Hillebrand (20) in 1903, and by A. V. Bleininger (21) in 1904.

The low-heat cements used in Parker Dam were manufactured by the same four mills that furnished cement to Boulder Dam.

"Gel Deposits."—The incomplete chemical analyses in Table 1 are the only data that have been released on the composition of the "gel deposits" from cores taken from Parker Dam. These analyses were first made public in February, 1941 (6). The entire case of "gel deposits" collapses in the light of evidence that the cores were packed in damp sawdust for shipment to Denver, Colo. (22). Many woods contain organic acids that readily attack compounds in cements and aggregates. Evidences of acid action would be destroyed by exposing the samples to a high temperature. The nature of the material that was driven off in the "loss-at-ignition" test (Table 1) was not disclosed; nor was the temperature given. These losses seem to represent free water, although it may have been carbon dioxide, water of crystallization, alkalies, or many other compounds.

The material that the authors identified as water glass was probably formed in the crucible during the "loss-at-ignition" test. Water glass is formed only under the most favorable conditions and at a temperature high enough to fuse alkalies and silica; it certainly was not formed in this concrete.

Mortar-Bar Tests.—The writer made a serious effort to ascertain what the facts were with reference to the mortar-bar expansion tests reported by the authors, but was soon lost in conflicting tests and in "yes-no-maybe" language. Typical statements were:

Statement A (See Heading, "Summary").—

> "Aggregate which will give this trouble in concrete may be recognized if it produces expansion within a short time in test specimens made with high-alkali cement."

Statement B (Last Paragraph Under "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams").—

> "The test is useful only as an indication of possible troublesome combinations of reactive aggregates and high-alkali cements."

Statement A is positive and unequivocal, but it is completely nullified by Statement B. The key words in Statement B are "indication" and "possible." Used in science or engineering, "indication" is a "strong" word; Webster's

Dictionary gives the synonyms "manifestation, mark, evidence, signal, and proof." The word "possible" is "weak" and takes a position at the opposite end of the scale. Something that is "useful only as an indication" of a possibility is no indication at all. The net result of the two statements is a sort of double vacuum.

Another example is afforded by the sentences preceding Statement B:

Statement C.—

> "Although excellent correlations have been obtained between laboratory results and service performance, the mortar-bar expansion test has not been developed so that it can be relied upon as an infallible indication of troublesome combinations of cements and aggregates. Neither can it be considered as a satisfactory acceptance test for either cements or aggregates."

What were these "excellent correlations"? In no instance was the cement used in the tests, the same as that used in the dams which showed "deterioration due to alkali-aggregate reaction." In the case of "Crushed Phyllite, Buck Dam in Virginia" (Fig. 7), the test showed a very rapid expansion; in three months it was 0.4%, but, for the dam, expansion was not observed until the concrete was ten years old, and it required eighteen years to reach 0.5% (2). "Excellent correlations" would of themselves establish the test as an "infallible indication of troublesome combinations" of cement and aggregates. The positive assertion ahead of the comma in Statement C was promptly canceled by the contrary statement after the comma.

Statements A, B, and C are fair examples of what the authors have to say on the mortar-bar expansion test after using it for five years; but the tests in Fig. 7 cannot be accepted as evidence of alkali-aggregate reaction. A few of the reasons are: (*a*) The reader is not informed as to the composition or any other properties of the sands; (*b*) he is not told the alkali content or any other properties of the cements; and (*c*) he is not informed whether all high-alkali tests were made with the same cement. Perhaps the excessive expansion found with certain sands and high-alkali cement was due to high free lime that generally accompanies low burning temperatures. Furthermore: (*d*) With high-alkali cement, crushed andesite from Friant Dam showed, at three months, seven times the expansion of Parker sand, but in an earlier report Mr. Blanks (4*d*) showed that Parker andesite gave no appreciable expansion at three months; (e) at six months, with high-alkali cement, Owyhee sand showed eight times as much expansion as Parker sand, but there was no evidence to show that Owyhee Dam expanded several times as much as Parker Dam; and (*f*) no values were given for Owyhee and American Falls sands with low-alkali cement. Perhaps these tests showed more expansion than the high-alkali cement.

The writer finds no foundation for the claim of "excellent correlation" between the mortar-bar test and service performance. The mortar-bar tests are inconclusive and misleading, and bear no relation to what occurs in a dam. The conflicting treatment of the paper supports the writer's deductions.

Reactive Aggregates.—The entire burden of the paper is that alkali-aggregate reaction was the cause of the deterioration of concrete dams; but, when the reader inquires into the scientific basis for this hypothesis, and attempts to identify the "reactive aggregates," he encounters insurmountable dificulties.

Opaline Silica.—This material heads the list of rocks that "have been found to react with high-alkali cement." What is "opaline silica"? It is not defined by any dictionary in the New York Public Library; it does not appear in the index of the Encyclopædia Britannica; and it is not found in the index of Chemical Abstracts, started in 1907. A commercial house that has supplied mineralogical specimens from all parts of the world for eighty-two years could not fill an order for a sample of "opaline silica." Dana's "Manual of Minerology" has been a standard reference work for nearly one hundred years; "opaline silica" did not appear in any of the fifteen editions of this book published between 1848 and 1941. Opal is a form of hydrous silica; hence "opaline silica" is a redundancy which being translated becomes: "(hydrous-silica)—like silica."

Rhyolite.—"Some rhyolites" were found by the authors among the "more conspicuously reactive" aggregates; but a rhyolite (pumicite) was used to replace 20% of the cement in Friant Dam, and the authors "felt that pumicite has furnished some protection against expansion where the low-alkali cement was not provided" (see heading, "Corrective and Preventive Measures"). In other words, "some rhyolites" are reactive with high-alkali cement; but, when the rhyolite is very finely divided, contains 9% alkalies, and is called "pumicite," it is not harmful, but has distinct merits when used with a high-alkali cement.

Andesite.—The writer was struck by the use of the word "some," which occurred seven times as a modifier of various rock types that the authors claim to be reactive with high-alkali cement. Fortunately, there is evidence by which to determine what was included in "some andesites." Early papers by the authors (6)(22)(4d) claimed that andesite was the principal reactive aggregate in Parker sand. In 1941, however, Mr Blanks (4d) published the results of tests on mortar bars with a high-alkali cement and 10% of Parker andesite crushed to four different finenesses. All tests showed negligible expansion at one, two, and three months. The authors now give, in Fig. 7, a curve for "crushed andesite, Friant Dam," which shows a very high expansion. The native rock at Boulder Dam is described as "andesite breccia," but, according to the authors (see heading, "Progressive Development of Alkali-Aggregate Deterioration in Concrete Dams"):

> Statement D.—
>
> "The only place where alkali-aggregate reaction had been definitely identified at Boulder Dam, after eight years of service, was in the lining of a drainage tunnel through some wet rock."

Obviously, this rules out Boulder Dam andesite, although the same high-alkali cements were used as at Parker Dam. In two out of three instances andesite has been found nonreactive. This reduces "some" to less than one third. It is more logical to conclude that andesite is nonreactive, and that repeat tests on the same material gave conflicting results.

Other Rock Types.—In view of what has been written herein under "andesite," little weight can be given to the authors' claims (see heading, "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams") that:

Statement E.—

> "Some of the more conspicuously reactive aggregate materials include: Opaline and other siliceous rocks such as some cherts, some siliceous limestones, some chalcedonies and intimate opal-chalcedony admixtures; certain acid to intermediate volcanic rocks such as some andesites and rhyolites, including tuffs and glasses of similar composition; and miscellaneous rock types such as phyllite."

The authors' term "other siliceous rocks" (a meaningless classification in regions where all rocks are siliceous) just about exhausts the rock types that are claimed to be reactive. The only conclusion that the writer can draw from the data and the statements of the paper is that the authors failed to name a single recognizable rock type that is reactive with high-alkali cement.

Alkali-Silica Reaction.—The paper encourages readers to believe that an alkali-silica reaction had been identified as the cause of the "alkali-aggregate disease in concrete dams," but the expression generally used was "alkali-aggregate reaction." The following is typical of the misleading inferences of the paper (see heading, "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams"):

Statement F.—

> "Far too little is known about the specific mineral constituents of various rock types which contain silica in forms susceptible to reactivity with alkalies in cement to permit positive predetermination of troublesome combinations by petrographic analyses."

To make such a statement regarding "silica in forms susceptible to reactivity with alkalies" begs the question; it merely asserts something that has not been proved. Dozens of scientists have devoted their lives to the study of silica. The properties of the various forms of silica that occur in nature are fairly well understood. There is no evidence to show that the authors made any attempt to determine whether or not these forms are reactive with alkalies. Alkalies are among the most widely distributed compounds in nature. The fact that silica in sand and gravel has not been destroyed by alkalies is of itself strong evidence that it is not reactive.

The only parts of the paper that bear on this question are the high silica content of one of the "gel deposits" in Table 1, and the statement that "The gels may be transparent, closely resembling ordinary water glass***." The writer has shown that: (*a*) No credence can be given to the inexpert and incomplete chemical analyses of the "gels"; (*b*) water glass cannot possibly be formed in the concrete; and (*c*) not a single recognizable rock type was identified as reactive with high-alkali cements. In other works, the paper contains no evidence of alkali-silica reaction.

Before the hypothesis of alkali-silica reaction becomes acceptable, the authors must explain:

(1) If certain constituents of Parker sand were attacked by cement alkalies in the dam, why were they not long ago destroyed by the same alkalies in Williams River water (a tributary to the Colorado River)?

(2) If 5 lb of cement alkalies is a menace to a cubic yard of concrete, why was the aggregate not long ago destroyed by 225 lb of the same alkalies that they contain?

(3) Parker Dam cements contained 16 to 47 times as much silica as alkalies. Why did not this silica combine with the alkalies during hydration of the cement?

(4) Parker Dam cement had 1.2% alkalies; the mortar contained 0.3% of cement alkalies. The "gel deposits" had 17% alkalies, or 55 times as much as the mortar. How can the cement alkalies move about so freely within the hardened concrete? Why did this high concentration of alkalies occur in the hardened concrete and not in the cement paste alone, or in the aggregate alone?

The mere statement of the foregoing considerations discredits the hypothesis of alkali-silica reaction in concrete. In the case of Parker Dam, the authors gave this hypothesis a slight semblance of credibility by: (*a*) Incomplete, inconsequential tests, (*b*) foggy language, and (*c*) playing down or failing to present important information on concrete materials and test methods.

Solution of an Enigma.—In the foregoing paragraphs the writer has shown that: (*a*) The mere assertion that there are "rock types which contain silica in forms susceptible to reactivity with alkalies in cement," does not constitute a demonstration; (*b*) incomplete chemical analyses cannot be accepted as a basis of a hypothesis of alkali-silica reaction; (*c*) contradictory statements on the results of mortar-bar tests make those tests valueless; and (*d*) such expansion as was found was probably due to causes other than alkali-aggregate reaction. The remainder of this discussion is constructive in that it solves the "enigma" of the failure of Parker Dam.

Parker Dam Climate.—The school geography used by the writer had printed across the map of the southwestern part of the United States: "The Great American Desert." At Parker Dam the sun shines nearly 100% of the possible hours, shade temperatures reach 125° F, and concrete surface temperatures 145° F. The air is almost devoid of moisture; relative humidities of 6%, 5%, and 4% are frequently recorded. In parts of this desert 10-yr periods have passed without any measureable rainfall. It is doubtful whether a large concrete structure has been built any place in the world where more severe combinations of high temperature and low humidity were encountered. The U.S.B.R. has used the terms "blistering desert," and "almost unbearable heat," to describe the conditions at Boulder Dam, which is 155 miles north of Parker Dam.

Concreting Parker Dam.—In many important features of the design and construction of Parker Dam, there was failure to take account of the severe climate, and well-known properties and behavior of concrete were ignored. Three examples are given:

(1) Grinding of Aggregates in Mixer.—Concrete was mixed in 4-yd batches. The specifications required concrete to be mixed $2\frac{1}{2}$ min. Since 1870, leading

authorities have repeatedly warned against overmixing to such an extent as to produce excessive breaking or grinding of aggregates. Three important series ot tests were conducted before concreting was begun on Parker Dam in 1937. The late W. A. Slater, M. Am. Soc. C. E. (23), made such tests in 1930; S. C. Hollister, M. Am. Soc. C. E. (24) in 1931; and W. A. Blanchette (25) in 1934. All studies showed that long mixing, using gravel up to 1¼ in., resulted in grinding large quantities of aggregates to the fineness of cement. Little argument will be required to show that even with modest times of mixing, excessive grinding occurs with gravel up to the size of a football. An ideal grinding machine is created by 17,000 lb of water, cement, sand, and gravel as large as 6 in. The writer has shown (26) that at Grand Coulee Dam (on the Columbia River, Washington), 4-yd mixers produced rock dust equivalent to 26% of the weight of the cement in 2½ min, and 95% in 15 min. There are several reasons for the belief that there was more mixer grinding at Parker Dam than at Grand Coulee Dam.

(2) Rate of Concreting.—The rate of placing concrete should be restricted to permit the dissipation of part of the heat of hydration of the cement. Parker Dam Specifications provided (27):

> "The rate of placing concrete in any panel or block of the dam shall be such that not more than 5 ft. shall be placed in 72 hours, and not more than 30 ft. in depth shall be placed in 30 days unless specifically authorized by the contracting officer."

Construction records show that, in the hottest months of the year, neither of the foregoing provisions was enforced. In many instances 10 ft or 15 ft of concrete was placed in 72 hours. Instead of limiting the depth to 30 ft in 30 days, 45 ft to 70 ft was placed in a month. In three instances, 60 ft was placed in a month; in seven instances, 65 ft; and in six instances, 70 ft.

(3) Curing Concrete.—The importance of adequate curing of concrete has been well understood since 1920. How was the challenge of this "blistering desert" met at Parker Dam? The Specifications required (27):

> "For concrete made with low-heat or moderate heat cement the period of moist curing shall be extended to not less than three weeks to correspond to the minimum curing period of two weeks for concrete made with standard portland cement. The method of keeping the concrete moist shall be by continuous sprinkling, spraying, or other methods approved by the contracting officer."

A concession of one week (which was not enforced) was made on account of the low-heat cement, but no concession whatever was made on account of sun temperatures up to 145° F or the near-zero humidity. The upper, thin, reinforced concrete sections of the dam were not cured by "continuous sprinkling, or spraying," but by three coats of a patented curing compound that was poorly adapted to the conditions.

Cracking of Parker Dam.—On this job every effort should have been made to restrict mixing water to a minimum. By a better grading of aggregates, and a method of mixing that minimized mixer grinding, the mixing water in a cubic yard of concrete could have been reduced from 250 lb to 175 lb. All concrete should have been effectively water cured for the entire summer after the main portion of the dam was finished early in 1938. Instead, the concrete contained a great excess of mixing water, and the curing was not up to the standard practice in regions with a favorable climate. Surface cracking at Parker Dam was due to too much mixing water and to inadequate curing. The effects of these factors were well understood long before this dam was begun. It is not necessary to search for a mysterious alkali-aggregate reaction to explain these cracks.

The first twelve pages of the paper give the impression that serious deterioration was shown by the internal expansion that caused surface cracks in concrete dams; in the remainder of the paper the authors' attempt to demonstrate that such cracks "would appear to be of minor importance." The work "crack" (cracks, cracking, crazing) was used about forty times, but the authors concentrated the reader's attention on surface "random-pattern cracking." Not once did they refer to structural cracks in either the dam or the superstructure. The structural cracks contradict the alkali-aggregate hypotheses of the paper.

Expansion Measurements at Parker Dam.—To the writer, the curves in Fig. 10, presented to "indicate progressive expansion in the concrete of Parker Dam," have a meaning entirely different from that suggested by the paper. There is a well-known cause of concrete expansion that has nothing to do with alkali-aggregate reaction, which certainly was present in this dam—namely, temperature rise due to the hydration of the cement. This effect of the heat of hydration has long been recognized, and has generally been partly counteracted by an embedded-pipe system of cooling the concrete. Cooling was not applied to the abutments, however, and it is probable that the cooling of the other portions of the dam was ineffective, since the cooling medium was river water and cooling was delayed until serious damage had occurred.

The trend of the curves in Fig. 10 shows a net expansion, in the 5-ft to 10-ft range, of about 0.00013 per yr. Assuming a coefficient of thermal expansion of 0.0000055, this expansion would be accomplished by a temperature rise of 24° F per yr. If this continued for five years, from the time the concrete was placed until the end of 1942, it means a total rise of 120° F.

Parker Dam has five 50-ft by 50-ft gates. The two abutments, outside of the gate system, are about 375 ft long. The total horizontal movement into the gate openings in five years would then be: $0.00013 \times 5 \times 375 \times 12 = 2.9$ in. In the same way there would be a "hump" of about $2\frac{1}{2}$ in. in the middle of the dam due to vertical expansion. This placed the gates, the gate-operating structure, and the roadway bridges in a gigantic vise where they were crushed like eggshells. It is not surprising that there was considerable "binding of gates" which the authors mention three times.

The expansion, in which the authors (see heading, "Symptoms and Diagnosis of Alkali-Aggregate Deterioration in Concrete Dams") mistakenly saw "signs of abnormal expansive movements in concrete which accompany alkali-aggregate reactions," was due to hydration of cement. The measured expansion (or computed temperature rise) enables one to estimate the excess stress developed in the restrained concrete in the dam proper. Assuming a modulus of elasticity of 4,500,000 lb per sq in., the stress would be: 0.00013 × 5 × 4,500,000 = 3,250 lb per sq in. Part of this excess stress near the top of the dam was relieved, no doubt, by pushing the crown of the arch upstream. In an earlier discussion (28) the writer gave some evidences of similar high stresses in Boulder Dam, due to unconsidered temperature rise, as a result of continuing hydration of cement.

That the writer's analysis is not mere theory is shown by two other facts: (*a*) During construction, a wedge of concrete about 100 ft long broke off where the downstream corner of one of the abutments joined the rock; (*b*) the reinforced concrete girders that carry the highway over the 50-ft gate openings showed, within a few months after completion, that they had been squeezed and crushed like so many eggshells. The foregoing phenomena were clearly not due to alkali-aggregate reaction; they can be accounted for readily by temperature rise of the concrete; they were not mentioned by the authors.

Missing Data.—A large number of extensometers and thermometers were embedded in Parker Dam. Instead of giving these data which have been available from the beginning, the authors base their conclusions on expansion and temperatures as measured in four shallow holes that were drilled in an abutment several months after the dam was known to be in a precarious condition. The deepest of these holes was 3% of the maximum depth of the dam.

It seems obvious that the "concrete temperature" curve at the top of Fig. 10 does not represent the interior of the dam; the dam temperature could not possibly show seasonal variations of 40° F. A study of the curves suggests that the temperatures for the 30-in. hole were plotted; the points do not, in general, coincide with the dates of expansion readings in the 12-in., 60-in., or 120-in. holes.

The authors are requested to give for Parker Dam: (*a*) Concrete temperatures for, say, April, 1938, 1939, 1940, 1942, and 1945—in an abutment at mid-depth of the gate opening and in the middle of the dam 50 ft below tailwater level; (*b*) the horizontal movement of each abutment into the gate opening; (*c*) the rise of the top of the dam; (*d*) the upstream movement of the crown of the arch; and (*e*) all temperature readings taken in the four holes drilled in an abutment.

Conclusions.—This discussion is a condensation of a more voluminous study of the paper. The space available makes it necessary to omit many significant features, and merely to state some of the conclusions without supporting data or arguments.

General.—

(1) The paper was notable for its many contradictory statements; practically every positive assertion of the authors was modified or nullified by contradictory statements elsewhere in the paper.

(2) To the writer it appears that the authors did not avail themselves of evidence that contradicts the hypothesis of the alkali-aggregate reaction.

(3) The photographs that were given to illustrate expansive cracking of dams clearly show cracks to be due to contraction of concrete.

(4) The only general conclusion that can be drawn logically from the paper is that dams should not be built of concrete. The writer does not subscribe to that conclusion.

Alkali-Aggregate Reaction.—

(5) The "gel deposits" from Parker Dam concrete probably resulted from attack by organic acids; this accounts also for the "chalky, lifeless appearance" of the concrete. These phenomena were not due to alkali-aggregate reaction.

(6) The resemblance of the "gel deposits" to water glass probably resulted from a manufacture of a glass in the crucible at the high temperature of the ignition test. It is certain that water glass was not formed in the concrete. There was no evidence to show that the "gel deposits" were harmful to concrete.

(7) Five years of "intensive investigation" failed to identify a single rock type that reacted with high-alkali Portland cement. The hypothesis of alkali-silica reaction has no basis except foggy language, unsupported assertions, and trivial circumstances.

(8) The "yes-no-maybe" language of the paper makes it impossible to determine what the authors' conclusions were with reference to the mortar-bar expansion tests. The tests that have been reported are contradictory and misleading.

(9) The laboratory tests were in general meaningless, due to limited scope, lack of scientific controls, and faulty technique. In most instances the material tested did not remotely resemble the concrete used in dams.

(10) The authors' blanket indictment of all types of concrete aggregate "with the possible exception of pure limestone" (that does not occur in Nature) is not supported by data in the paper; it is contradicted by one hundred years of experience by the concrete industry.

Failure of Parker Dam.—

(11) Since January, 1940, it has been fashionable to attribute concrete failures to alkali-aggregate reactions. The evidence shows that Parker Dam was in a precarious condition early in 1940, less than two years after completion. Failure was at once attributed by U.S.B.R. to an excess of 0.6% of alkalies in the cement that they had designed especially for this work.

(12) Concrete specifications were inadequate for this "blistering desert" climate; the few ineffective requirements were ignored.

(13) Abnormal surface cracking was due to excessive volume shrinkage of concrete as a result of rapid evaporation of mixing water. The excessive quantity of mixing water resulted from poorly graded and contaminated aggregates and from excessive mixer grinding. Surface cracking could have been reduced to negligible proportions by exercise of well-recognized precautions with reference to materials, proportions, and curing.

(14) The damage to Parker Dam is much more serious, and from a cause entirely different from that suggested by the paper. Unconsidered temperature rise due to hydration of the cement resulted in a destructive expansion that the authors mistakenly attributed to alkali-aggregate reaction. This placed

five large gates, the gate-operating structure, and the roadway bridges, in a gigantic vise, where they were crushed like eggshells.

(15) Too rapid placing of concrete, although prohibited by the Specifications, contributed to this destructive expansion.

(16) There is no evidence to show that high-alkali cement contributed in any way to the cracking, expansion, or failure of the dam. There is no reason to think the results would have been different if a low-alkali cement had been used.

(17) The measured expansion, given in the paper, corresponds to a computed compressive stress in the concrete of 3,250 lb per sq in. in excess of that for which the dam was designed.

(18) The trouble at Parker Dam was inherent in the proportions of concrete mixes and the concreting methods. If information that had long been available to the profession had been used, there is every reason to believe that this dam would be in perfect condition today—a constant reminder that (as stated by the U.S.B.R. in 1942) concrete "is in reality a simple and practical art."

R. F. Blanks,[12] and H. S. Meissner,[13] Members, Am. Soc. C. E.—Since the paper was written, another dam, afflicted with expansion and accompanying cracking, has come under observation. Stewart Mountain Dam was built in 1929 and 1930 on the Salt River in Arizona, with cement from two mills that later supplied low-heat cement of high-alkali content (1.25% and 1.13% $Na_2O + K_2O$) for Parker Dam. The same two mills also furnished cement for the upper part of Coolidge Dam, built in 1927–1928 on the Gila River in Arizona, the upper part of which structure was described in the paper as suffering from expansive cracking. Fig. 12, illustrating the deterioration of concrete in Stewart Mountain Dam, is typical of all concrete in which reaction between aggregate and high-alkali cement has been found. Mortar-bar expansion tests have been made with sand, taken from the river near the original aggregate deposit, using the high-alkali and low-alkali cements of Fig. 7. After 18 months the specimens containing high-alkali cement show 0.33% expansion, whereas those containing low-alkali cement show only 0.02% expansion. Further evidence of reaction is to be noted in Fig. 13, which shows gel oozing from a concrete core recently drilled from the structure, after the core had been stored in a fog room for 22 days.

Stewart Mountain Dam is mentioned because Mr. Proctor implies that more of this type of deterioration has appeared in structures erected since 1930 or 1935 than in older concrete work, and he considers that much of the trouble has occurred where "new types" of cement have been used. Of the several affected hydraulic structures discussed in the paper—American Falls Dam, Buck Dam, Coolidge Dam, and Owyhee Dam, together with Stewart Mountain Dam—were all built prior to the period mentioned and did not contain "new-type" cement.

---

[12] Chf., Div. of Eng. and Geological Control and Research, Bureau of Reclamation, U. S. Dept. of the Interior, Denver, Colo.

[13] Civ. Engr., Materials Laboratory, Bureau of Reclamation, U. S. Dept. of the Interior, Denver, Colo.

Mr. Proctor advances the theory that cements passing the Merriman tests (which are incorporated in cement specifications of the New York City (N. Y.) Board of Water Supply—B.W.S.), particularly the sugar solubility test, would not have caused expansion in concrete. Results of the Merriman tests are available for the cements used in Parker Dam and, for convenience, these have been listed in Table 9, together with the B.W.S. specification limits for the tests and for the cement composition. None of these cements meet the B.W.S. specifications completely, although all meet the sugar solubility test, which is considered the criterion of complete burning. However, the allowable composition range permitted by B.W.S. is extremely narrow—much more so than any range that has ever been used by the Bureau of Reclamation (U.S.B.R.). Mr. Proctor believes that the expansion trouble has appeared with the introduction of the new-type cements, but it should be apparent that few of the older cements would have passed these rigid specifications entirely. Therefore, it cannot be presumed that older cements have good service records because they are similar to present-day B.W.S. cements.

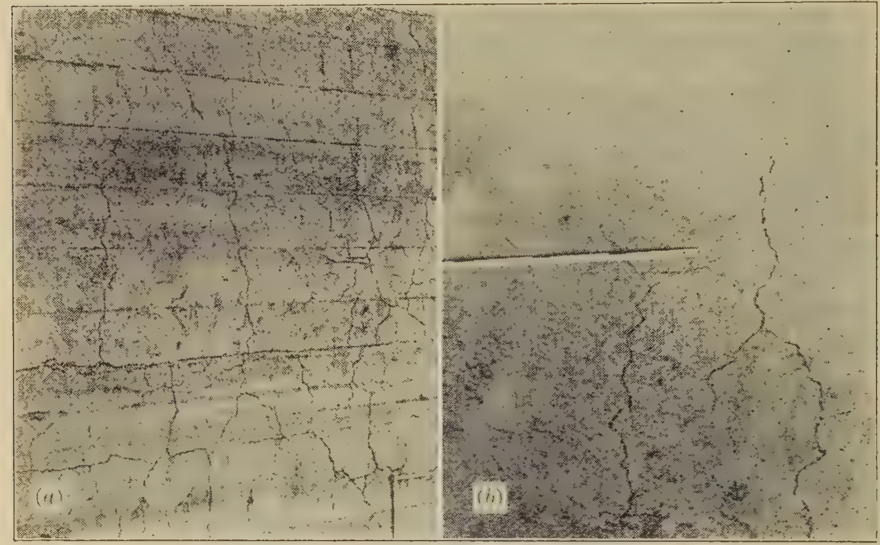

Fig. 12.—Deterioration of Concrete in Stewart Mountain Dam

In response to Mr. Proctor's inquiry, the values of the sugar solubility index for the cements used in the expansion tests shown in Fig. 7 are as follows:

Cement	Cloud point	Clear point
Low alkali	18.6	25.5
High alkali	2.9	2.9

They are not in the order that he evidently suspects since the low-alkali cement, with which the reactive aggregates did not expand, fails to meet the B.W.S. limits. The high-alkali cement which produces expansion with the reactive aggregates, on the other hand, is an acceptable product by the standard of the sugar test. Fig. 7 and Table 9 supply good evidence that a low sugar solubility does not guarantee low expansion, when the aggregates are reactive.

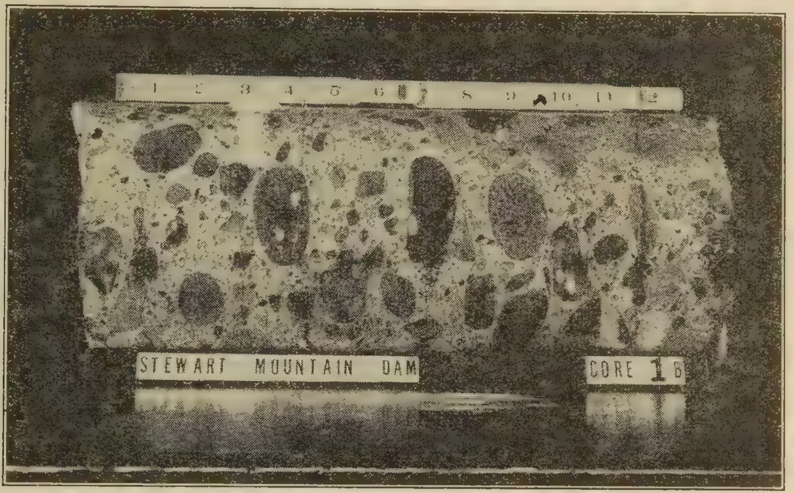

FIG. 13.—GEL CAN BE SEEN OOZING FROM THIS CONCRETE CORE, AT THE 2-IN. AND 3-IN. MARKS OF THE RULER

TABLE 9.—COMPARISON OF CEMENTS USED IN PARKER DAM

Description	B.W.S. limits[a]	Cement PV	Cement PC	Cement PM	Cement PR
Percentages:

Clear	10.0	2.5	2.7	2.3	2.0

[a] Limits specified by the New York, N. Y., Board of Water Supply (B.W.S.); maximum except as indicated by [b]. [b] Minimum limits specified by B.W.S.

Mr. Proctor has suggested that some kind of carbon dioxide test be investigated. Inasmuch as he tested eighty samples and found that only two cements showed reasonable resistance to carbon dioxide, it does not appear that the test is discriminatory. The only apparent connection between this test and the present discussion is that a watertight cement should prevent migration of alkalies. Watertightness, as indicated by absorption, is a function of several variables, such as aggregate grading, water-cement ratios, and curing—all large as opposed to the cement variable. Although it may be possible to rate cements in the laboratory by holding other variables constant, practically the results would mean nothing because variability in field conditions would have so much larger an effect on mass concrete.

Like Mr. Abrams, Mr. Proctor appears to assign the cause of cracks in Fig. 1 to drying shrinkage and has made estimates of the amount of over-all expansion (that would have to take place to ascribe the cracks to this cause) by summing up the crack openings. Fig. 1 was intended to portray typical expansive cracking. Admittedly, shrinkage of the concrete surface, caused by drying, aids in producing such cracks; however, it is not the underlying cause in the cases discussed. The photograph from which Fig. 1 was made was retouched slightly for reproduction, in order to reveal more clearly the detail that was intended to be shown, and Mr. Proctor was thus mislead in attempting to estimate the size of cracks shown and from them to postulate the accompanying amount of over-all expansion. Messrs. Proctor and Abrams (and perhaps also many other readers) are to be excused for diagnosing Figs. 1, 8, and 12 as examples of cracking due to drying shrinkage. This was also the impression of many U.S.B.R. engineers on first viewing the cracks at Parker Dam. Such a simple explanation, however, does not fit the conditions, which include evidence of increasing internal volume. Other concrete in the vicinity of the afflicted structures does not suffer from drying, and the concrete in question cannot be shown to possess any but ordinary sensibility to drying shrinkage. The cracks exhibited in Figs. 1, 8, and 12 are open and are not filled with deposits; they are fairly wide and form a pattern larger than that resulting from the crazing usually associated with drying shrinkage. The concrete between the cracks has all appearances of soundness, although the microscope will sometimes reveal additional minute cracks.

Mr. Burris' discussion calls attention to the methods employed by petrographers in identifying rocks and minerals. In this connection, his comments may be of interest to those not sufficiently familiar with the apparatus and techniques to comprehend, fully, the integration of the various procedures. The interpretations given in the paper are supported by detailed petrographic studies of this same nature conducted in the U.S.B.R. laboratories in Denver, Colo.

Mr. Burris states:

> "* * * it is logical to assume that the further release of sodium from the feldspars as well as from the cement would tend—through chemical reaction with the silica in feldspars and cements—to promote expansion even in a low-alkali cement but at a slower rate than in the case of a high-alkali cement."

In summarizing his conclusions he states, further, that:

> "* * * both cement and aggregate must contain an excess of available free alkalies to cause expansion and that when either cement or aggregate is practically free of alkalies no serious difficulty has been encountered."

If it is correctly understood from these statements that Mr. Burris believes that sodic feldspars react in a deleterious manner with high-alkali cement; and, furthermore, that expansive reactions take place only when the aggregate contains alkali-bearing constituents, he is mistaken on both counts. Mr. Stanton (4*e*) made autoclave tests on several feldspars and other materials immersed in sodium carbonate and sodium hydroxide solutions, but found only opal and parts of specimens of highly reactive siliceous magnesian limestone to be affected. Expansions obtained for laboratory mortar bars fabricated with high-alkali cement and several types of aggregates are shown in Table 10, from which it is evident that the more sodic plagioclase feldspars do not expand significantly with high-alkali cement, although several aggregates that do not contain more than traces of soda expand markedly. The data shown in Table 10 for a given aggregate represent the greatest expansion obtained with that aggregate when mixed with crushed pegmatite quartz in various percentages—the test series for each aggregate comprising seven groups.

TABLE 10.—PERCENTAGE OF EXPANSION OF LABORATORY MORTAR BARS FABRICATED WITH HIGH-ALKALI CEMENT

Quartz, mixed with:	6 months	12 months
Microcline	0.017	0.021
Albite	0.018	0.041
Oligoclase	0.002	0.003
Andesine	0.022	0.051
Opal	1.723	2.218
Novaculite	0.499	0.537
Chalcedony	0.227	0.264

Mr. Burris raises the question as to how positively and how completely some of the mineral constituents of fine-grained rocks can be identified with the microscope when he states:

> "The structure of the thin section of rock and the texture of the individual minerals contained therein are usually among the first of the many properties determined by the petrographer."

There are some minerals that cannot be determined uniquely with the microscope, and under these circumstances it is often necessary to resort to microchemical tests and other means of identification. Aside from rarer instances of this kind most rock-forming minerals are readily identifiable by a skilled petrographer; but, after a mineral name such as "lussatite" or even "chalcedony" has been applied, there are still numerous questions that remain unanswered. Chalcedony produces an X-ray diffraction pattern virtually indistinguishable from that of quartz; but there are differences in the optical properties of quartz and chalcedony since these two varieties of silica behave differently as concrete aggregates. Some investigators have concluded that chalcedony probably is not a single-phase system but may be a mixture of two or three components. It is probable that some of these fundamental questions concerning silica minerals will not be further resolved with the microscope but will require X-ray or electron diffraction for ultimate resolution. When knowledge on this subject has become sufficiently complete to indicate what is present in some of these so-called minerals, it may be possible to decide what is reacting with the cement alkalies, and thus to explain why some cherts are reactive whereas others are not deleteriously reactive. Petrographers have progressed in discovering many of the constituents of rocks that are capable of interaction with cement alkalies, but this work is not finished.

In his discussion concerning "popouts" such as that shown in Fig. 11, Mr. Burris appears to conclude that where such "popouts" are not observed on the surface of expanding concrete, particularly as at Parker Dam, the expansion might be attributed to reaction within the cement. He further suggests:

> "* * * that the possibility of opaline silica from the limestone remaining in the cement, because of too low kiln temperatures, and uniting with free alkalies remaining in the cement for the same reason, should be investigated thoroughly as a possible source of this expansion."

However, data obtained in the U.S.B.R. laboratories indicate that neat cement bars fabricated with high-alkali cement, particularly the ones used at Parker Dam and the one used in the tests of Fig. 7, usually do not expand and that the exceptional cases where expansion did occur can probably be accounted for in terms of other characteristics of the cement.

Mr. Burris discusses Parker andesites briefly and alludes to the feldspars being too sodic for these rocks to be classified as andesites. However, Mr. Burris apparently has noticed also that the andesites are somewhat altered by hydrothermal processes because he comments that one of the alteration products is calcium carbonate. He does not state just what term he would apply to these rocks containing "* * * albite and * * * oligoclase as the prevailing feldspar," but presumably he is aware of the hydrothermal process called "albitization" in which more calcic feldspars are altered to more sodic varieties. Thus, it is probable that Mr. Burris would speak of these as "albitized andesites," although the additional adjective contributes comparatively little to the general scope of the problem inasmuch as andesites do not have to be albitized to be reactive. Actually, some of the andesites are only insignificantly altered whereas others are greatly altered; some are weathered and others are comparatively unweathered. Many intermediate and acid types are present in addition to andesites, including rhyolites, dacites, and trachytes, and these show various amounts of hydrothermal alteration and weathering.

Mr. Burris uses several adjectives whose meanings are not entirely self-evident. For example, reference is made to "free alkalies" and "pure silica." The adjective "free" in referring to chemical oxides usually means uncombined with other oxides present, but probably Mr. Burris does not believe that the alkalies of cement clinker are largely in the uncombined state—most investigators do not concur in such an opinion. However, it is apparent that such alkalies are readily released by hydration and hydrolysis when the cement is wetted. "Pure silica" apparently refers to some form of silica other than opal or silicates, but it is not clear whether it means quartz, tridymite, or cristobalite. Also, the writers do not understand why Mr. Burris discusses a contact metamorphic rock, such as one containing wollastonite, in a manner implying a relationship to the siliceous limestones mentioned by the writers. There is no relationship; the term siliceous limestones was not intended to include marbles or contact metamorphic rocks and there is nothing inherent in the connotation of this term to suggest including these rocks. Mr. Burris is perfectly correct, however, in stating that the siliceous limestones to be avoided are those that contain silica derived from organic matter such as Radiolaria and diatoms which are detected, by the aid of the polarizing microscope, to be noncrystalline or amorphous.

The discussions of Messrs. Kammer, Stanton, Spencer, and Chadwick supply valuable additional information which should aid toward a better understanding of this type of deterioration in concrete. These investigators have provided factual data and useful information from their experiences.

Mr. Stanton adds to the list of materials reactive with high-alkali cement and states that, of the active andesites, all have a glassy groundmass as a common characteristic. The increased activity observed in a synthetic andesitic glass when it is artificially weathered is of great interest because so many of the suspect andesites possess unmistakable signs of preconcrete alteration.

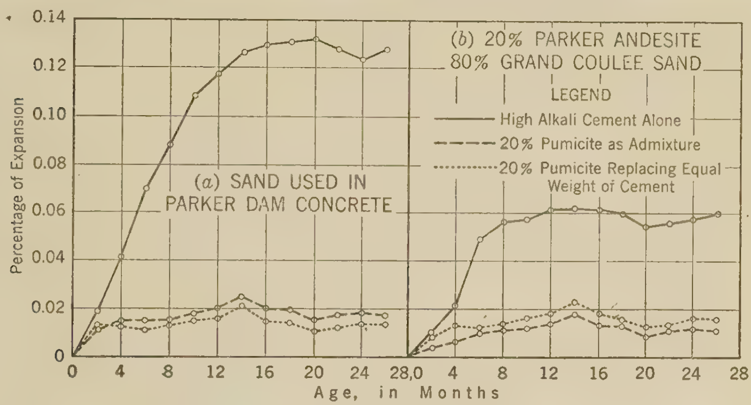

FIG. 14.—EFFECT OF PUMICITE ON EXPANSION

Since Fresno pumicite was used in Friant Dam, and there previously has been assurance that such use afforded protection against expansion from the reactive aggregate in this dam, the data in Table 6 are disturbing. However, in previous work Mr. Stanton, and O. J. Porter, M. Am. Soc. C. E., L. C. Meder, and Allen Nicol (8*a*) have shown pumicite (not necessarily Fresno pumicite) to be almost as effective as Monterey shale in reducing expansive reaction. Another statement by Mr. Stanton (4*f*) is also comforting:

> "The addition of a pozzolanic material seems to be effective, as 25% pumicite substituted for an equivalent weight of high-alkali cement reduced the expansion to a negligible amount at early periods."

The expansion of mortar bars made with two types of reactive aggregates (Fig. 14) was reduced to an insignificant amount when 20% of Fresno pumicite, by weight of cement, was either added to the mix or used as a cement replacement. Mortar bars 1 in. by 1 in. by 10 in. were made with reactive aggregate and cement (mix, 1:3) containing 1.44% of total alkalies ($Na_2O + 0.658\ K_2O = 1.21\%$). They were cured in sealed containers in the presence of moisture at 100° F.

Concrete cores taken from Friant Dam show no evidence of gel formation where pumicite was used in the mix, although some slight amount of gel was found in cores containing high-alkali cement alone. There is substantial evidence, therefore, that Fresno pumicite has aided in preventing expansion in Friant Dam, where an aggregate now known to be reactive was used.

Mr. Witt makes it clear that he has not been convinced, by the paper or any of the many articles (8*b*) on the subject, that concrete can deteriorate because alkalies in the cement react with some aggregates. Many cement manufacturers, however, do not share this skepticism; they agree that a considerable volume of concrete is suffering because some cements and aggregates do not "get along" agreeably with each other. One producer (29) has made this statement,

> "* * * this does not permit the manufacturer of portland cement to put the matter aside; there are probably cases in which low-alkali cement should be used, and the problem of making it economically is therefore of considerable importance."

The discussion by Mr. Kammer is significant in this connection. He considers a case where reactive aggregates were used successfully with low-alkali cement in contrast to the failures noted with cement of high-alkali content. There are a growing number of cement consumers who have been convinced of the necessity for controlling the alkali content of cement and who are demanding that it be limited when aggregates known or suspected of activity must be used. Also (in Mr. Witt's words), "* * * serious, although far less common, is the lag between application and research accomplishments."

Mr. Abrams presents one major theme—that the cracking in Parker Dam is not due to the cause ascribed by the writers but to the extreme temperature and drying conditions at the site, coupled with defective technique. He maintains that (conclusion (2)) "* * * the authors did not avail themselves of evidence that contradicts the hypothesis of the alkali-aggregate reaction"; and (conclusion (3)) "The photographs that were given to illustrate expansive cracking of dams clearly show cracks to be due to contraction of concrete." The possibility of extreme drying conditions being responsible for the cracking was once explored and found untenable under most of the evidence. The writers will not deny that the climate at Parker Dam is hot and dry; but official data of the U. S. Weather Bureau show that, although extremely low humidities are frequently encountered in this region, the average relative humidity is far from the low values that readers might infer from Mr. Abrams' discussion. For instance, the average relative humidity recorded at Yuma, Ariz. (the closest station to Parker Dam where such records are kept), over the period from 1940 to 1945 is 44%. Whereas Mr. Abrams infers that no rain might fall at Parker Dam in a ten-year period, the average yearly precipitation is about 5.5 in.—only 0.5 in. less than at Boulder Dam. Whereas Mr. Abrams quotes shade temperatures of 125° F, the mean annual temperature at Parker, Ariz., is about 71° F, which is not greatly different from that at Boulder Dam.

Regardless of how severe the climate may or may not be, drying is not responsible for the cracks in Parker Dam. Two pumping plants, built by the Metropolitan Water District coincidently with Parker Dam and in the same vicinity, have not developed these cracks, although they have been subject to all the rigors described by Mr. Abrams—neither has the powerhouse at Parker Dam. Abundant evidence that the concrete in Parker Dam is expanding is presented in the paper. More such evidence has been presented elsewhere (5) (6).

Another important point is that, although the aggregates used in the pumping plants and powerhouse have been proved reactive when used with high-alkali cement, they did not cause expansion in those structures because they were built with low-alkali cement. In contrast, Gene Wash and Copper Basin dams, built during the same period as Parker Dam with the identical aggregate and high-alkali cement, are expanding and have suffered similarly to Parker Dam. Mr. Abrams further attributes the cracking at Parker Dam to (*a*) the use of large (4-yd) mixers and (*b*) an inordinately long mixing time of 2½ min. The concrete for Copper Basin Dam was mixed for 1½ min in a 2-yd mixer and that for Gene Wash Dam was mixed for the same period in a 1-yd mixer and yet both dams have developed irrefutable expansive cracking. Except for the size of batches, the concrete was identical in the three dams; the materials were all batched in the same plant.

Mr. Abrams states that the U.S.B.R. requirements for curing Parker Dam concrete were (*A*) inadequate for the "blistering desert" conditions and (*B*) poorly enforced. It is left to the reader to decide if three weeks of continuous sprinkling or spraying with water is not as much as has been demanded for the curing of concrete in any region. At least, it is one week more than was given the concrete in the pumping plants just referred to, which did not crack under the "blistering desert" conditions. Mr. Abrams is incorrect in stating:

> "The upper, thin, reinforced concrete sections of the dam were not cured by 'continuous sprinkling, or spraying,' but by three coats of a patented curing compound that was poorly adapted to the conditions."

The fact is that all exposed concrete on the dam itself was thoroughly cured for three weeks as directed. The curing compound mentioned was applied to the inside surfaces of the hollow piers in which a high humidity would naturally obtain and where it is believed that even better curing was achieved than elsewhere.

Mr. Abrams states also that:

> "By a better grading of aggregates, and a method of mixing that minimized mixer grinding, the mixing water in a cubic yard of concrete could have been reduced from 250 lb to 175 lb. * * * Surface cracking at Parker Dam was due to too much mixing water * * *."

The writers know of no mass concrete, with maximum size of aggregate restricted to 6 in., which could be made satisfactory and workable with as little as 175 lb of water. The concrete-making properties of the Parker Dam aggregates were thoroughly investigated with trial mixes of various gradings, and with no combination could a water content approaching 175 lb per cu yd be used to produce a satisfactory mix, even in a small mixer. Again, however, Mr. Abrams' argument that "cracking at Parker Dam was due to too much mixing water" fails when attention is directed to the perfect concrete in the near-by Gene Wash and Intake pumping plants which contained 100 lb more water per cubic yard than was present in the Parker Dam concrete. The subject of grinding action in large mixers is treated in some detail by Mr. Abrams, who supplements his comment by reference to his previous discussion of a paper by S. P. Wing, M. Am. Soc. C. E., Valens Jones, and R. E. Kennedy, M. Am. Soc. C. E. (26). Those who are interested in the details of this subject should also read the authors' reply to the discussion (26*a*). To describe a mixer as an "ideal" grinding machine, as Mr. Abrams does, is certainly an exaggeration.

In referring to Fig. 10, Mr. Abrams states,

> "It seems obvious that the 'concrete temperature' curve * * * does not represent the interior of the dam; the dam temperature could not possibly show seasonal variations of 40° F."

The temperatures shown are in fact the averages at the bottom of the 12-in., 30-in., 60-in., and 120-in. holes, and it was expected that the reader would so regard them. In spite of the foregoing statement, the concrete does show seasonal variations of more than 30° F at a depth of 10 ft below the roadway. Mr. Abrams has attempted to relate the expansion reported by the writers to volume change that would accompany "unconsidered temperature rise, as a result of continuing hydration of cement." He visualizes: "* * * the gates, the gate-operating structure, and the roadway bridges in a gigantic vise where they were crushed like eggshells." To some extent he was led to this distorted picture by the statements concerning "binding of gates" which "the authors mention three times." Nevertheless, nothing was written in the paper to suggest that the gates at Parker Dam were binding. The gates at Coolidge Dam were binding, as stated by the writers, and data were cited in the paper (1)(2) to support the other statements. The conditions reported necessitated the repairs described by Mr. Kammer in his discussion of this paper.

After going through some calculations which appear highly speculative to the writers, Mr. Abrams comes to the conclusion that by 1942 the internal temperature of Parker Dam had risen some 120° F. Similar assertions were made concerning Boulder Dam (28) which have been adequately refuted by showing that no temperatures faintly approximating that value are to be found in the dam. As requested, the writers report the temperature in the middle of Parker Dam 50 ft below tailwater, at El. 315, to be 65° F minimum and 69.8° F maximum as of 1944. In the abutment at middepth of the gate opening, during 1943, the temperature was 70.6° F minimum and 77.6° F maximum.

Mr. Abrams refers to "inexpert and incomplete chemical analyses," "inconsequential tests," foggy language," and then proceeds as follows:

> "Many woods contain organic acids that readily attack compounds in cements and aggregates. Evidences of acid action would be destroyed by exposing the samples to a high temperature. The nature of the material that was driven off in the 'loss-at-ignition' test (Table 1) was not disclosed; nor was the temperature given. These losses seem to represent free water, although it may have been carbon dioxide, water of crystallization, alkalies, or many other compounds."
>
> "The material that the authors identified as water glass was probably formed in the crucible during the 'loss-at-ignition' test. Water glass is formed only under the most favorable conditions and at a temperature high enough to fuse alkalies and silica; it certainly was not formed in this concrete."

The paper states that the gels may resemble ordinary water glass, not that they are ordinary water glass. The paper clearly identifies the location of this gel (Fig. 3) as being on the interior (broken) surface of a core—not on the outside surface in contact with sawdust. Certainly the gel did not form in the crucible. The remarks on the formation of water glass, therefore, are completely irrelevant as well as entirely erroneous. An authoritative description of both wet and dry methods for producing silicate solutions from silica and alkalies has been published by J. G. Vail (30). The production of sodic silicas does not necessarily depend on the fusion temperature of alkalies and silica, but can be achieved at temperatures below 100° C. In a study of the quaternary system soda-lime-silica-water at 25° C, George L. Kalousek (31) reports gel analyses similar to those given in this paper. He also reports analyses of gels synthesized in the laboratory.

To clarify this issue on gel, Fig. 15 is presented, showing a gel body recently picked from the downstream surface of Copper Basin Dam. This material is shown just as found, oozing from a crack, and by analyses consists of:

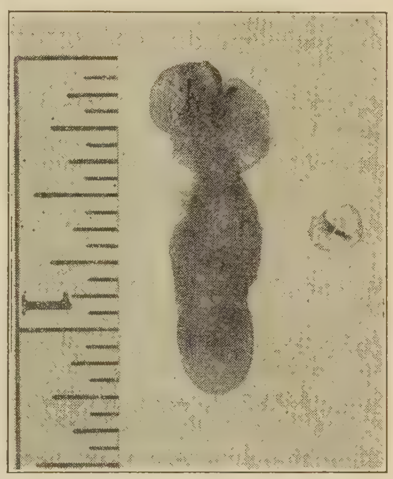

Fig. 15.—Gel, Taken from the Downstream Face of Copper Basin Dam

Chemical	Proportion (%)
Loss on ignition	26.8
Sulfur trioxide, SO_3	0.9
Silica, SiO_2	45.5
R_2O_3	0.7
Lime, CaO	0.0
Magnesia, MgO	0.0
Sodium oxide, Na_2O	20.0
Potassium oxide, K_2O	4.1
Total	98.0

The smallness of the sample (0.6 g), made it impossible to separate the part represented in "loss on ignition" into its components, or to make further analyses to determine constituents other than those listed.

The relationship between the damp sawdust and the formation of a sodic silica gel is somewhat obscure in spite of Mr. Abrams' allusion to organic acids and their attack on cements and aggregates. These gels can be, and have been, produced by the interaction between high-alkali cements and reactive aggregates in the laboratory by the U.S.B.R., the California State Division of Highways, the Public Roads Administration, and by other reputable agencies. The formation of these gels has nothing to do with sawdust or organic acids.

These gels have been produced from aggregates used at Parker Dam in laboratory bars and cylinders in the complete absence of sawdust.

Mr. Abrams asks:

> "If certain constituents of Parker sand were attacked by cement alkalies in the dam, why were they not long ago destroyed by the same alkalies in Williams River water (a tributary to the Colorado River)?"

This question is not pertinent to the problem of the paper. The water of the Bill Williams River ultimately will destroy the sand through chemical attack and, in a geologic era or two, all the sand in the river bed will be completely destroyed by chemical weathering processes—that is, if man can devise a method of preventing its being carried away by the natural currents of the river. Simultaneously, the sand thus destroyed will be replaced by other sand which forms farther upstream.

The "alkalies" in the Bill Williams River water are balanced chemically by such ions as carbonates, chlorides, sulfates, etc. The water of the river is principally saline although slightly basic, in contradistinction to the solutions that exist in hydrating cement, which are strongly basic. Thus, the relationship between the behavior of the aggregates in the river water and their behavior in concrete does not seem pertinent to the discussion.

Mr. Abrams disposes of alkali reaction at Parker Dam by a series of illogical processes and erroneous assumptions but he disregards a large number of other structures that have similarly suffered this type of disintegration. He questions the very existence of alkali reaction when he states,

> "Five years of 'intensive investigation' failed to identify a single rock type that reacted with high-alkali Portland cement. The hypothesis of alkali-silica reaction has no basis except foggy language, unsupported assertions, and trivial circumstances."

This sweeping statement is not in any way consistent with the facts. Experience gained from laboratory bars and from concrete structures indicate that there are several rock types which have proved reactive with high-alkali cement. The writers have stated what some of these rock types are, and others have been described by Messrs. Stanton, Kammer, Spencer, and Chadwick in their discussions of the paper.

The writers feel that neither Mr. Abrams' approach nor his deductions give any material help in solving the problem presented for discussion in this paper. Considerable of his discussion involves trivial matter, concerning which they are loath to burden the reader. As an example, exception is taken to the term "opaline silica," in which redundancy is recognized, but which has enjoyed use by prominent authorities (32)(33) as well as by Mr. Burris in his discussion of this paper.

MOVING LOADS ON RESTRAINED BEAMS AND FRAMES

BY R. C. BRUMFIELD, M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. R. W. STEWART, NATHAN D. BRODKIN, T. F. HICKERSON, MAX W. STRAUSS, D. A. MACKENZIE, CHARLES E. SCHAFFNER, J. KALB, G. ROLSMA AND F. W. GIESEKING, STANLEY S. SCHURE, ALEXANDER DODGE, FREDERICK S. MERRITT, ALFRED B. HEISER. T. B. RIGHTS-PHIL M. FERGUSON, LEON BESKIN, BRUCE JAMEYSON, CHARLES W. DOHN, CLIFFORD PETERSEN, A. A. EREMIN, AND R. C. BRUMFIELD.

SYNOPSIS

Engineers have long been familiar with the criterion for placing a load on a simple beam, for maximum moment under one of its concentrations, which requires that the center of the span bisect the distance from the center of gravity of the load to the concentration in question. There is also that other criterion for placing the load for maximum moment at a given point, which requires that the average load in each segment of the span shall be the same as that throughout the span. When the ends of a beam are restrained these criteria cannot be applied; and the problem is further complicated when the object is to find the loading position for maximum moment at the restrained ends. In the past the problem of placing moving loads on fixed spans has usually been solved, rather laboriously, by the use of influence lines.

In this paper the concept of the transmission coefficient will be introduced and equations expressing its value will be derived. From the idea of the transmission coefficient will be developed a method for computing the restraining bending moments at the supports of restrained beams, due to any combination load placed on the span. The resulting equations will be maximized and criteria developed for placing the load in position for maximum bending moment at the support and out in the span. A new concept will be introduced for the sign or sense of the bending moment in rigid frames; and methods will be developed for distributing the moment to the frame in a single operation.

Although the methods contained in this paper may be rendered applicable to beams of all types, the present scope will be limited to straight beams of uniform cross section. Other applications will be outlined but not discussed.

NOTE.—Published in May, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Prof., Civ. Eng. Dept., The Cooper Union, New York, N. Y.

1. Definitions and the Nomenclature of Unusual Terms

As far as practicable, the effort is to conform with standard letter symbols in common use for structural analysis, and these symbols are defined where they first appear in the paper. Inherent in the usefulness of the paper, however, are certain symbolisms peculiar to the method itself, and the nomenclature needs to be understood clearly to grasp the full import of the paper. Such special symbols are as follows:

C = transmission coefficient, a dimensionless fraction by which a bending moment, introduced into one end of a span by forces outside the span, is multiplied in order to obtain the induced bending moment at the opposite end of the same span. This coefficient becomes identical with commonly used "carry-over factor" when its direction of transmission is toward a fixed support.

U = moment of inertia of the loading group, which is equal to the sum of the products of the separate concentrated loads of the group and the squares of their respective distances from the center of gravity of the group.

r = radius of gyration of a series of loads with fixed spacing, found by taking the square root of the quotient that results from dividing the moment of inertia of the group of loads by the total load.

λ = span distribution ratio, $\frac{r}{L}$, or the radius of gyration of the loading group divided by the length of the span on which the load is placed.

S = modulus of dissymmetry, or the algebraic sum of the products of the individual concentrated loads of a group and the cubes of their respective distances from the center of gravity, distances on the right being considered positive and those on the left negative.

e = radius of dissymmetry, or the cube root of the quotient found by dividing the modulus of dissymmetry by the total load.

ϵ = dissymmetry span ratio, $\frac{e}{L}$, the quotient found by dividing the radius of dissymmetry of the loading group by the length of the span in which the load is placed.

i = stiffness index, the product of the span ratio $Q \left(= \frac{L}{I} \right)$ of a member and the quantity $(2 - C)$.

R = restraint index which, for a particular member at a joint, is equal to the reciprocal of the sum of the reciprocals of the stiffness indexes of all other members radiating from the same joint.

m = moment split. For a particular member, moment split is that number by which the moment delivered to the joint by a second member of the same joint is multiplied to obtain the induced moment in the first member.

t = torque split. For a particular member of a joint the torque split is that number by which artificial torque, applied to a joint by some means such as a crank, is multiplied to obtain the induced moment in the particular member to which the split applies.

Q = the quotient found by dividing the span length of a member by the moment of inertia of the span. (It will be noted that this is the reciprocal of the "K-value" often used.)

2. THE TRANSMISSION COEFFICIENT

The theorem of three moments is familiar to engineers as a tool of computation. It can be derived simply from the use of the second principle of moment areas. When any number of spans radiate from a common rigid joint, the theorem of three moments may be applied to any pair of them, if one member of the pair actuates rotation at the common joint and the other opposes it. Let the two spans being considered be given the numbers 1 and 2. Let the quotients found by dividing the lengths of the spans by their respective moments of inertia $\left(\frac{L}{I} = \frac{1}{K}\right)$ be Q_1 and Q_2. If there are single loads W_1 and W_2 in each of the spans, placed at distances $k_1 L_1$ and $k_2 L_2$, respectively, from the left supports, the theorem of three moments is stated as follows:

$$M_{1L} Q_1 + 2\,(M_{1R} Q_1 + M_{2L} Q_2) + M_{2R} Q_2 = -\,W_1 Q_1 L_1 (k_1 - k^3{}_1)$$
$$-\,W_2 Q_2 L_2 (2\,k_2 - 3\,k^2{}_2 + k^3{}_2) \ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

The subscripts L and R refer to the left and right of the spans. When no loads exist in either of the two spans, the right-hand side of the equation becomes zero.

The three contiguous spans, AB, BC, and BD, in Fig. 1, radiate from a common, rigid joint B. The supports at A, B, C, and D are free supports.

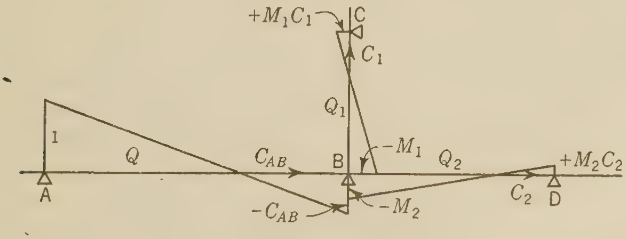

FIG. 1

The spans, as indicated, may continue indefinitely away from the joint B, at supports A, C, and D. Their connections beyond these points are wholly immaterial to this discussion, except as expressed by the transmission coefficient. There are two transmission coefficients C for any span, one in either of the two directions. The letters used to designate the span are used as subscripts to denote the direction of transmission in the span. Thus C_{AB} denotes that coefficient which transmits moment from A to B; C_{BA} that coefficient transmitting moment from B to A.

In Fig. 1, a unit positive couple is assumed to have been introduced into span AB, at end A, from the left. By definition of transmission coefficient, this induces C_{AB} at the opposite end of span AB. The bending moment C_{AB} is negative, according to the ordinary mechanics of materials concept of bending moment, since the two couples cause a reverse curvature in member AB. The moment $-C_{AB}$ divides at joint B, and induces two unknown moments $-M_1$ and $-M_2$, at joint B, in spans BC and BD. These in turn induce moments of $+M_1 C_1$ and $M_2 C_2$ at the outer ends of their respective spans. Remembering that there are no loads in either of the three spans, the theorem of Eq. 1 may be applied to span AB, in combination with either of the other two; thus:

$$Q - 2\,Q\,C_{AB} - 2\,Q_1\,M_1 + M_1\,Q_1\,C_1 = 0 \quad \text{(2)}$$

from which:

$$-M_1 = \frac{2\,Q\,C_{AB} - Q}{Q_1\,(2 - C_1)} = \frac{2\,Q\,C_{AB} - Q}{i_1} \quad \text{(3a)}$$

and, by analogy,

$$-M_2 = \frac{2\,Q\,C_{AB} - Q}{Q_2\,(2 - C_2)} = \frac{2\,Q\,C_{AB} - Q}{i_2} \quad \text{(3b)}$$

Now the sum of M_1 and M_2 must be equal to C_{AB} in order to have equilibrium at joint B. Adding the values of M_1 and M_2, in Eqs. 3, in terms of C_{AB}, and equating them to C_{AB}:

$$C_{AB} = \frac{Q}{2\,Q + \dfrac{1}{\dfrac{1}{i_1} + \dfrac{1}{i_2}}} \quad \text{(4)}$$

The value of C that appears in the stiffness index i is that one which transmits moment away from the joint of the span, toward which C_{AB} transmits moment.

As defined in Section 1 the reciprocal of the sum of the reciprocals of the stiffness indexes of the receiving members of a joint is known as the restraint index, R, of the transmitting member. If one member of a joint transmits bending moment to that joint, the other members all resist the rotation of the joint due to this moment. The restraint index for this transmitted moment, or rather for the transmitting member, is made up of the reciprocal of the sum of the reciprocals of the stiffness indexes of all the resisting members of the joint. These include all members except the transmitting member. The transmission coefficient C of any particular resisting member, which appears in the stiffness index of that member, will be that one which transmits moment away from the joint under consideration. With these concepts in mind, Eq. 4 can be written:

$$C = \frac{1}{2 + \dfrac{R}{Q}} \quad \text{(5)}$$

The Q-value in Eq. 5 is that of the member whose C-value is being computed. The restraint index R contains the entire effect, on C, of all the restraining members, including those directly and remotely connected. When R becomes zero, the value of C becomes 0.5. This is true for a beam with fixed ends. This value of 0.5 is the greatest possible value of C for straight beams of uniform section. Greater values than this may be had when the beam is of non-uniform section. When R becomes infinite in value, the computed value of C

becomes zero. This occurs in the case of a free support. Negative values of the coefficient occur for curved beams.

3. Values of Moment Split

Eq. 5 gives the value of the transmission coefficient for a beam. It is also desirable to know how the moment, which arrives at a joint, such as joint B, Fig. 1, is divided between each of the two receiving members 1 and 2. The multiplier that gives this division is termed the moment split for the receiving member. Such values are readily deduced from the former computation.

Dividing Eq. 3*a* by Eq. 3*b*:

$$M_1 = M_2 \frac{i_2}{i_1} \tag{6}$$

Then:

$$M_1 + M_2 = M_2 i_2 \left(\frac{1}{i_1} + \frac{1}{i_2} \right) = M_2 \frac{i_2}{R} \tag{7}$$

In the case under consideration, C is equal to $M_1 + M_2$, and

$$M_2 = C_{AB} \frac{R}{i_2} \tag{8a}$$

and

$$M_1 = C_{AB} \frac{R}{i_1} \tag{8b}$$

in which R is the restraint index for the member, which delivered the moment to the joint, and i is the stiffness index of the (receiving) member whose part of the moment division is being sought. The moment split is the ratio of the two, or:

$$m = \frac{R}{i} \tag{9}$$

The sum of these m-values for all the receiving members to which moment divides, from a particular actuating member at the joint, must be equal to unity.

4. Restraining Moments in a Loaded Beam

When the transmission coefficients of a span are known, it is possible to compute, accurately and without the concept of fixed-end moments, the induced restraining moments due to loads placed on the span.

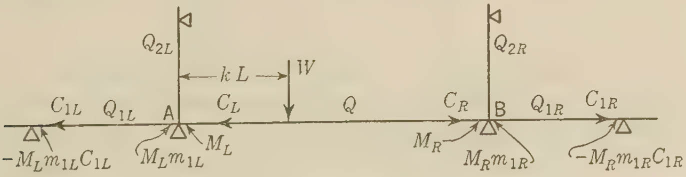

Fig. 2

In Fig. 2, span AB is loaded with a single concentrated load W, placed at a distance $k L$ from the left support. The span AB has the two transmission coefficients C_R and C_L, toward the right and left, respectively. Its Q-value is designated without subscript. The span is shown restrained, at the left and right ends, by two spans at either end. These are designated, in all respects by number-letter subscripts, as 1R—that is, No. 1 span on the right, etc.

Let it be assumed that the induced bending moment due to W, in span AB, at the left end, is M_L, and at its right end is M_R. The induced bending moment in span 1L at joint A will then be $M_L\, m_{1L}$, and at its outer end will be $-M_L\, m_{1L}\, C_{1L}$. A similar set of moments exists in span 1R as shown.

The theorem of three moments, shown in Eq. 1, may now be applied first to the pair of spans AB and 1L, and second to span AB and span 1R. Thus:

$$\begin{aligned} &- M_L\, m_{1L}\, C_{1L}\, Q_{1L} + 2\,(M_L\, m_{1L}\, Q_{1L} + M_L\, Q) \\ &\qquad + M_R\, Q = -\, W\, Q\, L\,(2\,k - 3\,k^2 + k^3) \qquad (10a) \end{aligned}$$

and

$$\begin{aligned} &M_L\, Q + 2\,(M_R\, Q + M_R\, Q_{1R}\, m_{1R}) \\ &\qquad - M_R\, m_{1R}\, C_{1R}\, Q_{1R} = -\, W\, Q\, L\,(k - k^3) \qquad (10b) \end{aligned}$$

Segregating the M_L-terms and the M_R-terms in each of these equations:

$$M_L \left[\frac{2\,Q + m_{1L}\, Q_{1L}\,(2 - C_{1L})}{Q}\right] + M_R = -\, W\, L\,(2\,k - 3\,k^2 + k^3) \qquad (11a)$$

and

$$M_L + M_R \left[\frac{2\,Q + m_{1R}\, Q_{1R}\,(2 - C_{1R})}{Q}\right] = -\, W\, L\,(k - k^3) \qquad (11b)$$

By definition: $Q_{1L}\,(2 - C_{1L}) = i_{1L}$; $Q_{1R}\,(2 - C_{1R}) = i_{1R}$; $m_{1L} = \frac{R_L}{i_{1L}}$; and $m_{1R} = \frac{R_R}{i_{1R}}$. Therefore, Eqs. 11 become:

$$M_L \left(2 + \frac{R_L}{Q}\right) + M_R = -\, W\, L\,(2\,k - 3\,k^2 + k^3) \qquad (12a)$$

and

$$M_L + M_R \left(2 + \frac{R_R}{Q}\right) = -\, W\, L\,(k - k^3) \qquad (12b)$$

An inspection of Eq. 5 will show that Eqs. 12 may finally be written:

$$\frac{M_L}{C_L} + M_R = -\, W\, L\,(2\,k - 3\,k^2 + k^3) \qquad (13a)$$

and

$$M_L + \frac{M_R}{C_R} = -\, W\, L\,(k - k^3) \qquad (13b)$$

Eqs. 13 now may be solved simultaneously for the two unknown quantities M_L and M_R, with the following results:

$$M_L = -\, W\, L\, \frac{C_L}{1 - C_R\, C_L}\, [(2\,k - 3\,k^2 + k^3) - C_R\,(k - k^3)] \qquad (14a)$$

and

$$M_R = -\, W\, L\, \frac{C_R}{1 - C_R\, C_L}\, [(k - k^3) - C_L\,(2\,k - 3\,k^2 + k^3)] \qquad (14b)$$

Eqs. 14 give values of the induced bending moments, at the supports of any restrained beam, when a single load W is applied at any point in the span. The negative sign of the bending moment indicates the usual concept of positive and negative bending moment—that is, that the radius of curvature extends from the beam in the same direction as the positive inducing force presses against the beam.

The accuracy of Eqs. 14 may be verified readily. Let the case of a single span be considered, which is fixed at the right end, freely supported at the left end, and is loaded with a single load W at the center. In this case, C_R is 0.5, C_L is 0.0, and k has the value of 0.5. Substituting in Eq. 14b:

$$M_R = -W\,L\,\frac{0.5}{1-0}\left[(0.5 - 0.5^3) - 0\right] = -\frac{3}{16}\,W\,L$$

Eqs. 14 may be transformed readily into suitable equations for computing the restraining effects of uniform loads. In Fig. 3 is shown a single span with a uniform load of w pounds per foot throughout its length. A single differential portion of this load is indicated at the distance $k\,L$ from the left. Its value is obviously $w\,L\,dk$. This differential load may be considered in the equations as a concentrated load, of which an infinite number make up the total uniform load. Their complete effect may be had by integration, thus:

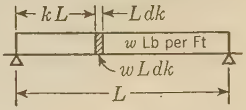

Fig. 3

$$M_L = -w\,\frac{C_L}{1 - C_R\,C_L}\,L^2 \int_0^1 \left[(2\,k - 3\,k^2 + k^3) - C_R\,(k - k^3)\right] dk \quad \text{..(15)}$$

Integrating and substituting the limits, the expression for beams uniformly loaded throughout is:

$$M_L = -\frac{w\,L^2}{4}\,\frac{C_L}{1 - C_R\,C_L}\,(1 - C_R) \quad \text{...............(16)}$$

Similarly:

$$M_R = -\frac{w\,L^2}{4}\,\frac{C_R}{1 - C_R\,C_L}\,(1 - C_L) \quad \text{...............(17)}$$

In verification of Eqs. 16 and 17, let the beam previously considered, with a fixed right support and a free support at the left, be loaded with w pounds per foot. Then: $M_R = -\frac{w\,L^2}{4}\,0.5\,(1 - 0) = -\frac{w\,L^2}{8}$.

5. Restraining Moments Due to Combination Loads

Eqs. 14 are entirely serviceable for the case of a span with restrained ends, loaded with a single load. They may be made to serve also for a span loaded with a series of concentrations, by computing the separate effects and adding them algebraically. This is tedious, and therefore it is desirable to modify the equations to apply to the case of a span loaded with a series of loads with fixed spacing such as a truck load, a locomotive load, etc. When so modified the net effect of all loads in the series may be computed at one operation.

In Fig. 4 a single restained span carries two concentrations, W_1 and W_2. The sum of these two loads is W. The center of gravity of the load lies at a distance $\bar{k}\,L$ from the left support. Each of the loads in the series lies at a distance $a_n\,L$ from the center of gravity of the entire group. Thus W_1 is distant $a_1\,L$ from the center of gravity. By definition, the fraction a has the peculiar property of being negative when the load which it measures lies to the left of the center of gravity, and positive when to the right. All values of a will then reverse sign, when the load is turned around.

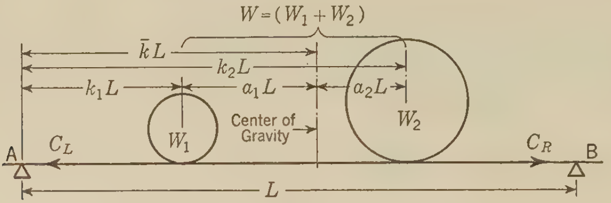

FIG. 4

For the purposes of substitution in Eqs. 14, it is obvious from Fig. 4 that:

$$k_1 = \bar{k} + a_1 \qquad (18a)$$

and that

$$k_2 = \bar{k} + a_2 \qquad (18b)$$

also,

$$A_R = \frac{C_R}{1 - C_R\,C_L} \qquad (19)$$

Substituting these values of k in Eq. 14b and expanding:

$$M_{R1} = -L\,A_R\,W_1\,\{\bar{k} + a_1 - \bar{k}^3 - 3\,\bar{k}^2\,a_1 - 3\,\bar{k}\,a^2_1 - a^3_1$$
$$-\,C_L\,[2\,(\bar{k} + a_1) - 3\,(\bar{k}^2 + 2\,\bar{k}\,a_1 + a^2_1) + \bar{k}^3 + 3\,\bar{k}^2\,a_1 + 3\,\bar{k}\,a^2_1 + a^3_1]\} \qquad (20a)$$

plus

$$M_{R2} = -L\,A_R\,W_2\,\{\bar{k} + a_2 - \bar{k}^3 - 3\,\bar{k}^2\,a_2 - 3\,\bar{k}\,a^2_2 - a^3_2$$
$$-\,C_L\,[2\,(\bar{k} + a_2) - 3\,(\bar{k}^2 + 2\,\bar{k}\,a_2 + a^2_2) + \bar{k}^3 + 3\,\bar{k}^2\,a_2 + 3\,\bar{k}\,a^2_2 + a^3_2]\} \qquad (20b)$$

In Eqs. 20, let $W_1 + W_2$ be equal to W. Adding vertically the like terms of the right-hand side of Eq. 20:

$$\begin{aligned} M_R = -L\,A_R\,\{&W\,\bar{k} + (W_1\,a_1 + W_2\,a_2) - W\,\bar{k}^3 - 3\,\bar{k}^2\,(W_1\,a_1 + W_2\,a_2) \\ &- 3\,\bar{k}\,(w_1\,a^2_1 + W_2\,a^2_2) - (W_1\,a^3_1 + W_2\,a^3_2) \\ &- C_L\,[2\,W\,\bar{k} + 2\,(W_1\,a_1 + W_2\,a_2) - 3\,W\,\bar{k}^2 - 6\,\bar{k}\,(W_1\,a_1 + W_2\,a_2) \\ &- 3\,(W_1\,a^2_1 + W_2\,a^2_2) + W\,\bar{k}^3 + 3\,\bar{k}^2\,(W_1\,a_1 + W_2\,a_2) \\ &+ 3\,\bar{k}\,(W_1\,a^2_1 + W_2\,a^2_2) + W_1\,a^3_1 + W_2\,a^3_2]\} \end{aligned} \qquad (21)$$

In Eq. 21, let: The moment of inertia of the loading group about its own center of gravity equal—

$$\Sigma(W_n\,a^2_n\,L^2) = U \qquad (22a)$$

the modulus of dissymmetry of the loading group about its own center of gravity equal—

$$\Sigma(W_n\, a^3_n\, L^3) = S \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22b)$$

and, by definition of the center of gravity—

$$\Sigma(W_n\, a_n\, L) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22c)$$

Eq. 21 may then be rewritten:

$$\begin{aligned} M_R = -\, W\, L\, A_R \Bigg[& -\bar{k}^3 + \bar{k} - \frac{3\,\bar{k}\,U}{W\,L^2} - \frac{S}{W\,L^3} \\ & - C_L \left(2\,\bar{k} - 3\,\bar{k}^2 - \frac{3\,U}{W\,L^2} + \bar{k}^3 + \frac{3\,\bar{k}\,U}{W\,L^2} + \frac{S}{W\,L^3} \right) \Bigg] \ldots\ldots (23) \end{aligned}$$

Now according to the ordinary definition, the radius of gyration of the loading group is equal to the square root of the quantity U/W. Similarly, the radius of dissymmetry of the loading group may be defined by the equation:

$$\epsilon^3 = \frac{S}{W} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Making these substitutions in Eq. 23:

$$\begin{aligned} M_R = -\, W\, L\, A_R \{ & -\bar{k}^3 + \bar{k}\,(1 - 3\,\lambda^2) - \epsilon^3 \\ & - C_L\,[\bar{k}^3 - 3\,\bar{k}^2 + \bar{k}\,(2 + 3\,\lambda^2) - 3\,\lambda^2 + \epsilon^3]\} \ldots\ldots\ldots (25a) \end{aligned}$$

Similarly:

$$\begin{aligned} M_L = -\, W\, L\, A_L \{ & \bar{k}^3 - 3\,\bar{k}^2 + \bar{k}\,(2 + 3\,\lambda^2) - 3\,\lambda^2 + \epsilon^3 \\ & - C_R\,[-\,\bar{k}^3 + \bar{k}\,(1 - 3\,\lambda^2) - \epsilon^3]\} \ldots\ldots\ldots\ldots (25b) \end{aligned}$$

Eqs. 25 are perfectly general and will give the bending moments at the supports of a restrained beam induced by any combination loading except a pure couple.

The equations are entirely usable in the form in which they appear. Their use is greatly simplified, however, by the aid of a curve which obviates the necessity of determining the detailed values of the k-functions and λ-functions for each case. In Fig. 5, the following quantities have been platted for all ordinary values of λ:

$$B = -\,\bar{k}^3 + \bar{k}\,(1 - 3\,\lambda^2) \ldots\ldots\ldots\ldots\ldots\ldots (26a)$$

and

$$D = \bar{k}^3 - 3\,\bar{k}^2 + \bar{k}\,(2 + 3\,\lambda^2) - 3\,\lambda^2 \ldots\ldots\ldots\ldots (26b)$$

With these substitutions, Eqs. 25 reduce to:

$$M_R = -\, W\, L\, A_R\,[B - \epsilon^3 - C_L\,(D + \epsilon^3)] \ldots\ldots\ldots (27a)$$

and

$$M_L = -\, W\, L\, A_L\,[D + \epsilon^3 - C_R\,(B - \epsilon^3)] \ldots\ldots\ldots (27b)$$

in which

$$A_R = \frac{C_R}{1 - C_R\,C_L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (28a)$$

and

$$A_L = \frac{C_L}{1 - C_R C_L} \quad \text{(28b)}$$

The curves in Fig. 5 are readable accurately to three places, and as a result Eqs. 27 are entirely usable, with satisfactory accuracy, when only slide-rule work is involved.

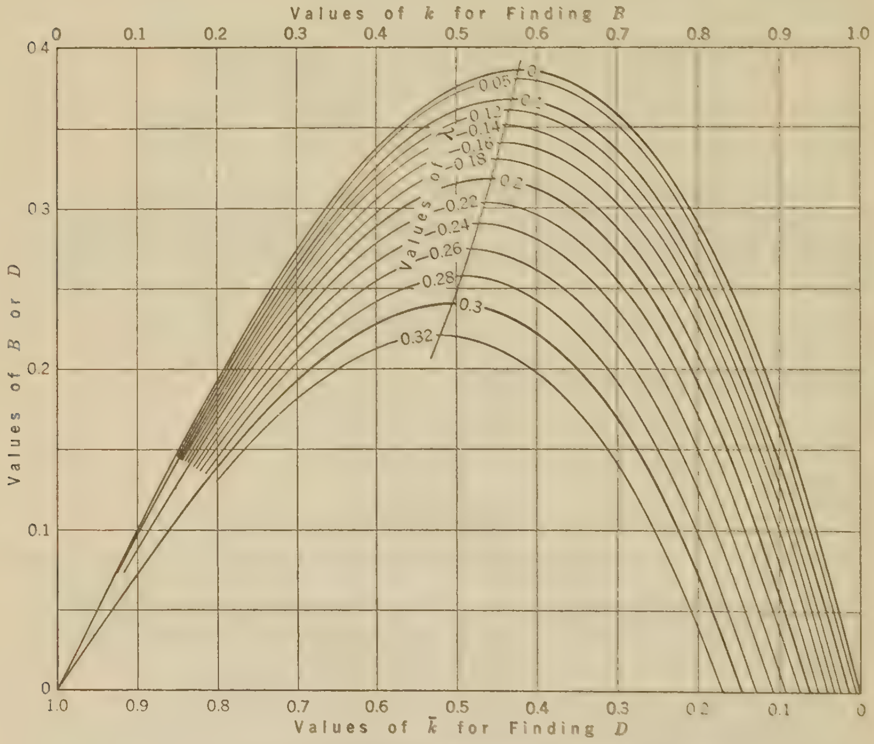

Fig. 5.—Curves for the Solution of Eq. 26

As an example of the use of Eqs. 27, let it be required to find the bending moments at the right and left supports of a beam with fixed ends, which is 30 ft long, and which carries a pair of truck concentrations spaced at 12 ft, weighing, respectively, 4 tons and 8 tons. Let the 8-ton concentration be placed at the span center with the 4-ton wheel to the left.

Let the center of gravity be a distance z from the 8-ton wheel; then: $z = \frac{4 \times 12}{12} = 4$ ft; $U = 4 \times 8^2 + 8 \times 4^2 = 256 + 128 = 384$ ton-ft²; $S = 256 \times (-8) + 128 \times 4 = -2{,}048 + 512 = -1{,}536$ ton-ft³; $\lambda^2 = \frac{384}{12 \times 900} = 0.0355$; $\lambda = 0.189$; $\epsilon^3 = -\frac{1{,}536}{12 \times 30^3} = -0.0047$; and $\bar{k} = \frac{15 - 4}{30} = 0.367$.

From Fig. 5: $B = 0.276$; and $D = 0.310$. Substituting in Eqs. 27: $M_R = -12 \times 30 \frac{0.5}{1 - 0.5^2} [0.276 + 0.0047 - 0.5 (0.310 - 0.0047)] = -360 \times 0.667 \times 0.1281 = -30.8$ ft-tons; and $M_L = -360 \times 0.667 [0.310 - 0.0047 - 0.5 (0.276 + 0.0047)] = -360 \times 0.667 \times 0.1650 = -39.6$ ft-tons.

6. Maximum Bending Moment Due to Moving Loads

In Eqs. 25 only two variables are involved, when the load is moved on the span, if it retains fixed spacing in movement—the bending moment, and the ratio $\bar{k}$. The designer may take a derivative of M with respect to $\bar{k}$, equate this to zero, and solve for $\bar{k}$, in the resulting quadratic equation. When this is done for each of the two equations, the following two criteria are obtained for placing a load in a restrained span in order to produce maximum bending moment at either of the two restrained supports: For maximum bending moment at the right support—

$$\bar{k}_R = \frac{C_L}{1 + C_L} \pm \sqrt{-\lambda^2 + \frac{1 - 2C_L}{3(1 + C_L)} + \left(\frac{C_L}{1 + C_L}\right)^2} \quad \ldots\ldots (29a)$$

and, for maximum bending moment at the left support—

$$\bar{k}_L = \frac{1}{1 + C_R} \pm \sqrt{-\lambda^2 + \frac{C_R - 2}{3(1 + C_R)} + \left(\frac{1}{1 + C_R}\right)^2} \quad \ldots\ldots (29b)$$

Eqs. 29 give the proper locations of the center of gravity of any fixed spacing loading in any restrained span, in order to produce maximum bending moment at the respective supports to which they apply. It is significant that these locations involve only two variables. For maximum moment at the right support the location depends upon the span distribution ratio, and the character of the support at the left end of the beam, as expressed through the coefficient C_L. Similarly, for maximum bending moment at the left support, the location of the load involves only the span distribution ratio and the character of the support at the opposite or right end as expressed through C_R. The dissymmetry of the load is not a factor. The support at the right end may vary in its restraint from fixity to a free support; yet the location of the moving load for maximum bending moment at this support will remain unchanged if the character of the left-hand support is unaltered. Of course, this fact does not prevent the actual maximum from varying in value, as the degree of restraint varies.

Eqs. 29 apply to all kinds of loads, with the exception of a pure couple, which will be treated separately as a special case. Most frequently it is necessary to use the equations in connection with loads, all of which act in the same direction against the beam upon which they are placed. For convenience, the equations have been platted in the form of curves for such cases, in Fig. 6, applying to either of the equations. These curves might well have included only the transmission coefficients from 0 to 0.5, if they were to be used only with beams of uniform section. The curves are also useful in connection with beams of variable section, and for that reason the coefficients represented have been extended to unity.

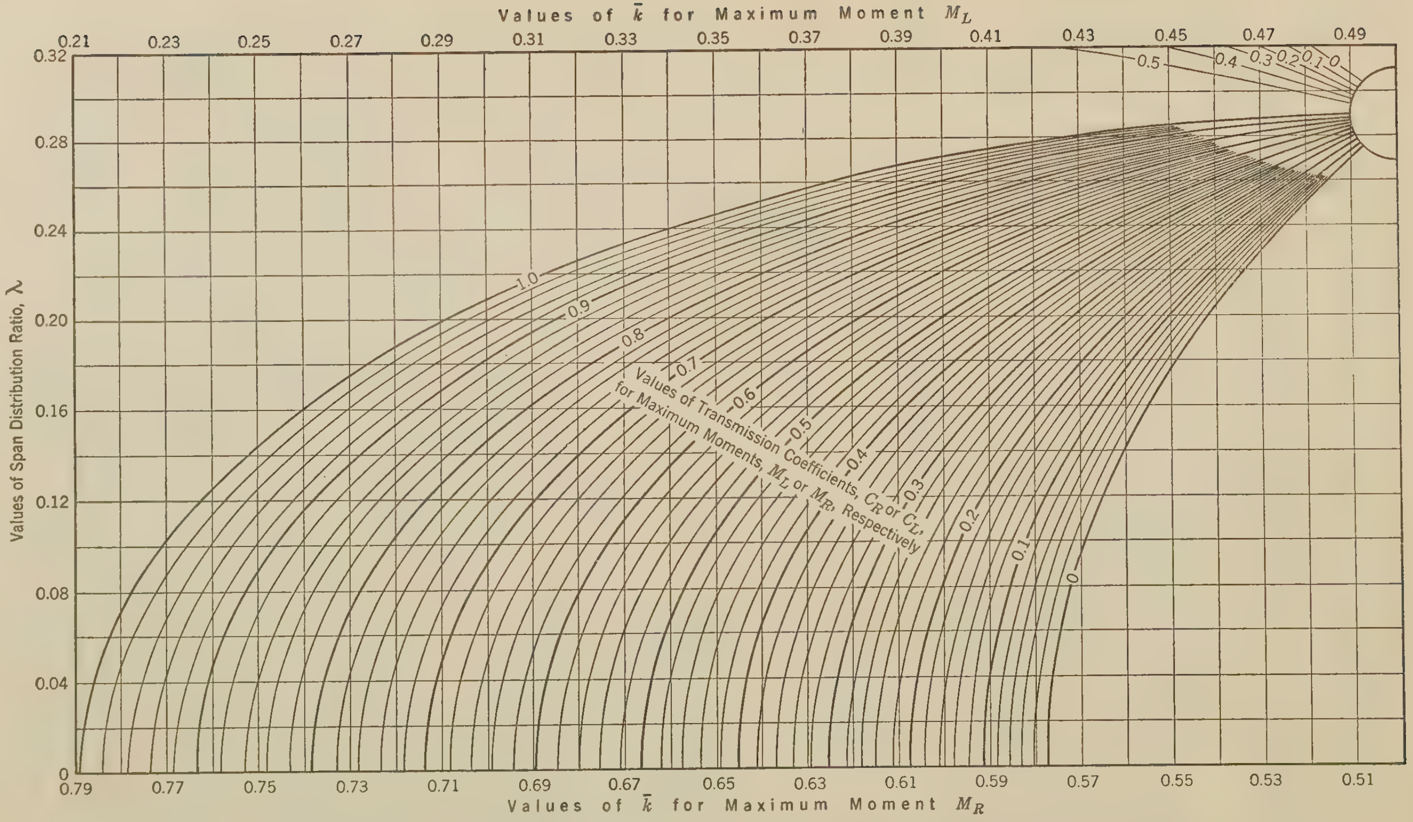

Fig. 6.—Curves for $\bar{k}$ to Give Maximum Bending Moment, for Various Loads, at the Left and Right Supports of Any Span of Any Restrained Beam (for Values of λ Greater than 0.289 the $\bar{k}$-Scales Should be Interchanged)

Example.—Let it be required to find the position of the load, in the problem given in Section 5, in order to produce maximum bending moment at the right support, and to compute this bending moment: $\lambda = 0.189$; and $C_L = 0.5$.

Enter Fig. 6 at $\lambda = 0.189$ and follow across horizontally to the value of $C_L = 0.5$, then follow vertically down to the lower horizontal scale, to read: $\bar{k}_R = 0.6075$. For this value of $\bar{k}$ and the value of λ given, the designer next finds, from Fig. 5, that $B = 0.318$ and $D = 0.289$. Then $M_R = -12 \times 30 \frac{0.5}{1 - 0.5^2} [0.318 + 0.0047 - 0.5 (0.289 - 0.0047)] = -360 \times 0.667 \times 0.1805 = -43.3$ ft-tons.

This represents an increase of about 40% over the bending moment obtained with the heavy wheel at the span center.

Fig. 6 represents only a part of the range of results possible with Eqs. 29. When the loads do not all act in the same direction (as would be the case when a column rests on a girder and carries a bending moment at its base in addition to the direct compression in the column), one of the two forces that make up the bending couple acts in a direction opposite to that of the direct compression and the other force composing the couple. In such a case, particularly when the couple is large and the direct compression small, the center of gravity lies outside the loading group, even outside the span in many cases. When such loads occur, λ^2 may be either positive or negative and much greater than represented in Fig. 6. The equations must be solved directly for $\bar{k}$ in such a case. Any value of $\bar{k}$ either positive or negative is useful for computing the moment that will cause the loading group to lie entirely on the span.

7. SIGNIFICANCE OF SPAN DISTRIBUTION RATIO AND DISSYMMETRY SPAN RATIO λ

When loads act in one direction only, the span distribution ratio, λ, becomes a measure of the distribution of the load throughout the span. If λ is small, the load lies bunched near a point. If it is large the load is distributed more generally like a uniform load. In fact, the point at the upper right of Fig. 6 through which all the curves pass represents the value of λ of 0.289 for a uniform load throughout the span. In practice, for loads in one direction only, the value of λ will not exceed this value.

As previously mentioned, the span distribution ratio is a controlling factor in determining the position of the load for maximum bending moment at either of the supports. This is evident from Eqs. 29. A large value of λ will reduce the quantity under the radical in either equation.

As will be shown subsequently, λ is also an important factor in determining the position of a moving load in order to produce maximum positive bending moment under one of the concentrations in the span.

The dissymmetry span ratio, as its name indicates, measures the degree of dissymmetry of the load with respect to its own center of gravity. When perfect symmetry exists the modulus of dissymmetry is always equal to zero. The converse is not always necessarily true—that, when the modulus is zero, perfect symmetry, in the ordinary sense of the word, must necessarily exist.

In determining the position of the load for maximum bending moment at the supports, the modulus of dissymmetry gives the proper orientation, in order to produce the greatest possible maximum. An examination of Eq. 27*a* will readily show that, for a particular load, M_R is greatest when B and ϵ^3 are additive. This occurs when ϵ^3 is negative. Likewise the greatest possible maximum occurs at the left support when ϵ^3 is positive. The sign of ϵ^3 reverses when the load reverses on the span, although the sign of λ does not change.

It is true that judgment might place the heavy concentration nearest the support at which a maximum is being sought, as the foregoing rules do. Nevertheless, in many cases of mixed loading, the proper orientation is not surely evident. The sign of ϵ^3 is an infallible criterion for the proper orientation.

The value of ϵ^3 is ordinarily small for loads which all act in the same direction against the beam. In cases of bastard couples (parallel unequal forces in opposite directions), however, where the center of gravity falls considerably outside the loading group, the value of ϵ^3 may become quite large and of determining importance in the magnitude of the bending moment.

8. Maximum Positive Bending Moment in Span, at a Given Concentration

Eqs. 27 give the bending moments at the restrained supports, and Eqs. 29 give the proper positions of the load to produce maximums. It is also often desirable to locate the load properly, so that it will produce a maximum positive bending moment under a given concentration out in the span. The designer is interested only in the moment under a concentration, since maximum bending moment occurs at a point of zero shear and shear may only change, in a straight beam, at a load concentration.

In Fig. 7(*a*), a span of length L is loaded with three fixed spacing concentrations W_1, W_2, and W_3, whose center of gravity lies at a distance $\bar{k}$ from the left support. It is required to place the combination load in the proper position for maximum bending moment under the concentration W_2. The simple beam bending moment diagram is shown in Fig. 7(*b*), with the moment under W_2 indicated as $WL(1 - \bar{k})(\bar{k} + a_2)$ − a constant. This represents the simple beam left reaction, times the distance to W_2, minus the constant, which is W_1 times the distance from W_1 to W_2. The separate complete bending moment diagrams, produced on the simple beam, by the two restraining couples at the ends, are represented in Figs. 7(*c*) and 7(*d*) by the two triangles, whose vertical legs are labeled M_L and M_R. The bending moment produced by each of these restraining couples

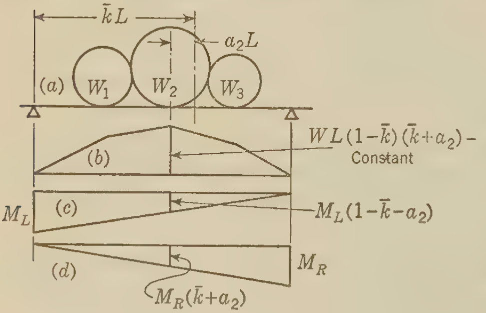

Fig. 7

under W_2 is marked on the respective triangles as $M_L\,(1 - \bar{k} - a_2)$ in the case of the diagram for M_L, and as $M_R\,(\bar{k} + a_2)$ for M_R.

The net bending moment under W_2 will now be the sum of the three separate ordinates, marked on the three bending moment diagrams. It is given by the following equation:

$$M_{W2} = W\,L\,(1 - \bar{k})\,(\bar{k} + a_2) - \text{a constant} + M_L\,(1 - \bar{k} - a_2) + M_R\,(\bar{k} + a_2) \quad \text{(30)}$$

There are potentially only two variables in Eq. 30, when the load is moved. These are (1) the bending moments under W_2 and (2) the value of $\bar{k}$. Taking the first derivative of M_{W2} with respect to $\bar{k}$, equate this expression to zero, and solve for $\bar{k}$, thus locating the position of the load for maximum bending moment under W_2:

$$\frac{dM_{W2}}{d\bar{k}} = W\,L\,(1 - 2\,\bar{k} - a_2) + (M_R - M_L) + \frac{dM_R}{d\bar{k}}\,(\bar{k} + a_2) + \frac{dM_L}{d\bar{k}}\,(1 - \bar{k} - a_2) \quad \text{(31)}$$

Eq. 31 may be set equal to zero after proper substitutions are made for the various quantities (which have been only indicated in this paper). Thus the values of M_R and M_L are the right-hand sides of Eqs. 25*a* and 25*b*, respectively. The values of $dM_R/d\bar{k}$ and of $dM_L/d\bar{k}$ are determined by taking the derivatives of Eqs. 25, and these values are substituted in Eq. 31. The process is not difficult but the algebra is tedious. It will not be given herein, but the result will be indicated.

The following substitutions can be made for combinations of factors:

$$q_1 = (C_R + 2\,C_R\,C_L + C_L) \quad \text{(32a)}$$

$$q_2 = (C_L + C_R\,C_L) \quad \text{(32b)}$$

$$f_3 = 4\,q_1 \quad \text{(33a)}$$

$$f_2 = 3\,(q_1\,a - 4\,q_2) \quad \text{(33b)}$$

$$f = 6\,q_1\,\lambda^2 + q_2\,(4 - 6\,a) + 2\,(3\,C_L - C_R - 1) \quad \text{(33c)}$$

and

$$\kappa = 2\,C_L - 1 + a\,(1 + C_R) + q_2\,(6\,\lambda^2 - 2\,a) - q_1\,(3\,a\,\lambda^2 + \epsilon^3) \quad \text{(34)}$$

It is to be noted that the symbol a in Eqs. 33 and 34 denotes that value which applies to the particular load under which a maximum bending moment is to be sought. This is a_2 in the case under discussion. When Eq. 31 is equated to zero, with the indicated substitutions, it reduces to:

$$f_3\,\bar{k}^3 + f_2\,\bar{k}^2 + f\,\bar{k} = \kappa \quad \text{(35)}$$

When the values of C_R and C_L each become zero, reducing the case to a simple beam, Eq. 35 reduces to the ordinary criterion for placing a load on a simple beam for maximum bending moment under a given concentration.

Because of limitations of space no example of the use of Eq. 35 is offered; but its solution is not difficult if a table of squares and cubes is used in connection with a cut-and-try method of solution. It is sufficient to state that Eq. 35 gives results very little different from those of the ordinary criterion for simple beams, in cases where the values of C_R and C_L are equal, or approximately equal. In such cases the criterion for simple beams may be used for the load placing, with satisfactory accuracy.

Even in cases where there is a decided difference in the restraints at the two ends of the beam, the simple beam criterion is useful for a preliminary estimate of load position. If it is remembered that the criterion of Eq. 35 will always place the load somewhat nearer the end of low restraint than does the simple beam criterion, and if such a shift is made arbitrarily according to acquired judgment, it is possible in most cases to avoid the use of the more complicated criterion of Eq. 35.

The criterion of Eq. 35 gives the position of the load for maximum bending moment under a particular load, where this moment is due to the moving load only, and is not a combination with any dead load that may exist on the span. It is easily possible to extend the foregoing procedure to the case of the absolute maximum produced by combining live-load and dead-load bending moments. It is usually sufficiently accurate and safe to add the maximums due to the two causes as separately obtained.

After the load is placed, it is desirable to find the actual bending moment under the wheel, by first using Eqs. 27 to find the restraining moments at the supports, and then determining the positive bending moments from these, using the laws of equilibrium.

9. Bending Moments at Supports of a Restrained Beam Due to a Pure Couple

Eqs. 27, for the restraining bending moments at the supports of a loaded span, do not apply in the case of a pure couple. The center of gravity of a pure couple lies at an infinite distance to one side of the center point between the forces that comprise the couple. As a result the moment of inertia and the modulus of dissymmetry of the load about its own center of gravity become meaningless. The span distribution ratio and the dissymmetry span ratio also lose their meaning. Since these values may not be computed they cannot be substituted in the equations and these are therefore rendered valueless for computing the restraining moments, resulting from a couple on the span.

Eqs. 14, however, may be modified in such a manner as to be valid for a couple. Fig. 8 shows a clockwise couple, composed of two equal forces W, acting in opposite directions against a span of length L, and spaced at a distance $2\,b\,L$ apart. The center point between forces is placed at a distance $k\ L$ from the left support. The load nearest to a support, $-W$, is at a distance $(k - b)\ L$ from the left support, and the farther load is at a distance $(k + b)\ L$. The value $(k - b)$ may now be substituted for k in Eq. 14a. The resulting equation will give the bending effect of the left-hand load in terms of the location of the center point between couples. The value $k + b$ may next be substituted in the same equa-

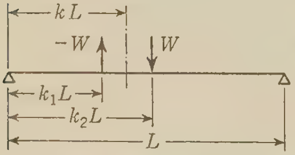

Fig. 8

tion with a second equation resulting which gives the independent effect of the right-hand load, in inducing bending moment at the left support.

If the first equation is now subtracted from the second (since the effect of the left-hand load is opposite to that of the right-hand load), the resulting equation will give the net effect of the couple in inducing bending moment at the left support.

When these steps are taken, remembering that the value T of the couple is $T = 2\,W\,b\,L$, there results:

$$M_L = -\,T\,A_L\,[2 - 6\,k + 3\,k^2 - C_R\,(1 - 3\,k^2) + b^2\,(1 + C_R)] \quad \text{..(36}a\text{)}$$

and

$$M_R = -\,T\,A_R\,[1 - 3\,k^2 - C_L\,(2 - 6\,k + 3\,k^2) - b^2\,(1 + C_L)] \quad \text{..(36}b\text{)}$$

The two equations, Eqs. 36*a* and 36*b*, give the restraining moments at the two supports of any restrained beam loaded with a couple placed at any point in the span. A negative sign of the bending moment here means the same thing it has meant in all the other equations for restraining moment—that the radius of curvature of the beam as bent at the support extends from the beam in the same direction as that force of the couple, which is considered positive, presses against the beam. The couple T is considered positive when it is clockwise from the viewpoint of the observer. Otherwise it is negative.

As a practical matter, a couple must always be applied to the beam with a finite distance between the forces which make it up. Actually the distance may be so small with respect to the length of the span to which the couple is applied that its effect is negligible, and so the couple is assumed applied at a point. In such a case the designer is tacitly assuming that the force W is infinite and that the value of b is zero, but that the product of infinity and zero is a positive constant, the couple. When it is desired to use Eqs. 36 in this manner, b becomes zero and the last term on the right side drops out. The equations are otherwise unchanged.

Care should be exercised, in using the equations, to remember that they give the restraining moments at the supports. When the couple moves up to the restrained support it is necessary to distinguish carefully between the restraining moment at the support and the bending moment out in the beam at the couple, a differential distance from the support. They are not the same.

Eqs. 36 may now be differentiated with respect to k, equated to zero, and criterions so developed for placing the couple in proper position for maximum bending moment at either support; thus, for maximum M_L—

$$k = \frac{1}{1 + C_R} \quad \text{........................(37)}$$

and, for maximum M_R—

$$k = \frac{C_L}{1 + C_L} \quad \text{........................(38)}$$

Eqs. 37 and 38 give the proper position of the couple in order to produce a truly mathematical maximum bending moment at the support. Eqs. 36, of course, are formulas of influence lines for the bending moments at the supports.

The mathematical maximums to which Eqs. 37 and 38 refer are at the points of zero slope of these curves. It is important to remember that these mathematical maximums are not always greatest bending moments. Greater bending moments than the mathematical maximums sometimes occur when the couple is placed at the supports. This happens in the case of a beam with fixed ends.

The positions of a couple, in order to produce zero bending moment at the support, may also be found readily by equating Eqs. 36 to zero, and solving for k. It is of interest to note that a couple occupies the same position in the span in order to produce zero bending moment at a support as would be occupied by a single concentrated load in order to produce maximum bending moment at the same support. Such positions accordingly may be read directly from Fig. 6.

It is also possible to develop equations for the bending moment out in the span, at differential distances from the forces that make up the couple. From these follow other interesting conclusions similar to the foregoing. Space limitations do not permit their inclusion herein.

10. Frame Characteristics and Their Computation

Equations have been developed for computing the bending moments due to loads placed on beams with restrained ends. Criteria have also been derived which place the loads properly to produce various kinds of maximum bending moments. The use of all of these requires a knowledge of the value of the transmission coefficients of the loaded span. If the effects of the loads are to be distributed to any frame, of which the loaded beam is a part, the designer must also know the transmission coefficients of the connecting beams and the moment splits at the joints. Often sidesway and lateral forces are involved which make it imperative to know the value of torque splits at the joints. All these terms—transmission coefficient, moment split, restraint index, and torque split—are included under the covering term, "frame characteristics."

Expressions have been developed for the value of the transmission coefficient and the moment split. Expeditious methods for computing the remaining characteristics, in order that the foregoing equations may become useful, are developed as follows.

The torque split is related very closely to the moment split, the only difference being the number of members that affect its value. The torque-split value for a member is that fraction by which any torque applied to a joint of a frame (artificially, as by a crank) must be multiplied in order to obtain the induced bending moment in that particular resisting member. The moment split does the same thing. The difference between the two lies in the fact that, in the case of the moment split, one of the radiating members of the joint is used as a vehicle for applying the torque, which is its own bending moment.

The member that applies torque, since it actuates the joint, cannot also participate as a resisting member. In the case of torque applied artifically to the joint, all the members act as resisting members. Thus, in the case of the moment split, all the members except one act as resisting or receiving members, and in the case of torque split all the members act as receiving members.

It is desirable, from the standpoint of ease of computing frame characteristics, that the expressions for torque split and for moment split be interrelated.

Writing R_B for the restraint index in bending for member 1 of a four-member joint, and R_T for the restraint index in torsion for the joint, from analogy with Eq. 9 for moment split, t_1 for torque split is:

$$t_1 = \frac{R_T}{i_1} = \frac{1}{i_1\left(\frac{1}{i_1} + \frac{1}{i_2} + \frac{1}{i_3} + \frac{1}{i_4}\right)} \qquad \text{(39)}$$

However, when member 1 is the transmitting member, its restraint index is:

$$R_B' = \frac{1}{\frac{1}{i_2} + \frac{1}{i_3} + \frac{1}{i_4}} \qquad \text{(40)}$$

Therefore:

$$t_1 = \frac{1}{1 + \frac{i_1}{R_{1B}}} \qquad \text{(41)}$$

Thus, when the restraint index has been computed for a member, the torque-split value for the same member may be found simply by dividing the stiffness index by the restraint index, adding 1 mentally, and taking the reciprocal of the result.

It is possible, of course, to compute frame characteristics for a small frame by using Eq. 5 directly for coefficients, Eq. 9 for moment splits, and Eq. 41 for torque splits. Such a procedure lacks order, and is conducive to errors. It has been found more satisfactory to use a tabular form of computation. In this form the equations are used, but they are used by rule, and more or less unconsciously.

Table 1 with its accompanying sketch will be used to illustrate this method of computation. It is designed with a view to keeping the computations in order, having them in such form that errors are reduced to a minimum, and rendering the procedure routine, as follows:

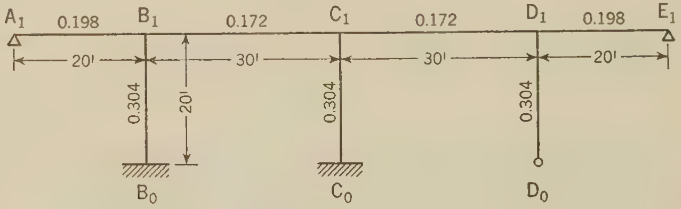
1. Enter all members of the successive joints in Col. 1, except joints at which the frame terminates at a fixed support, such as point B_0, or at a free support, such as point A_1. It is not necessary but is desirable to enter the members in the same order for all joints. Usually the member radiating downward is entered first, followed by successive members, clockwise around the joint in order. The letters that represent each member should read away from the joint, thus: C10 denotes the column $C_1 C_0$; 1CB denotes the member $C_1 B_1$; and 1CD denotes the member $C_1 D_1$—all originating at joint C_1. Since in general each member connects with two joints, each will appear twice in the table, once under each of its two connecting joints.

2. Enter the Q-values for each member in Col. 2. They appear at the centers of members in the diagram of Table 1. These Q-values, as previously defined, are the ratios of the span length divided by the moment of inertia. For some purposes (such as the determination of angular rotations at the joint, these ratios should be computed with length and moment of inertia of the section in the same units. For the purpose of computing frame characteristics,

however, they need not be in the same units. If all lengths are in feet and moments of inertia are in inches, the computed characteristics will be the same as if all were in the same units. The essential requirement is that all members and joints be treated on the same basis.

3. At the right side of each Q-value entered in Col. 2, Table 1, place the appropriate quantity $(2 - C)$ in so far as the C-values are known. The transmission coefficient to be used for a particular member is that value of C which transmits moment away from the joint in connection with which the member appears. In the case of the frame in Table 1 the coefficients of connecting members toward joints A_1, B_0, C_0, D_0, and E_1 are all known since these joints are either free or fixed. These known coefficients will be sufficient to solve the entire frame in this case. When sufficient coefficients are not so known, it is necessary to estimate some of them, as will be demonstrated subsequently.

TABLE 1.—COMPUTATION OF FRAME CHARACTERISTICS



Member	Stiffness Index		Re-straint index R	Transmission Coefficient C (Eq. 5)		Moment Split m (Eq. 9)			Torque split, t (Eq. 41)
	$Q(2-C)$ =	i		Value	Member				
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
Joint B_1									
B10	0.304 (2 − 0.5)	0.456	0.1665	0.392	C_{B01}	(01)	0.387	0.465	0.268
1BA	0.198 (2 − 0)	0.396	0.1763	0.346	C_{1AB}	0.420	(AB)	0.535	0.308
1BC	0.172 (2 − 0.329)	0.287	0.212	0.310	C_{1CB}	0.580	0.613	(CB)	0.424
Joint C_1									
C10	0.304 (2 − 0.5)	0.456	0.146	0.403	C_{C01}	(01)	0.391	0.389	0.243
1CB	0.172 (2 − 0.310)	0.291	0.1785	0.329	C_{1BC}	0.502	(BC)	0.611	0.381
1CD	0.172 (2 − 0.294)	0.293	0.1775	0.330	C_{1DC}	0.498	0.609	(DC)	0.376
Joint D_1									
D10	0.304 (2 − 0)	0.608	0.1669	0.392	C_{D01}	(01)	0.395	0.321	0.215
1DC	0.172 (2 − 0.330)	0.288	0.240	0.294	C_{1CD}	0.579	(CD)	0.679	0.455
1DE	0.198 (2 − 0)	0.396	0.1955	0.334	C_{1ED}	0.421	0.605	(ED)	0.330

4. Compute the i-values for all members whose C-values away from the joint are known. In Table 1, this may be done at once for members B10 and 1BA for joint B_1; member C10 for joint C_1; and members D10 and 1DE for joint D_1 (Col. 3, Table 1).

5. At some of the joints all i-values except one should be known. For the frame in Table 1, this is true of joints B_1 and D_1. The R-value, for that member, whose i-value is missing at each joint, may now be computed, since it

depends upon all the i-values except its own. This is evident from an examination of Eq. 4 in Section 2. Eq. 40 may be written into an equivalent form:

$$R = \frac{i_2}{1 + \frac{i_2}{i_3}\left(1 + \frac{i_3}{i_4}\right)} \qquad (42)$$

The order in which the i-values appear in Eq. 42 is immaterial. It is convenient to use the lowest value in the numerator and the successively higher values in order. For three-member joints, such as the present example, the parentheses in the denominator of Eq. 42 drop out. Using joint B_1 as an example, the i-values for members B10 and 1BA are known. Under the number 0.396 on the slide rule the divisor 0.456 is set. To the quotient 0.869, unity is added mentally, and the divisor 1.869 is set under 0.396 to give the proper restraint index, 0.212 as entered in Col. 4, Table 1, for member 1BC.

6. For all members, except those at a two-member joint, the R-value is checked at once by computing the moment-split values for its member. In this case the R-value 0.212 is divided by the i-value of member B10 to give the moment-split value for this member as 0.465. It is next divided by 0.396 to yield the moment split for member 1BA as 0.535. These moment splits are for member 1CB, when it transmits moment toward the joint, as indicated in Col. 9. It is seen that the sum of 0.465 and 0.535 is unity. This would not have been true if there had been an error in computing the R-value from the two i-values.

7. The C-value for member 1CB may now be computed with confidence, since the R-value upon which it depends has been checked. The R-value computed for member 1BC was derived from i-values which involve coefficients away from joint B_1. The derivation of Eq. 5 will show that the transmission coefficient that results from this value of R is then toward the joint. The subscripts for C are accordingly reversed in entering them in Col. 6. The coefficient value 0.310 is computed by dividing the R-value 0.212 by the Q-value of the member, 0.172, adding 2 mentally, and taking the reciprocal of the result.

8. The value of C_{1CB} computed in step 7 is now substituted in its proper place under joint C_1. From this the i-value for the member 1CB may be computed. All the i-values at this joint are now known, except for member 1CD. Its R-value of 0.1775 may then be computed, and from it the moment splits, for the member, and the value of C_{1DC} just as was done in step 7. The new coefficient is substituted under joint D_1 and the operations repeated until all coefficients and moment splits ore obtained.

9. Torque splits may now be computed by Eq. 41, if the effects of sidesway and wind moments are to be analyzed. Otherwise, the torque-split values will not be needed. The value of 0.268 in Col. 10, Table 1, is found by taking the ratio (on the slide rule) of 0.456 to 0.1665, adding unity mentally, and taking the reciprocal of the result. The torque splits for the joint must add to unity just as the moment splits, which is a check on computations. Other torque splits are found in exactly the same manner, always dealing with the i-values and R-values in any single horizontal line.

11. THE ESTIMATION OF THE VALUES OF COEFFICIENTS

It frequently occurs that not enough coefficients are known in advance of computing the frame characteristics to permit the analyst to begin a tabular computation. Also it may be necessary occasionally to investigate the adequacy of a particular beam of a frame, without computing the characteristics of the entire frame. In such cases it is highly desirable to be able to make an accurate estimate of the value of the coefficients for a particular beam. This can be done readily with an accuracy which is ordinarily within 1%; and in any case the error is never great enough to affect the value of the coefficient beyond the third place to the right of the decimal point.

Eq. 5, for the value of the coefficient, may be expanded into the following form for a four-member joint:

$$C_1 = \cfrac{1}{2 + \cfrac{1}{Q_1}\,\cfrac{1}{\cfrac{1}{Q_2(2 - C_2)} + \cfrac{1}{Q_3(2 - C_3)} + \cfrac{1}{Q_4(2 - C_4)}}} \quad \ldots\ldots (43a)$$

The expressions for the *i*-values of the restraining members all contain the quantity $2 - C$. It is true that these C-values are all different. It is readily conceivable, however, that there is some kind of an equivalent C which, if inserted uniformly into the three parentheses in the denominator of Eq. 43*a*, would give the same result for the coefficient being computed by the equation as if the exact C-value for each member had been used. With this concept in mind, this equivalent coefficient may be called C_e, and Eq. 43*a* can be written:

$$C_1 = \cfrac{1}{2 + \cfrac{1}{Q_1}\,\cfrac{2 - C_e}{\cfrac{1}{Q_2} + \cfrac{1}{Q_3} + \cfrac{1}{Q_4}}} = \cfrac{1}{2 + \cfrac{1}{Q_1}\,\cfrac{Q_2(2 - C_e)}{1 + \cfrac{Q_2}{Q_3}\left(1 + \cfrac{Q_3}{Q_4}\right)}} \quad \ldots\ldots (43b)$$

Either part of Eq. 43*b* may be used for computation. The right-hand part has been arranged for convenient use with the slide rule, as was done for computing restraint indexes in Eq. 42, step 5, Section 10.

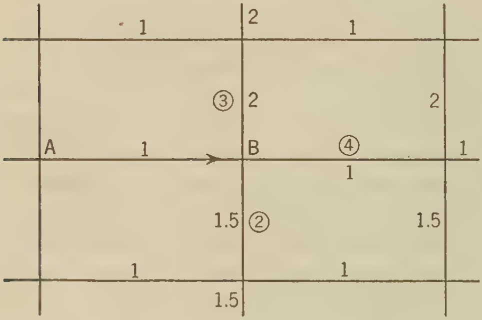


FIG. 9

Let it be required to estimate the value of the coefficient toward the right, of member AB, of the beam shown in Fig. 9. The Q-values of the beam itself, and of the restraining beams on the right, are shown by the numbers, 1, 1.5, 2, etc., in the centers of the spans. The restraining members have been given the numbers shown in circles.

For estimating coefficients in restraining members away from joint B, certain principles should be kept in mind:

1. A stiff member connecting into a limber member will have a low coefficient;
2. Many members, acting as a restraint, tend to raise the coefficient;
3. A member, restrained by a single member of its own stiffness, has a coefficient of approximately 0.29; and
4. The maximum value of the coefficient is 0.5 and the minimum value is 0.0.

By inspection note that restraining member 2 connects into members, at its end away from joint B, two of which are stiffer than, and one as stiff as, itself. One may judge its coefficient away from joint B to be approximately 0.4. Likewise, the coefficient for member 3 is perhaps about the same, and for member 1 about 0.3. Estimating that C_e is 0.35 and inserting it in Eq. 43*b*, in order to obtain a close approximation of C_{AB}:

$$C_{AB} = \frac{1}{2 + \frac{1}{1}\frac{1\,(2 - 0.35)}{1 + \frac{1}{1.5}\left(1 + \frac{1.5}{2}\right)}} = \frac{1}{2 + 1.65 \times 0.461} = 0.363.$$

This estimate will be accurate within the third decimal place. It can be seen readily that a considerable error may be made in C_e without great effect on C_{AB}. Thus, if the analyst had assumed C_e to be 0.4 instead of 0.35, the value of C_{AB} would be 0.366, and, if he had assumed 0.3 instead of 0.35, C_{AB} would be 0.359.

Such estimated coefficients may be used with entire confidence in computing frame characteristics. The exact value of the coefficient will be obtained, in the course of the computation, and finally may be used instead of the estimated value. No further correction need be made for errors in estimation, however, unless the exact value should differ from the estimated value beyond the third decimal place. In the writer's experience this does not occur.

These estimated coefficients are sufficiently accurate to be used in connection with the equations for restraining moment, in order to make spot checks of particular beams under special loads.

12. The Sense of the Bending Moment

It is obvious from the frame characteristics of Table 1 that bending moment may be distributed to the frame at a single operation. Before this is done, it is necessary to define the sense of the bending moment in such a manner as to avoid confusion. The concept of positive and negative bending moment has been abandoned for the purposes of making moment distribution, for the following reason: In courses in mechanics of materials, bending moment is defined as positive for horizontal beams when the beam is concave upward and negative when the beam is concave downward. These bending moments are also defined as positive when the algebraic sum of moments of forces on the left of a section is clockwise about the section and negative if counterclockwise, the definitions being reversed when forces on the right are considered.

Such definitions serve well for horizontal beams, but when the beams radiate in all directions, as they do in a frame, these definitions become confusing. Even though a proper distinction of sense of bending moment is developed for the frame in terms of plus signs and minus signs, such a distinction is likely to be confused with the old concept of plus and minus bending moment, which was so well learned in elementary studies.

For these reasons bending moment is designated as "normal" or "reverse." "Normal bending moment" is defined as follows (see Fig. 10(*b*)):

> I. Bending moment is said to be normal at the end of a beam if, when the beam is cut from its frame and considered as a free body, a clockwise torque must be applied at the end to hold the beam in the same condition of stress to which it was subjected in the frame.

"Reverse bending moment" is defined as follows (see Fig. 10(*a*)):

> II. Bending moment is said to be "reverse" at the end of a beam if, when the beam is cut from its frame and considered as a free body, a counterclockwise torque must be applied to the end in order to hold the beam in the same condition of stress to which it was subjected in the frame.

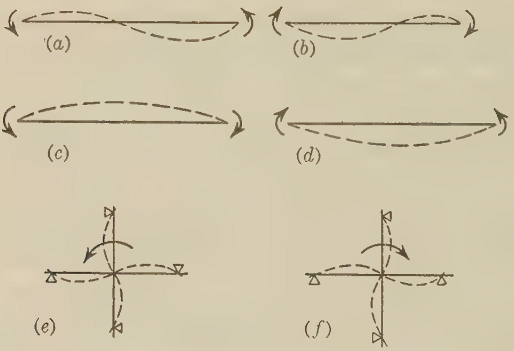

FIG. 10

Both definitions are consistent without regard to the end of the beam to which the torque is applied. Figs. 10(*c*) and Fig. 10(*d*) show bending moments of opposite senses at the two ends of the two members. These senses of the bending moment may be defined equally well in terms of the joint from which the member radiates. Thus, for normal bending moment (see Fig. 10(*e*)):

> III. Bending moment is said to be normal in the end of a member when the member is so flexed at that end as to resist the effect of a clockwise torque, artificially applied to its connecting joint.

For reverse bending moment (see Fig. 10(*f*)):

> IV. Bending moment is said to be reverse at the end of a member when the member is so flexed at that end as to resist the effect of a counterclockwise torque artificially applied to the joint to which the member end connects.

13. Distribution of Bending Moment to the Frame

Bending moment may be distributed to the frame at a single operation by the following rules:

1. Determine the sense of the bending moment at the ends of the beam of origin according to definitions I and II or III and IV.
2. Multiply the bending moment at the end of the beam of origin by the moment-split values for each of the receiving members, the member of origin being considered the transmitting member, and so obtain the part of the bending moment induced in each. Change the sense of the bending moment as it passes through the joint at the end of the member of origin and enter each portion of the moment for the proper receiving member.
3. Each of the bending moments, as obtained in rule 2, is now multiplied by that transmission coefficient, of the member in which it occurs, which transmits moment away from the joint, in order to obtain the induced bending moment at the opposite end of the member. It is entered here without change in sense.
4. At each succeeding joint proceed as in rule 2 and repeat rule 3 after the moment passes through the new joint.
5. The distribution of the moment is completed under the following conditions:

   (*a*) When it reduces to a negligible portion of its value at the origin;
   (*b*) When it arrives at a fixed or free support; and
   (*c*) When, as in most cases, it is carried only two joints beyond the joint of origin.

6. In order that all joints may remain balanced, distribution should cease just after the moment has passed through the last joint, not as it arrives.

An example will serve to illustrate the application of rules 1 to 6 for the distribution of bending moment, as well as to sum up the methods of computing bending moments in restrained beams. Let it be required to place two moving loads of the highway H-10 type on the two spans 1BC and 1CD in Table 1 each in position for maximum bending moment at joint C_1. Let it then be required to compute the two maximum bending moments and the simultaneous bending moments at the opposite ends of the respective beams, and to distribute these four bending moments to the frame. The loading type is shown in Fig. 11, with the center of gravity located. The computation follows: $U = 3 \times 11.2^2 + 12 \times 2.8^2 = 376.3 + 94.1 = 470.4$; $S = 376.3 \times (-11.2) + 94.1\,(2.8) = -4{,}214 + 263 = -3{,}951$; λ^2 (either span) $= \dfrac{470.4}{15 \times 900} = 0.0348$; $\lambda = 0.187$; and $\epsilon^3 = \pm \dfrac{3{,}951}{15 \times 27{,}000} = \pm 0.00975$ (sign depends on orientation).

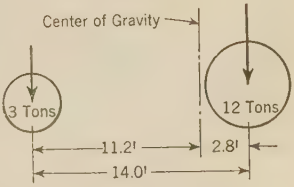

Fig. 11

From Fig. 6, using the coefficients from Table 1 (see also Fig. 12), the maximum bending at joint C_1 is: In span 1BC, $k_R = 0.580$; and in span 1DC,

$\bar{k}_L = 0.422$. Entering Fig. 5, with these values and the value of λ:

Symbol	Span 1BC	Span 1DC
B	0.323	0.302
D	0.302	0.323
A_L	$\dfrac{0.310}{1 - 0.310 \times 0.329} = 0.345$	$\dfrac{0.330}{1 - 0.330 \times 0.294} = 0.365$
A_R	$\dfrac{0.329}{0.898} = 0.366$	$\dfrac{0.294}{0.903} = 0.326$

The two loads have been shown, properly located with respect to the two joints B_1 and C_1, in the respective spans 1BC and 1CD in Fig. 12.

Next, with Eqs. 27, compute the bending moments induced at the right and left of the loaded spans: In span 1BC—

$$M_{1BC} = -15 \times 30 \times 0.345\,[0.302 - 0.0098 - 0.329\,(0.323 + 0.0098)]$$
$$= -28.4 \text{ ft-tons}$$
$$M_{1CB} = -15 \times 30 \times 0.366\,[0.323 + 0.0098 - 0.310\,(0.302 - 0.0098)]$$
$$= -39.9 \text{ ft-tons (due to placing for maximum moment)}$$

and in span 1CD—

$$M_{1CD} = -15 \times 30 \times 0.365\,[0.323 + 0.0098 - 0.294\,(0.302 - 0.0098)]$$
$$= -40.5 \text{ ft-tons (due to placing for maximum moment)}$$
$$M_{1DC} = -15 \times 30 \times 0.326\,[0.302 - 0.0098 - 0.330\,(0.323 + 0.0098)]$$
$$= -26.8 \text{ ft-tons.}$$

Fig. 12

These bending moments may now be entered in Fig. 12, for distribution to the frame. For this purpose it is conventional to place normal bending moment on the right and reverse bending moment on the left. Two columns will be seen in Fig. 12 for each member end. For horizontal beams, under gravity loading, the bending moment is always reverse on the left of the loaded span and normal on the right. The bending moments computed will be seen in Fig. 12 according to this classification.

The moment-split values which are required for the purpose have been copied from Table 1, and are shown adjacent to the joints of the loaded beams, with arrows indicating the direction of moment flow.

As an example, consider the moment 28.4 ft-tons, at the left end of span 1BC. First multiply it by the moment-split value 0.465 to obtain 13.20 ft-tons as the moment at B10. This is entered as normal moment since it has passed through a joint. The same moment multiplied by 0.535 gives the value 15.20 in beam 1BA which is also entered as normal moment. The 13.20 is now multiplied by the coefficient 0.5 of its member away from B_1, to give 6.60 also normal at the support end B_0.

In a similar manner, 39.9 is multiplied by 0.609 and by 0.391 to give the reverse moments it induces in members 1CD and C10. These are entered, as are the values obtained from the 40.5 ft-ton moment times its appropriate splits, and those from the 26.8 ft-ton moment. It should be particularly noted that, in the beginning of its distribution, moment flows only outward from the loaded span of origin, and does not cross that span.

In placing the distributed moments, it will be seen that the point of origin has been noted beside each. This is only precautionary to provide for rechecking in case of possible necessity.

When the moments are all distributed, the algebraic sum is taken, at each member end, and noted by the summation sign below as the final bending moment at that point. For instance, the 20.72 ft-tons of reverse moment at member 1BC is equal to 28.4 − 7.68. The algebraic sum of all the total moments at any joint must add to zero. At joint B_1 the sum of the two normal moments 9.63 and 11.09 is equal to the reverse moment in member 1BC of 20.72. This is a check on the net bending moments as indicated by the summation signs.

The method outlined is entirely satisfactory for small frames. When large frames, involving many members and joints, are to be solved, a much more comprehensive method is used. This method involves a moment-distribution chart for each joint. Its bookkeeping arrangement is so designed that there is a minimum chance of error. One distribution also is sufficient for all purposes, including live-load and dead-load moment distribution, wind moments, and sidesway, as well as loading for maximum moment at every point in the frame. It is too lengthy to include in the present paper.

14. Coordination with the Method of Successive Approximations

The method of solving rigid frames by successive approximations, as proposed by Hardy Cross,[3] M. Am. Soc. C. E., starts, as does the slope deflection method, with fixed-end moments for loaded members. As a result there can be little coordination of the methods of computing moments in loaded members. The Cross method of distributing moments to a frame can be shown to be a special case of the method here outlined. That method consists essentially of the distribution, at a single joint, of an opposing torque equal to the unbalance at that particular joint; the outer ends of connecting members being considered as fixed, or in case they connect into a pinned support, as freely supported. This partial distribution is made successively, a single joint at a time, until error diminishes to a negligible amount.

---

[3] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

The Cross method then involves a torque split for a joint, whose members connect into either fixed or free supports at their outer ends, and transmission coefficients toward fixed ends or free ends, which were previously pointed out to be either 0.5 or 0. It will be remembered that, in the Cross method, the value of I/L is termed K, which is the reciprocal of the Q-value used in this paper.

The expression for the torque split, Eq. 39, Section 10, may be expanded as follows, for a four-member joint—

$$t_1 = \frac{1}{Q_1(2 - C_1)} \times \frac{1}{\frac{1}{Q_1(2 - C_1)} + \frac{1}{Q_2(2 - C_2)} + \frac{1}{Q_3(2 - C_3)} + \frac{1}{Q_4(2 - C_4)}} \quad \ldots (44a)$$

Assume that members 1, 2, and 3 connect to fixed or locked joints at their outer ends and that member 4 connects to a pinned or free support, the transmission coefficients or carry-over factors for the first three members will be 0.5 and for the fourth 0.0. Inserting these values in Eq. 44*a* and appropriate values of K for the reciprocals of $Q \left(= \frac{1}{L/I} = K \right)$: $t_1 = \frac{K_1}{1.5} \times \frac{1}{\frac{K_1}{1.5} + \frac{K_2}{1.5} + \frac{K_3}{1.5} + \frac{K_4}{2.0}}$; or:

$$t_1 = \frac{K_1}{K_1 + K_2 + K_3 + 0.75\,K_4} \quad \ldots\ldots\ldots\ldots\ldots (44b)$$

Eq. 44*b* will be recognized as the well-known Cross expression for what has been called torque-split value in this paper. The equation is written to apply to the particular joint under discussion, with three members fixed at the outer ends, and the fourth freely supported.

15. Other Applications of the Transmission Coefficient

The uses of the concept of the transmission coefficient, which have been outlined in this paper, represent only a very limited number of the purposes to which it has been adapted. It may be of interest to list some of its other applications.[3,4] It has been adapted to the placing of moving loads for greatest

shear both at the support and in the span, just as was done for maximum bending moment. An equation for elastic deformation has been developed from its use, which is perfectly general and applies to the entire beam, irrespective of the intervention of concentrated loads and supports. This equation has certain important uses. The transmission coefficient has been developed for straight beams of variable section, with restrained ends. For such beams its values theoretically may become infinite, but actually do not ordinarily exceed unity. It has been applied to curved beams, in which the coefficient is often negative. Curved beams, in fact, are reduced to the same status as straight beams, the formulas for the former reducing to those of the latter when curvature disappears. Moment splits, torque splits, and the effects of a movement of the supports may be computed for curved beams. The concept enables the beam which is a member of a noncoplanar frame to be solved by the formulas outlined herein. The number of factors that affect coefficients of such a beam is greater than that for coplanar beams; but, once the coefficients are computed, a beam in a noncoplanar frame may be loaded in quite the same manner as outlined for a coplanar straight beam, and moments computed by the same formulas.

16. ACKNOWLEDGMENT

The methods outlined, as well as most of those indicated, have been thoroughly tested in professional engineering practice, in and around the City of New York, N. Y. In this process a great many valuable suggestions have been received, for which acknowledgment is made.

The writer also wishes to express his thanks to Lawrence Perez, Assoc. M. Am. Soc. C. E., for carefully reading this paper.

DISCUSSION

R. W. Stewart,[5] M. Am. Soc. C. E.—The "transmission coefficient" and "restraint index" used in this paper are special beam and structure constants of a rather complex nature. The "moment of inertia of the loading group," "radius of gyration of a series of loads with fixed spacing," the "span distribution ratio" of the loads; and the "modulus of dissymmetry," "radius of dissymmetry," and "dissymmetry span ratio" constitute quite an array of rather complex functions all relating to the loads.

Using the theorem of three moments as the starting point and deriving the transmission coefficients by the use of Eqs. 1, 2, 3, and 4 involve algebraic work that can be avoided, and which, unless extensively supplemented, is not applicable to structures having members of variable section.

Why not make direct use of the basic constants of flexure[6,7] to obtain the transmission coefficients? This will simplify the analysis, increase the yield of valuable coefficients, and obtain an automatic check of the computations. Fig. 13 will then replace Table 1.

Fig. 13(*a*) shows the torque (998.4) necessary at joint B_1 to produce unit rotation at end E_1. All moments at the ends of members due to this torque are also shown. This enables not only all transmission coefficients for individual members in a direction away from point B_1 to be taken from the figure but it also yields the transmission coefficient from point B_1 to any other joint in the frame or from any joint to any other joint which is more remote from point B_1. The transmission coefficient across an individual member is obtained by dividing the moment at the end farther from point B_1 by the moment at the end nearer point B_1. In all cases these agree, to the last decimal place, with the values in Table 1. The transmission coefficient from any joint to any other joint which is more remote from point B_1 is obtained by dividing the moment at the more remote joint by the moment at the less remote joint. For example, the transmission coefficient from the left end of member B_1C_1 to the top of column D_1D_0 is $\frac{9.87}{424.0} = 0.0233$. To obtain the transmission coefficients in the opposite direction a computation is made (Fig. 13(*b*)) beginning with a rotation of unity at end A_1 and resulting in a torque of 998.4 at point D_1. This agreement with the torque obtained in computing Fig. 13 is an automatic check by Maxwell's theorem of reciprocal deflections (angular) and indicates that the computations for Figs. 13(*a*) and 13(*b*) are free from error. Fig. 13(*c*) shows the effect of a torque of 225.1 at point C_1. The right half of Fig. 13(*c*), including the center pier, is copied from Fig. 13(*a*). The left half is obtained by one setting of a slide rule. The torque of 225.1 is the sum of the resisting moments about joint C_1.

The "torque split" and the "moment split" at each joint can also be taken from Fig. 13. These agree with the author's values. A similar quick computa-

FIG. 14.—INFLUENCE LINES FOR MOMENT, INCLUDING THE EFFECT OF SIDESWAY

tion of transmission coefficients and moment and torque splits for a structure involving variable moment of inertia has been published.[8]

The author's computation for placing two wheel-load assemblies on the structure illustrated by Fig. 12, so as to obtain the maximum moment over the center pier, is of mathematical interest. However, it neglects the effect of sidesway. For the problem illustrated in Fig. 12, the effect of sidesway is so small, due to the nearly symmetrical condition of both the structure and the loads about the joint of critical moment, that it can be neglected. If the maximum moment at the top of pier B_1B_0 were to be computed, it would be necessary to include the effect of sidesway in order to justify the refinement of finding the exact position of the load for the maximum moment.

The manner in which sidesway can affect the position of loads for maximum moment is illustrated in Fig. 14, which shows two of the complete set of influence lines that were computed for the actual design of a two-span rigid frame bridge of the type shown. In Fig. 14(*b*), the effect of the sidesway is to divide the right span at point Z into two sections in one of which the moment at point A produced by the load is positive and in the other negative. In order to obtain the maximum moment at point A not only span AB but also fractional span ZC would have to have loads properly placed therein. The writer does not find in the paper any means of locating the Z-points (intermediate points of zero influence) in a structure, or of determining whether such points exist. Fig. 14(*c*), which is the influence line for point 1 in Fig. 14(*a*), illustrates another complication which will occur if railway loading is used. The distance AZ is too short to accommodate the wheel base of a locomotive and tender, so that for maximum positive moment at point 1 some of the wheels of the assembly will be at the right of point Z no matter which way the locomotive is faced. A still further contingency which is not infrequent is the reversal of the direction of the bending moment in a column due to sidesway. How could the author's method of procedure be applied to such a condition?

For a good design of a concrete rigid frame bridge, in which both the maximum positive and maximum negative moments must be computed from point to point in order to properly locate ends of reinforcing bars, the writer sees no escape from the computation of complete influence lines. This can be done in a very moderate length of time by a computer who has a thorough knowledge of the work. There are not very many engineers who would approve constructing the $60,000 structure illustrated in Fig. 14 to a poorly detailed design rather than a well detailed design in order to save from two to three man-days of computing work.

Fortunately the operation of placing trucks having variable spacing on a structure is not required by the design specifications in general use. The truck trains which have been heretofore specified by the American Association of State Highway Officials all have fixed distances between trucks, and the trucks all face in the same direction. At present, either a single truck wheel assembly or a single concentration superimposed on a uniform load is specified. This eliminates the necessity for positioning independent wheel assemblies.

---

[8] "Relative Flexure Factors for Analyzing Continuous Structures," by Ralph W. Stewart, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 527.

To give the author's method practical value it will be necessary to demonstrate its extension to variable moment of inertia and to the various contingencies due to sidesway introducing Z-points and reversing the direction of bending moment in a member.

NATHAN D. BRODKIN,[9] ASSOC. M. AM. SOC. C. E.—In this paper Professor Brumfield presents not only a new method for determining the position of moving loads to produce maximum moments in continuous beams, but—what seems of greater importance—he has developed a new and comparatively simple method for analyzing continuous frames so that moments may be distributed in one operation. The method described by Professor Brumfield finds its basis in certain structural concepts which, although well known, have seldom been as logically or lucidly integrated into a practical system of analysis. Utilizing these concepts, the author has developed a method of solution based on determining the exact values of the carry-over factors of the members of a structure.

In a rigid-frame structure, the elastic restraining effects of the various members are interrelated and the constants of the structure, dependent only on this interrelationship, govern the law of distribution of moments throughout the structure. The author terms these constants "frame characteristics" and gives simple equations and a procedure for finding and tabulating them. Distribution of moments from an originating member to the remaining members of the structure then becomes possible in a single arithmetical operation.

The author states in Section 4 that it is "possible to compute, accurately and without the concept of fixed-end moments, the induced restraining moments due to loads placed on the span." This is quite true. However, the writer would like to indicate certain simplifications that can be made in Eqs. 27 for use with static loading, such as is usually encountered in the design of building frames, through the introduction into these formulas of the fixed-end moment concept.

From an inspection of Eqs. 26 it is seen that the restraining conditions of the beam ends have no effect on the values of B and D, these values remaining constant for any given system of beam loading. Any known condition of restraint may therefore be applied to the ends of the beam, and the values of B and D then may be expressed in terms of such restraint. For convenience, a condition of total restraint will be applied. Under such a condition, $C_L = C_R = 1/2$, and the values of M_R and M_L in Eqs. 27 become the well-known fixed-end moments M_{fR} and M_{fL}, respectively. The values of A_R and A_L in Eqs. 28 become 2/3, and Eqs. 27 may then be written in the following form:

$$M_{fR} = -W\,L \times \tfrac{2}{3} \times \left[B - \epsilon^3 - \tfrac{1}{2}\,(D + \epsilon^3)\right] = -\frac{W\,L}{3}\,(2\,B - D - 3\,\epsilon^3) \quad \text{..(45a)}$$

and

$$M_{fL} = -W\,L \times \tfrac{2}{3} \times \left[D + \epsilon^3 - \tfrac{1}{2}\,(B - \epsilon^3)\right] = -\frac{W\,L}{3}\,(2\,D - B + 3\,\epsilon^3) \quad \text{..(45b)}$$

---

[9] Civ. Engr., Board of Transportation, New York, N. Y.

Solving Eqs. 45 simultaneously for B and D yields the following:

$$B = -\frac{2\,M_{fR} + M_{fL}}{W\,L} + \epsilon^3 \qquad \text{(46a)}$$

and

$$D = -\frac{2\,M_{fL} + M_{fR}}{W\,L} - \epsilon^3 \qquad \text{(46b)}$$

Eqs. 46 express the values of B and D in terms of the fixed-end moments and the dissymmetry span ratio. When the loading is symmetrically placed on the beam the value of ϵ becomes zero. Substituting the values of B and D from Eqs. 46 into Eqs. 27 and simplifying, expressions for M_R and M_L in terms of the fixed-end moments M_f, and transmission coefficients are obtained as follows:

$$M_R = A_R\,[(2\,M_{fR} + M_{fL}) - C_L\,(2\,M_{fL} + M_{fR})] \qquad \text{(47a)}$$

and

$$M_L = A_L\,[(2\,M_{fL} + M_{fR}) - C_R\,(2\,M_{fR} + M_{fL})] \qquad \text{(47b)}$$

When one end of the beam is hinged and one end is restrained, Eqs. 47 reduce to either

$$M_R = 2\,M_{fRH}\,C_R \qquad \text{(48a)}$$

or

$$M_L = 2\,M_{fLH}\,C_L \qquad \text{(48b)}$$

in which M_{fRH} and M_{fLH} in Eqs. 48 are the fixed-end moments to be applied to the restrained end, the other end being hinged.

If the loading is symmetrically placed on the span and both ends are restrained, M_{fR} and M_{fL} in Eqs. 47 are equal. Substituting the single value M_f for M_{fR} and M_{fL}, Eqs. 47 become

$$M_R = 3\,A_R\,M_f\,(1 - C_L) \qquad \text{(49a)}$$

and

$$M_L = 3\,A_L\,M_f\,(1 - C_R) \qquad \text{(49b)}$$

It should be noted that the values of ϵ and λ do not enter into the solution of Eqs. 47 to 49 for M_R and M_L and need not be computed for static loading. They are, nonetheless, inherent in the values of the fixed-end moments M_{fR} and M_{fL}.

It is not intended that Eqs. 47 to 49 be used in place of Eqs. 27 when moving loads are under consideration. In such cases the values of ϵ and λ must be determined for finding maximum moments; but where the values of the fixed-end moments for static loads on building frames have been previously tabulated, Eqs. 47 to 49 afford a quick means for determining M_R and M_L. Such tabulations for the usual type of loading normally occurring in buildings may be found in various forms in texts and pamphlets.[10,11]

As an example of the application of Eqs. 47, the bending moments at the supports of beam B_1C_1 in the author's illustrative frame problem, with loading

---

[10] "Continuity in Concrete Building Frames," 3d Ed., Portland Cement Assn., pp. 7–13.

[11] "Analysis of Rigid Frames," by A. Amerikian, U. S. Government Printing Office, Washington, D. C., 1942, pp. 389–392.

as shown in Fig. 12, will be computed. Beam B_1C_1 has a span of 30 ft and concentrations of 3 tons and 12 tons located 6.2 ft and 20.2 ft, respectively, from joint B_1, the transmission coefficients being $C_L = 0.310$ and $C_R = 0.329$. For this case, $A_L = 0.345$ and $A_R = 0.366$. For a single concentrated load,

$$M_{fL} = -\frac{P\,a\,b^2}{L^2} \qquad (50a)$$

and

$$M_{fR} = -\frac{P\,a^2\,b}{L^2} \qquad (50b)$$

in which a is the distance from the left support to the load. With these values inserted in Eqs. 50, the fixed-end moments are as shown in Table 2. Substituting in Eqs. 47:

TABLE 2.—EXAMPLE OF THE APPLICATION OF EQS. 47

Load P (tons)	Position of Load, in Feet, from Either End		Fixed-End Moments, in Foot-Tons	
	a	b	M_{fL}	M_{fR}
3	6.2	23.8	−11.70	−3.05
12	20.2	9.8	−25.84	−53.30
Total	....	....	−37.54	−56.35

$$M_{1CB} = 0.366\,[(-112.70 - 37.54) - 0.310\,(-75.08 - 56.35)] = -40.1 \text{ ft-tons}$$

and

$$M_{1BC} = 0.345\,[(-75.08 - 56.35) - 0.329\,(-112.70 - 37.54)] = -28.3 \text{ ft-tons}$$

These values check with the author's results within the limits of slide-rule accuracy.

It is often necessary and convenient to know the deflection angles at the supports of restrained members. Expressions for the end slopes of a beam may also be derived in terms of the concepts introduced by Professor Brumfield.

From the mechanics of materials the end slopes θ_L and θ_R due to a single concentration P are given by the following equations:

$$\theta_L = \frac{Q}{6\,E}\,(2\,M_L + M_R) + \frac{P\,Q\,L}{6\,E}\,(2\,k - 3\,k^2 + k^3) \qquad (51a)$$

and

$$\theta_R = \frac{Q}{6\,E}\,(2\,M_R + M_L) + \frac{P\,Q\,L}{6\,E}\,(k - k^3) \qquad (51b)$$

When the rotation of the tangent to the elastic curve with respect to the normal position of the beam is clockwise at the left support and counterclockwise at the right support, the signs of θ_L and θ_R are positive.

Where combination loading is under consideration the quantity $2\,k - 3\,k^2 + k^3$ in Eq. 51a may by analogy be replaced by $\bar{k}^3 - 3\,\bar{k}^2 + \bar{k}\,(2 + 3\,\lambda^2)$

$- 3\,\lambda^2 + \epsilon^3$; or $D + \epsilon^3$. Similarly $k - k^3$ in Eq. 51*b* may be replaced by $-k^3 + k\,(1 - 3\,\lambda^2) - \epsilon^3$; or $B - \epsilon^3$. Eqs. 51 may now be written for combination loading as follows:

$$\theta_L = \frac{Q}{6\,E}\,(2\,M_L + M_R) + \frac{\Sigma P\,Q\,L}{6\,E}\,(D + \epsilon^3) \ldots\ldots\ldots\ldots (52a)$$

and

$$\theta_R = \frac{Q}{6\,E}\,(2\,M_R + M_L) + \frac{\Sigma P\,Q\,L}{6\,E}\,(B - \epsilon^3) \ldots\ldots\ldots\ldots (52b)$$

Substituting the values of M_R and M_L from Eqs. 27 into Eqs. 52, and simplifying, yield the following expressions for the slopes:

$$\theta_L = \frac{\Sigma P\,Q\,L}{6\,E}\,\{D\,(1 - 2\,A_L + A_R\,C_L) + B\,(2\,A_L\,C_R - A_R) \\ + \epsilon^3\,[A_R\,(1 + C_L) - A_L\,(2 + 2\,C_R) + 1]) \ldots\ldots\ldots\ldots (53a)$$

and

$$\theta_R = \frac{\Sigma P\,Q\,L}{6\,E}\,\{B\,(1 - 2\,A_R + A_L\,C_R) + D\,(2\,A_R\,C_L - A_L) \\ + \epsilon^3\,[-\,A_L\,(1 + C_R) + A_R\,(2 + 2\,C_L) - 1]\} \ldots\ldots\ldots\ldots (53b)$$

Eqs. 53 may be written in a simpler form by substituting the values of B and D previously derived in Eqs. 46, yielding the following expressions:

$$\theta_L = \frac{Q}{6\,E}\,[(2\,A_L - A_R\,C_L - 1)\,(2\,M_{fL} + M_{fR}) \\ + (A_R - 2\,C_R\,A_L)\,(2\,M_{fR} + M_{fL})] \ldots\ldots\ldots\ldots (54a)$$

and

$$\theta_R = \frac{Q}{6\,E}\,[(2\,A_R - A_L\,C_R - 1)\,(2\,M_{fR} + M_{fL}) \\ + (A_L - 2\,C_L\,A_R)\,(2\,M_{fL} + M_{fR})] \ldots\ldots\ldots\ldots (54b)$$

The writer has applied Professor Brumfield's system of analysis in practice to the solution of problems involving restrained beams, frames, and arches of both constant section and varying section. In most cases he has found the author's method more simple and more expeditious than any of the so-called classical methods of solution. The method of analysis presented in the paper can be generalized, formulas can be derived for members of variable section, and it can be shown that the case of constant moment of inertia is simply a special case of the general solution.

T. F. HICKERSON,[12] M. AM. SOC. C. E.—The "frame characteristics" treated in this paper are derived from the theorem of three moments. Similar frame characteristics introduced by the writer[13] were derived from modified slope-deflection equations in which the "degree of fixity" is introduced. Both methods are theoretically exact, are entirely independent of the loading or deformations (if small), and lead to bending moments at a single operation.

---

[12] Prof. of Applied Math., Univ. of North Carolina, Chapel Hill, N. C.

[13] "Statically Indeterminate Frameworks," by Thomas F. Hickerson, Univ. of North Carolina Press, 2d Ed., 1937, p. 204 (1st Ed., 1934).

The procedure for moving loads, and fixing their position on the framework to cause maximum bending moments, are treated thoroughly by the author. Necessarily these general bending-moment formulas for any loading combination (Eqs. 25) must be complicated even if they are supplemented with curves. Treating each individual case as a problem in itself (with fewer variables) offers an alternative procedure. One may arrive at a close approximation to the theoretical result after a few trial positions of the loads. This would be a relatively simple procedure. After solving several typical problems one would be in a better position to judge which of the two methods is preferable in practice.

Max W. Strauss,[14] Jun. Am. Soc. C. E.—Publication of this paper at long last makes available to the American engineering profession a method for the precise analysis of rigid frames that heretofore has been widely used in other countries. (A relatively small group in the United States, of which the writer is a member, had the privilege of studying under Professor Brumfield and thus was aware of this method prior to its present publication.)

The concept of an exact "carry-over factor" or "transmission coefficient" is not a new one. It can be traced back to the famous French engineer, Maurice Lévy, in whose great work[15] may be found the equivalent of many of the author's expressions. In the United States the concept was introduced in graphical form[16] by L. H. Nishkian and D. B. Steinman, Members, Am. Soc. C. E., as the method of conjugate points. More recently an analytic application of this concept was implied by Camillo Weiss,[17] M. Am. Soc. C. E. In his paper, Professor Brumfield presents a logical development of this analytic application.

Restraining Moments in a Loaded Span.—In Sections 4 and 5 of the paper, the author has derived expressions for the end moments in a loaded span due to the loads in that span. Eqs. 14, although quite simple, are limited in use to concentrated loads. For other loads or combinations of loads, the labor involved becomes somewhat tedious in that the analyst may either integrate Eqs. 14 (mathematically, if the particular loading so allows, as in Eq. 15, or otherwise mechanically), or use Eqs. 27 in conjunction with the curves of Fig. 5, Eq. 22*b*, and Eq. 24. However, much of this tedious labor can be avoided by a single expression that is applicable to any load or combinations of loads.

Eq. 14*b* may be rewritten—

$$M_R = -W L \frac{C_R}{1 - C_R C_L} [(2 k^2 - 2 k^3 + k - 2 k^2 + k^3) - C_L (2 k - 4 k^2 + 2 k^3 + k^2 - k^3)] \ldots\ldots (55)$$

Remembering that the fixed-end moments, M_{FR} and M_{FL}, for the right end and left end, respectively, for a concentrated load are given by

$$M_{FR} = (k^2 - k^3) W L \ldots\ldots (56a)$$

---

[14] Asst. Structural Engr., Dept. of Water Power, Los Angeles, Calif.

[15] "La Statique Graphique et Ses Applications Aux Constructions," by Maurice Lévy, Gauthier-Villars & Co., Paris, France, 1886–1888.

[16] "Moments in Restrained and Continuous Beams by the Method of Conjugate Points," by L. H. Nishkian and D. B. Steinman, *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 1.

[17] "Interrelation of Certain Structural Concepts," by Camillo Weiss, *ibid.*, Vol. 111 (1946), p. 391.

and

$$M_{FL} = (k - 2\,k^2 + k^3)\,W\,L \quad \text{(56b)}$$

and substituting these in Eq. 55, the latter becomes

$$M_R = -\frac{C_R}{1 - C_R\,C_L}\,[(2\,M_{FR} + M_{FL}) - C_L\,(2\,M_{FL} + M_{FR})] \quad \text{(57a)}$$

Although Eq. 57*a* is adequate, it can be simplified further. By collecting terms:

$$M_R = -\left[M_{FR}\,\frac{C_R\,(2 - C_L)}{1 - C_R\,C_L} + M_{FL}\,\frac{C_R\,(1 - 2\,C_L)}{1 - C_R\,C_L}\right] \quad \text{(57b)}$$

Substituting Eq. 4 for C_R and C_L, combining like terms, and then substituting Eq. 40, Eq. 57*b* reduces to

$$M_R = -\,[M_{FR}\,(1 - t_R) + M_{FL}\,t_L\,C_R] \quad \text{(58a)}$$

and, similarly,

$$M_L = -\,[M_{FL}\,(1 - t_L) + M_{FR}\,t_R\,C_L] \quad \text{(58b)}$$

in which t_R and t_L are obtained by Eq. 41 or from Col. 10 of Table 1.

Eqs. 58 have the advantage of being applicable to all types of loadings inasmuch as tables and curves for fixed-end moments for all types of loads are readily accessible in all standard reference books.

Stiffness and Restraint.—It seems to the writer that I/L, or K, affords a better mental image of the stiffness of a span than the author's L/I, or Q, since a stiffer beam is thus represented by a larger numerical value. Using larger numbers for stiffer beams avoids the mental juggling that must inevitably ensue if the reverse is adopted. Thus

$$i = \frac{2 - C}{K} \quad \text{(59)}$$

and if, furthermore, the stiffness index is defined as $1/i$ or r, instead of i, and the restraint index is defined as the sum of the stiffness indexes, then

$$r = \frac{1}{i} \quad \text{(60a)}$$

$$R' = \frac{1}{R} = S\,r \quad \text{(60b)}$$

and

$$C = \frac{1}{2 + \dfrac{K}{R'}} \quad \text{(60c)}$$

This is of more than academic interest since it would simplify the necessary calculations considerably. For example, if Col. 3 of Table 1 listed r, or $1/i$, instead of i, then Col. 4, which would list R' instead of R, would be obtained merely by the addition of the values in Col. 3 for the other members at that joint. The computer would not be required to obtain the reciprocal of the sum of the reciprocals of these values.

Transforming the author's expressions so as to utilize fixed-end moments serves the further purpose of illustrating the coordination of this method with the Cross method of successive approximations and the slope-deflection method. This is to be expected as all are based on, and derived from, the basic theorem of three moments.

D. A. MACKENZIE,[18] ASSOC. M. AM. SOC. C. E.—The analysis of continuous beams and frames supporting moving loads has been advanced considerably by the publication of this paper. Eqs. 29 and the curves of Fig. 6 are particularly useful. A precise mathematical formula now is available for locating the loads to produce maximum moments, instead of the more or less approximate methods commonly used in the past.

FIG. 15

The coefficients used for transmission (C), moment split (m), and torque split (t) may also be used as moment distribution factors and, once the loads are located on the span, the negative moments may then be found by fixed-end moments and direct moment distribution.

The author's example of Fig. 12 may be arranged as shown in Fig. 15 and the end moments readily found by that method.

Joint B_1 is first balanced to make $\Sigma M_{B1} = 0$. The moment (15.95) allocated to B_1C_1 is then multiplied by the carry-over factor ($C = 0.329$) to produce a moment of 5.25 ft-tons at joint C_1 which is then distributed to the other two members in proportion to their torque-split factor (t) or their moment-split factor (m), and the signs changed to make $\Sigma M_{C1} = 0$. These are carried over progressively to the other joints in the same manner; and the other joints are then balanced likewise.

The sign convention used is one which considers that a moment at the end of a member is positive if it tends to rotate the adjacent joint clockwise.

---

[18] Design Engr., Buffalo-Niagara Elec. Corp., Buffalo, N. Y.

The computations in this discussion were done by slide rule, which probably accounts for the slight difference from the author's values.

Of course, the moments could also be found by the Hardy Cross method, but, having already obtained the direct-moment factors, the amount of work involved in making the balancing and distributing computations is very small. The principal advantage of the direct method is its flexibility for determining maximum moments where some spans are loaded and others not loaded.

CHARLES E. SCHAFFNER,[19] JUN. AM. SOC. C. E.—The most serious handicap of the Brumfield method is that it is comparatively difficult to learn without the help of an instructor. This fact, in addition to its limited distribution, heretofore has retarded the adoption of the method. One naturally chooses an instrument that is easy to adopt, rather than one which requires much study, and perhaps the assistance of other engineers.

One point concerning the paper, as published, is open to criticism. This is that it was begun with complete definitions of the special nomenclature to be used. Because of the newness of the approach, it is necessary to use unfamiliar nomenclature. However, psychologically, it might be better if the author had defined the terms and symbols as needed, throughout the text, and then summarized them at the end of the paper, or at the end of each section.

The only familiar symbol that has been changed is the Q-value which is the reciprocal of the familiar "K-value." It is well that this change has been made because, for this particular method, it is more advantageous to have the value in the numerator than in the denominator. The algebraic manipulations are simplified. In addition, it must be remembered that all writing, derivations, and solutions are done initially by hand rather than by the typewriter. The use of Q thus eliminates the possibility of confusing K with the k frequently used to denote a proportionate part of the span length.

The actual simplicity of the method, once one is familiar with the fundamentals, will be apparent upon examination of Eqs. 14, 16, and 17, which are derived in straightforward fashion from the theorem of three moments. The author has verified the accuracy of each by simple examples.

Many engineers have a phobia against using any equations for which curves are plotted. The curves, shown in Figs. 5 and 6, aid in the solutions of Eqs. 26 and 29. However, they are not indispensable, as the equations can be solved easily should the curves be unavailable. In fact, as the author notes, Eqs. 25 need not be used. The separate effects of a series of concentrations may be computed by the use of Eqs. 14, 16, or 17, and these effects can be added algebraically. However, the computing time is reduced considerably by the use of Eqs. 25; and it is reduced much more if Eqs. 27 and Fig. 5 are used.

In Section 7, the author shows good judgment by explaining the significance of a number of the new terms. One of the faults inherent in most involved systems of computation is that the computer gradually tends to do things by rote, and thus loses understanding of the different steps through which he passes. These terms are not just invented terms, but have a definite physical meaning. Thorough understanding of their use and significance is essential.

---

[19] Instructor, Civ. Eng. Dept., The Cooper Union, New York, N. Y. (on military leave).

In Sections 6 and 8, the author succeeds where the proponents of all other methods have failed. He has shown how to locate the position of a moving load on a restrained beam for maximum bending moment, either at the support, or under one of the concentrations. This will provide a great reduction in the work and time necessary in analyzing this type of problem.

The derived equations, although not simple, can be handled competently, as the author shows in his illustrative example in Section 6. It is regrettable that no example of the use of Eq. 35 has been given, and that some of the steps in its development have been omitted. However, it is obvious that in a short paper, such as this, some things, ordinarily included, must be omitted. Thus some excellent algebraic manipulations have been eliminated from this treatment. One idea which tends to inspire confidence in the equations is the manner in which the author shows how each equation reduces to a well-known formula under simple beam conditions. Actually then, related simple beam formulas are only special cases of the more general formulas developed in this paper.

It is imperative to become familiar with the frame characteristics, as explained in Section 10. These new terms—transmission coefficient, stiffness index, restraint index, moment split, and torque split—and their interrelations are the basis of the method. A complete understanding of this material is essential to the proper use of the method. The arrangement, shown in Table 1, includes all the characteristics of the frame that are necessary for the analysis. In addition, the value of the table is enhanced by its self-checking features which eliminate practically all chances of error.

In the larger, more complicated frames, it is impossible to complete this table without resorting to the estimation of the value of a few of the coefficients. This operation (see Section 11), although quite simple, is invaluable. It enables the analyst to check key members rapidly without conducting a complete analysis.

One of the most frequent sources of error and confusion in the analysis of rigid frames has always been the sign or sense of the bending moment. The traditional "positive or negative" of courses in mechanics of materials is usually abandoned because of the confusion created by other than horizontal members. Directional signs or the terms, "clockwise or counterclockwise," usually are adopted; and actually that is what the author's "normal and reverse system" is. However, his concept, as given by his definitions, "pins down" the exact meaning of these terms, thus clarifying the physical picture in the mind of the user. These definitions, together with the other fundamentals, enable the analyst to picture exactly how each member of the frame reacts to different loading conditions. This gives the analyst a tremendous advantage over one who uses a system of positive and negative bending moment without attempting to picture the resultant bending of the frame.

In Section 13, Professor Brumfield mentions a moment-distribution chart for each joint. This is an excellent bookkeeping device. It must not be misconstrued, however, as an essential part of the method. Direct moment distribution, although a little cumbersome in the analysis of large frames, is no more so than that in the Hardy Cross system. The charts are something that the author has devised to facilitate computation. It has been the experience of the writer, working without these charts, that the method is easily adaptable to complicated reentrant frames. In one particular case it was used successfully on an airplane hangar upon which other men had worked, unsuccessfully, for much longer periods, with a number of other methods. When each of three other methods "bogged down" at a different sopt, this method was finally tried and the analysis was completed in a surprisingly short period. As the author states, one distribution is sufficient for all purposes, including sidesway.

In conclusion, the author remarks that the method has been extended to beams of variable section and restrained ends, and also to curved beams. The writer has done some work in this respect in arch analysis. Probably the most popular method of arch analysis is the "elastic center method." A comparison of the two methods would therefore be important.

The "elastic center method" is derived from the laws governing elastic displacements in ribs and frames—a fairly involved subject. This method is based upon some of the fundamental concepts of the moment-area method, familiar to all students of elementary mechanics of materials. It is developed from these concepts, in direct fashion, mainly through the use of the laws of statics. Therefore, where the Brumfield method would seem to be comparatively difficult to learn as applied to straight beams, it becomes the simpler method when applied to the more complex subject of curved beams of variable section. Every equation used is transformed into the corresponding orthodox straight beam formula as the radius of curvature of the beam approaches infinity.

These same equations, applied to arches, sewer rings, etc., can be used with equal facility for the analysis of ordinary frames, such as rectangular bents, saw-tooth roof frames, etc. This means, of course, great versatility and adaptability. Finally, the Brumfield method reduces the arithmetical work necessary in the elastic center method by at least one third. This is of inestimable value, as it is this part of the analysis that presents the greatest chance of error.

To summarize, the writer believes that this method will gain rapidly in popularity among engineers when they realize that its accuracy, ease of usage, and extreme adaptability far outweigh the initial time spent in learning it.

J. Kalb,[20] Esq.—As examples of unusual structures to which the Brumfield method has been applied successfully, two interesting frames are presented herein to advance the discussion of Section 15. For example, Fig. 16 represents, diagrammatically, one of the seven reinforced-concrete rigid-frame bents designed for a vocational high school to be constructed in New York, N. Y. The spans, sizes, loads, Q-values, and transmission coefficients for the frame, as well as the moment split at joint 2G, are shown in Fig. 16. These were

[a] N = normal moment and R = reverse moment. [b] Tension is positive. [c] Bending moments for maximum live load, and with direct force considered. [d] The last four items in this column (in parentheses) are the deflections at the joints indicated, in inches.

taken from computations such as those in Table 3 for joints 2G, 3G, and 3C. The values of Q are to be multiplied by 100 and the moments are in kip-feet. Members in the frame are identified by a coordinate system in which columns and supports are lettered and floors and roofs are numbered. Thus, joint C2 is in column C at floor level 2. The writer investigated the intrusion of the members in accordance with the principles developed by the author in his text,[4] because at several joints relatively limber members are framed into very stiff members.

[a] The lower-case letters in the moment-split column represent the possible radiating members at the joint under consideration, thus: (a), (b), (c), and (d) always refer to the members radiating downward, to the left, upward, and to the right, respectively, from the joint.

In connection with this design three facts are particularly noteworthy:

(*a*) The original design of member 3CG called for a haunched T-beam, increasing from 46 in. at its center to 72 in. at the center line of the columns. The analysis indicated that the columns, limited in size by the architect, would be overstressed. Changing this girder to one of constant depth required recomputations of frame characteristics only for those members framing into the joints at the ends of the girder.

(*b*) The results of the transmission and collection of the moments from the various joints are indicated for joint 3C. For example, the uniform load on 4BC transmitted 19 ft-kips to member 3CG, the sense of the moment being the same. Therefore, changes in loadings resulted only in changing the value of M_R and M_L for that particular load and noting its effect on the various joints to which it is transmitted.

(*c*) The critical values of the column moments were obtained by collecting the moments to give the maximum or minimum values, using the live-load percentages of the total loads.

Table 4 demonstrates the analysis of a Vierendeel truss used in the structural steel framing of New York City school buildings, the loadings, in kips, being as follows:

Load	P_A	P_B
Dead	13.7	17.9
Live	14.0	5.2
Total	27.7	23.1

The analysis of such a truss may be summarized into the following basic steps: (1) Compute the frame characteristics; (2) prepare torque transfer strips; (3) prepare torque-distribution charts; (4) compute moments due to loads between panel points and distribute; (5) distribute and collect artificial and neutralizing torques; (6) set up and solve shear bending moment equations; (7) obtain primary moments by substituting in the collections of artificial and neutralizing torques; (8) compute the direct stress; (9) find the artificial moments due to changes in length and distribute the neutralizing torques; (10) compute the vertical forces necessary to hold the lower chords horizontal and find the moments caused by the shears by substituting as in step 7; and (11) the total moment in any member is the algebraic sum of the moments found in steps 7, 9, and 10. For ordinary purposes, the practice of using two-joint distribution and neglecting the secondary stresses will limit the analysis to the first seven steps and reduce the time required approximately one half. The analysis for secondary stresses and the effect of placing the live load to give the maximum moments are included in Table 4. The deflections of this truss (see last four items in Col. 8, Table 4) are practically the same as those for the conventional type. Fig. 17 shows the distorted frame and the horizontal and vertical displacements of the panel points.

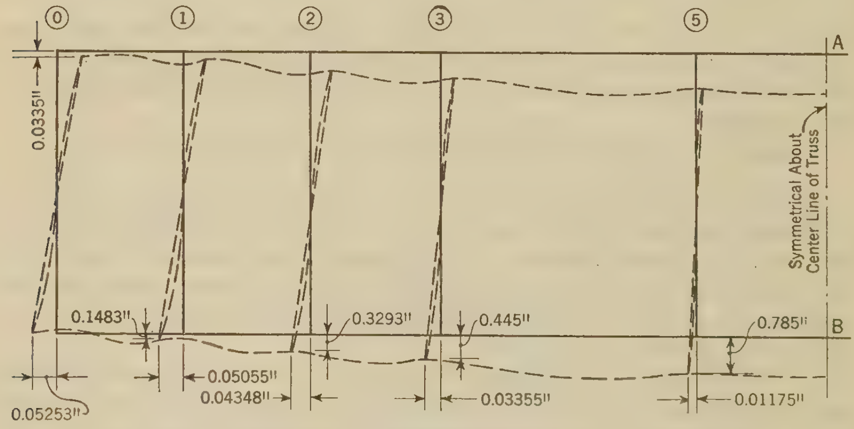

Fig. 17.—Distorted Frame

As a check on the accuracy of Professor Brumfield's method, the writer analyzed a Vierendeel truss whose solution[21] has appeared elsewhere. The results were in exact agreement.

Summary.—The adaptation of frame characteristics, which is the heart and soul of Professor Brumfield's system, cloaks each frame with scientific exactness. These frame characteristics make entirely clear every detail of the flow of moment through the frame, and they readily facilitate computations and the examination of computations in case of changes in loading on any member. They simplify the computations for critical values of moment and shear for any member, regardless of type of loading, by indicating the necessary pattern of loading required to give these values, thus enabling the designer to trace their effects to that member. By the formula and the principles stated in Section 11, the writer has estimated the transmission coefficients for non-reentrant frames with gratifying results both as to time saved and accuracy of results. The concept of normal and reverse bending moment introduced by Professor Brumfield yields a clear picture of the distorted frame and eliminates the possibility of error and confusion arising in complicated frames when the plus and minus signs are used.

The writer has applied Professor Brumfield's system, successfully, not only to frames with straight beams of variable sections but also to curved beams with variable sections and to noncoplanar frames. The entire system is thorough, well integrated, and readily applied.

G. ROLSMA,[22] ESQ., AND F. W. GIESEKING,[23] ESQ.—The concept of the transmission coefficient, as presented in this paper, provides a means for analyzing rigid frames regardless of shape or symmetry. Frames can be solved directly and completely for wind sidesway, moving loads, deflections, and settlement of supports. Expansion of the fundamental derivations furnishes the solution of each succeeding step. No additional theorems or assumptions are necessary. The fundamentals should be readily understood by the average engineer who is familiar with the three-moment theorem or the method of moment areas.

As a comment on Section 15 of the paper several "other applications" can be cited briefly. For example, the frame in Fig. 18(*a*) has been analyzed in the design of several stadia in New York, N. Y. A thorough study was desirable and the slight extra time required for computing coefficients was considered well spent as they were used in each succeeding step of the analysis. The frame characteristics in Fig. 18(*c*) were computed from the physical constants of the frame as outlined in Section 10 of the paper.

End moments were calculated, for all members of the frame, using Eqs. 16 and 17. For example, in the computations for joint C, $L_{CD} = 18.6$ ft and $L_{CB} = 16.0$ ft. The total design load, w, on member DB was 2.8 kips per ft, half of which was live load. Values of C_R and C_L are shown in Fig. 18(*b*). Substituting these values in Eqs. 16 and 17, $M_{CD} = \frac{28 \times 18.6^2}{4} \times \frac{0.41}{1 - 0.41 \times 0.284} \times 0.716 = 81$ ft-kips. Similarly, $M_{CB} = 56$ ft-kips. The end moments were then distributed to the frame in accordance with Section 13, except that moment-distribution charts were used, such as those for joint C in Fig. 19. Letters U, L, and R refer to the "under," "left," and "right" members, respectively, of the joint under consideration. The letters in the central column of each part of the chart indicate the joint of origin, and the lower-case letters at the sides show the particular member from which the distributed bending moment originates; thus: "a" denotes the under members, "b" denotes the left members, "c" the over members, and "d" the right members. Quantities next to the lower-case letters are live-load moments taken as a percentage of

the total moment, and are used for computing maximum and minimum moments. Moments of reverse sense are recorded in the left-hand column and normal moments in the right-hand column.

For example, at the U-member of joint C the 21 ft-kips (normal in sense) constitute 50% of the total moment from the d-member of joint C indicating removal of live load from member CB to produce maximum moment of 47 ft-kips. From the moment-distribution charts, live-load plus dead-load moments, and maximum moments and minimum moments, may be obtained rapidly for each member at all joints. The frame is now statically determinate for all possible loading conditions; and the reactions, column shears, and maximum positive bending moments are readily computed.

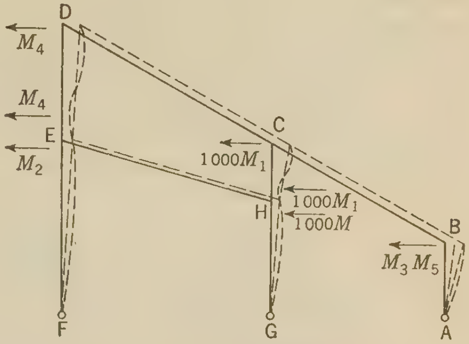

FIG. 20.—EFFECT OF SIDESWAY

Sidesway on an unsymmetrical frame, such as that in Fig. 18, may now be investigated easily by continuing the analysis. In general, the method is to assume that each joint has moved laterally to its final but unknown position as indicated by dashed lines in Fig. 20. At each end of all columns the designer places unknown bending moments sufficient to rotate the columns parallel to their original unstressed position. In this case 1,000 units of M were placed in top of column GH, 1,000 M_1 were placed at the top and the bottom of column HC. By comparing column FE to column GH: $M_2 = \frac{Q\,L}{Q_2\,L_2} \times 1{,}000\,M = \frac{3.13 \times 8.75}{5.69 \times 15.12} \times 1{,}000\,M = 318\,M$. Similarly, for the ends of the other columns, $M_3 = 8{,}350\,M$, $M_4 = 173\,M_1$, and $M_5 = 219\,M_1$.

Neutralizing torques, which are numerically equal but of opposite sense to the artificial bending moments placed at ends of columns, are applied at each joint and distributed to the frame. An example of a torque-distribution chart for joint C, in which 1,000 units of torque at joint C are distributed to the frame, is shown in Fig. 21. Such a chart is a valuable aid in distributing the neutralizing moments at a joint to the frame. After distribution, these neutralizing torques and the artificial bending moments are summarized for each member at all joints. Shears in the columns may now be expressed in terms of M and M_1, and, by the laws of equilibrium, simultaneous equations may be set up and solved for numerical values of M and M_1. These values of M and M_1 are then substituted back into the joint summary for each member, thus obtaining values of bending moments due to lateral deflection. A summary chart for joint C, similar in arrangement to Figs. 19 and 21, can then be prepared to show the artificial bending moments and neutralizing torques, and final moments due to sidesway.

Most engineers do not have time to study, thoroughly, all methods proposed; also, personal preferences often dictate the method to be used in solving rigid frames. Actually, one method may be more suitable for a particular problem than another, depending on the desired degree of accuracy and extent of analysis. The concept of transmission coefficients as presented, therefore, offers the following advantages:

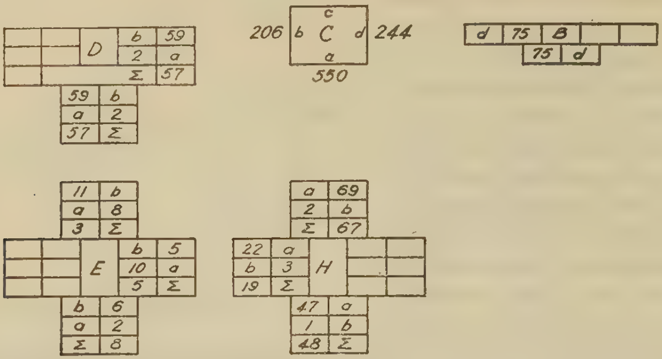

FIG. 21.—EXAMPLE OF CHART FOR THE DISTRIBUTION OF TORQUE FROM A GIVEN JOINT (JOINT C) TO ALL MEMBERS OF THE FRAME

(1) It is a perfectly general method of analysis and not a special means of solving a limited number of cases due to form or symmetry. In the frame presented by the writers the members are of uniform section. If some or all were of variable section, the procedure would be the same except that then the restraint triangles require modification.

(2) No approximations of the degree of end restraints of the members are necessary anywhere in the structure except at the base or foundation levels.

(3) The manner of bookkeeping suggested offers opportunity for detecting errors speedily and for observing the paths of moments through the frame. The resulting moments are obtained directly and accurately.

(4) The formulas, readily understood, lead to short cuts expressing, in a brief mathematical expression, ideas which would require many lines of written explanation. This is particularly true of the formula for moving loads which, together with the prepared graph, provides a direct and rapid method for placing moving loads of any composition upon restrained beams in position for the required maximum condition. Therefore, influence lines are not required. The case of frames loaded with uniform live load is illustrated in Fig. 19, the use of loading patterns and the attendant separate studies required for each pattern being obviated.

(5) The use of the concept of normal and reserve bending moment in place of the plus and minus signs removes much of the confusion in the old use of signs. The distortion of the frame is also more readily visualized.

The paper is a noteworthy contribution to engineering literature pertaining to the analysis of rigid frames. A study of the "concept of transmission coefficients" and the manner of approaching various problems cannot help but result in a greater understanding of the action of rigid frames under all types of loading and the method should not prove too difficult to master and remember.

Stanley S. Schure,[24] Esq.—The Brumfield method of analysis has several advantages over other comparable methods. For example, it is more direct and, in a number of cases, more simple than the Cross method. After he has computed the frame characteristics, the designer will be familiar with the structure. The effect of different loadings, or of changes in the original loading, can easily be traced.

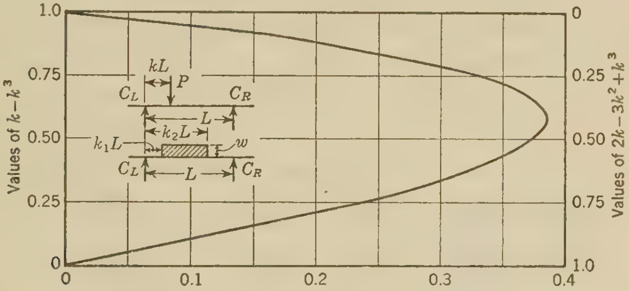

Fig. 22

To demonstrate this point, consider an ordinary continuous beam resting simply on five supports, with the four spans unequal in length. Assume the end supports to be partly fixed so that finite values of C will occur at the extremities by the beam. Formulas for the fixed moments in each span (see inset, Fig. 22) are computed as follows:

For concentrated loads—

$$M_R = -P\,L\,A_R\,[(k-k^3) - C_L\,(2\,K - 3\,K^2 + K^3)] \quad \ldots\ldots (61a)$$

and

$$M_L = -P\,L\,A_L\,[(2\,k - 3\,k^2 + K^3) - C_R\,(k-k^3)] \quad \ldots\ldots (61b)$$

For uniform loads—

$$M_R = -w\,L^2\,A_R\left[\frac{k^2_2 - k^2_1}{2}(1 - 2\,C_L) + (k^3_2 - k^3_1)\,C_L - \frac{k^4_2 - k^4_1}{4}(1 + C_L)\right] \quad \ldots\ldots (62a)$$

and

$$M_L = -w\,L^2\,A_L\left[\frac{k^2_2 - k^2_1}{2}(2 - C_R) - (k^3_2 - k^3_1) + \frac{k^4_2 - k^4_1}{4}(1 + C_R)\right] \quad \ldots\ldots (62b)$$

When $k_1 = 0$ and $k_2 = 1$, Eqs. 62 become

$$M_R = -\frac{w\,L^2}{4}\,A_R\,(1 - C_L) \quad \ldots\ldots (63a)$$

---

[24] Structural Designer, Standard Oil Development Co., Elizabeth, N. J.

and

$$M_L = -\frac{w\,L^2}{4}\,A_L\,(1 - C_R)\ldots\ldots\ldots\ldots\ldots\ldots(63b)$$

which may also be derived by substituting A_R-values and A_L-values in Eqs. 16 and 17, respectively. Values of $k - k^3$ and $2\,k - 3\,k^2 + k^3$ can be selected from curves such as Fig. 22. The succeeding step is to compute the frame characteristics similar to Table 1. For the example presented herein these characteristics are shown in Table 5. Finally, the restrained moments for each load, and the unbalanced moments from each span, are tabulated and the total moment is determined as shown in Table 6. As stated, the method is direct and simple. In a large percentage of cases the loads are concentrated or uniformly distributed, as in this example. For special loadings, such as locomotives, trucks, and variable distributions, the method described in Section 5 is applicable.

TABLE 5.—COMPUTATION OF FRAME CHARACTERISTICS, CONTINUOUS BEAM ON FIVE SUPPORTS

In computing frame characteristics the writer suggests a modification which produces the same results as the author's method. This procedure avoids the use of a slide rule and thus eliminates errors. It involves the use of tables of reciprocals such as those found in most handbooks. For instance, the writer would add the following data in a column to be inserted between Cols. 3 and 4, Table 1:

Member	$\frac{1}{i}$
Joint B₁	
B10	2.1930
1BA	2.5253

The proper values of $1/i$ are then added and the co-reciprocal of their sum is as the necessary R-value. For example, in member 1BC, joint B_1, 2.1930 + 2.5253 = 4.7183. The co-reciprocal of this value (0.212) is the value of $R_{1BC}\left(=\frac{1}{\frac{1}{i_1}+\frac{1}{i_2}}\right)$. Similarly for member 1DC, joint D_1, 1.6448 + 2.5253 = 4.1701, whose co-reciprocal (0.240) is the required value of R_{1DC}.

ALEXANDER DODGE,[25] ASSOC. M. AM. SOC. C. E.—The analysis of the frame shown in Table 1 was predicated on the assumption that no sidesway existed, which would hold true only if the ends A_1 and E_1 were hinged. However, this assumption is in conflict both with the sketch, in which the ends A_1 and E_1 are shown to be freely supported, and with the statement (see Section 10) "A free support, such as point A_1." It is inconceivable that the term "a free support" could ever be applied to the hinged end of a member. Furthermore, in modern rigid frames of the type shown, the bearing ends A_1 and E_1 are usually made free to move in a horizontal direction (to minimize shrinkage and temperature stresses) by the introduction of rockers or metal sliding plates; and the problem of determining the degree of lateral support, as a rule, is given due consideration in design. Therefore, with the information at hand, the degree of lateral support for this frame is an unknown quantity, depending on the position of a load and the amount of the downward reactions, as well as the coefficients of friction at points A_1 and E_1. This point should be clarified, so that no doubt is left in the reader's mind as to the type of a structure that is being analyzed. With loads placed as shown in Fig. 12, both ends A_1 and E_1 will be raised from their supports, provided this movement is not prevented by dead-load reactions, which, however, were not taken into consideration in the analysis. Therefore, the transmission coefficients will be changed and unbalanced shears in the columns will cause lateral deflections. Consequently, the characteristics of the frame will be altered to such an extent that an entirely new solution will result, although the changes will be slight because of the almost perfect symmetry of the frame and the loading.

The stated purpose of the paper (see "Synopsis") is to develop methods "for distributing the moments to the frame in a single operation," but the author has failed to show how this could be done because sidesway, present in the analysis of this frame, is disregarded. Moreover, the analysis of any rigid frame without sidesway can be reduced to an analysis of a continuous beam, and Eqs. 10 to 38 represent very special cases of structural concepts, belonging to the "beam class" rather than to the "frame class" of problems. The designer is interested not only in the bending moment under concentrated loads, but also (even for the very simple case treated in the paper) in negative moments at intermediate points; and these latter moments must be determined by some method not treated in the paper. A pure couple requires an entirely different set of computations using a very different concept, which makes the Brumfield analysis lengthy, nonuniform, and cumbersome.

---

[25] Engr., U. S. Engrs., Portland, Ore.

The derivation of exact partly restrained end moments due to loads on a member has been demonstrated by A. Strassner.[26] He showed the practical applications of the concept of transmission coefficients and presented a method of distributing the moment to the frame of a general type in two operations—(1) by distributing the moment in a single operation on the assumption that no sidesway exists and (2) finding the sidesway corrections (also a single operation). Mr. Strassner's original work is mostly graphical—probably the reason why his method has never attained popularity in the United States. Subsequently, an entirely algebraic method, called the "coefficients of unit moment" method,[27] was developed which took variable moment of inertia, as well as sidesway adjustments, into consideration.

On the assumption that there is no sidesway, the general equation of the exact partly restrained end moment at end A of a member AB, due to applied load on the member, is given by:

$$M'_A = M_A\,(1 + t_{ab}) + M_B\, t_{ba}\, Z'_{ab} \ldots\ldots\ldots\ldots\ldots\ldots (64)$$

in which t_{ab} and t_{ba} (the writer's "coefficients of unit moment" and Professor Brumfield's "torque split") represent the exact moment induced in a member at a joint due to a unit moment applied at the same joint; and Z'_{ab} is the coefficient of unit moment, or the moment at the partly restrained end A of the beam AB due to a unit moment at the hinged end B. Furthermore,

$$M_A = \frac{\dfrac{\phi_\beta\, 6\, I}{L^2}\,(M_{sa}) - \dfrac{\phi_\alpha\, 12\, I}{L^2}\,(M_{sb})}{4\,\phi_\alpha\,\phi_{ab} - \phi^2{}_\beta} \ldots\ldots\ldots\ldots\ldots (65a)$$

and

$$M_B = \frac{\dfrac{\phi_{ab}\, 12\, I}{L^2}\,(M_{sa}) - \dfrac{\phi_\beta\, 6\, I}{L^2}\,(M_{sb})}{4\,\phi_\alpha\,\phi_{ab} - \phi^2{}_\beta}; \ldots\ldots\ldots\ldots\ldots (65b)$$

In Eqs. 65: ϕ_β, ϕ_α, and $\phi_{\alpha b}$ are form factors, or constants of integration depending upon the variation in moment of inertia of a beam; and M_{sa} and M_{sb} are numerical values of the moment of the simple-beam, M/I-area, due to external loading on beam AB taken about points A and B, respectively. For a constant moment of inertia, Z'_{ab} in Eq. 64 is equal to:

$$Z'_{ab} = \tfrac{1}{2} f = C_{BA} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (66a)$$

After a slight rearrangement, Eq. 4 may be written:

$$C_{BA} = \tfrac{1}{2}\left[\frac{1}{1 + \dfrac{1}{2\left(\dfrac{Q}{i_1} + \dfrac{Q}{i_2}\right)}}\right] \ldots\ldots\ldots\ldots\ldots\ldots (66b)$$

[27] "Solution of Rigid Frames by Coefficients of Unit Moment," by Alexander Dodge, thesis presented to the University of Washington at Seattle, Wash., in 1939, in partial fulfilment of the requirements for the professional degree of Civil Engineer.

combining Eqs. 66:

$$\frac{1}{1+\dfrac{1}{2\left(\dfrac{Q}{i_1}+\dfrac{Q}{i_2}\right)}} = f \text{.....................} (67)$$

The left side of Eq. 67 is the mathematical expression of the symbolic definitions, but the "end fixity," f, has been shown to represent the clear physical concept, simply derived from the knowledge of the stiffnesses of the joining beams only;[28] that is,

$$f = \frac{\Sigma S_p}{\Sigma S_p + S} \text{.......................} (68)$$

A very simple relation also exists between the "end fixity" and the "transmission coefficient." When f is equal to unity (100% end fixity for the fixed end), the value of C equals 0.5; and, when f is equal to zero (0% end fixity for the hinged end), the value of C becomes zero also. For any variation of the moment of inertia and for a partial fixity, the simple linear relation still exists between f and C. Eq. 64 was developed with the expectation that it might be used on a broad scale in engineering practice, but this expectation has never been realized because in rigid frame analyses sidesway adjustments may modify, considerably, the results found by Eq. 64. Eqs. 18 through 38 belong to the same category and from the practical standpoint can scarcely prove satisfactory to designers.

FIG. 23.—COEFFICIENTS OF UNIT MOMENT

The exact partly restrained end moment in a member due to end translation is expressed by Eq. 64, except that, in this particular case (compare Eq. 65a):

$$M_A = \frac{M_B\,(\phi_\beta + 2\,\phi_\alpha)}{\phi_\beta + 2\,\phi_{\alpha b}} \text{....................} (69)$$

In Eq. 65, Eq. 69, and following discussion the modulus of elasticity is assumed to be constant; or $E = 1$.

---

[28] *Transactions*, Am. Soc. C. E., Vol. 111 (1946), p. 426.

Computation of "symbolic" quantities is a tedious process that has no physical meaning in a designer's mind. It will always be the source of numerous errors, especially if the computations are not performed as a matter of daily routine work. The introduction of unusual terms and definitions, such as S, e, ϵ, i, and R, which have no clear physical concepts, complicates the analysis unnecessarily, serves no particular purpose, and could be avoided. For example, if the frame in Fig. 12 were analyzed on the assumption that ends A_1 and E_1 were hinged, the necessary paper work would be limited to computations shown in Fig. 23, in which the author's basic Q-values have been replaced by the exact stiffnesses of the members as shown in Table 7.

TABLE 7.—EQUIVALENT S-VALUES, FRAME IN FIG. 12

Stiffness	A_1B_1	B_1B_0	B_1C_1	C_1C_0	C_1D_1	D_1D_0	D_1E_1
Q..........	0.198	0.304	0.172	0.304	0.172	0.304	0.198
S..........	15.15	....	17.46	....	17.46	9.87	15.15
S_p.........	....	13.16	....	13.16	....	....	....

Since the Cross method of analysis has been developed, it has been known that for members with fixed ends $S_p = 4\,I/L$ and for members with hinged ends $S = 3\,I/L$. Although Fig. 23 contains all characteristics that are recorded in Fig. 12, computation of the values shown in Table 1 is not necessary, and the procedure begins directly with step 6 of Section 10. The "moment split" m (the writer's "moment joint coefficient," J) for the members B_1A_1 and B_1B_0, respectively, will be

$$m_{ba} = \frac{S_p}{\Sigma S_p} = \frac{15.15}{15.15 + 13.16} = 0.535$$

$$m_{bb} = \frac{13.16}{28.31} = 0.465$$

$$\Sigma m_b = 1.000$$

The computations in step 7 would then be, by Eq. 68, $f = \frac{28.31}{28.31 + 17.46} = 0.620$; and $C_{1CB} = Z' = \frac{1}{2} f = 0.310$. In step 8 with $f = 0.620$ and the corresponding value[28] of $C' = 0.89$, the exact stiffness of the member B_1C_1 at joint C_1 is readily determined by the relation—

$$S_p = \frac{C'\,S}{C_d} \quad \text{.........................} (70)$$

—that is, $S_p = \frac{0.89 \times 17.46}{0.75} = 20.7$. In Eq. 70 the symbol C_d is a constant that can be read from design charts prepared by Thor Germundsson,[29] Assoc. M. Am. Soc. C. E. For a member of uniform section this constant is equal to 0.75. The value of S_p having been determined, the moment splits are computed thus: $m_{cb} = \frac{20.7}{20.7 + 13.16} = 0.611$; and $m_{cc} = \frac{13.16}{33.86} = 0.389$. The operations are repeated in this very simple and direct way until all characteristics are obtained.

---

[29] "Design of Continuous Frames Having Variable Moment of Inertia," by Thor Germundsson *Civil Engineering*, October, 1932, p. 647.

The torque splits, or "coefficients of unit moment," are also evaluated very simply and directly. For example, for joint B_1,

$$t_{ba} = \frac{S_p}{\Sigma S_p} = \frac{15.15}{15.15 + 13.16 + 20.9} = 0.308$$

$$t_{bb} = \frac{13.16}{49.21} = 0.268$$

$$t_{be} = \frac{20.9}{49.21} = 0.424$$

$$\Sigma t_b = 1.000$$

(b) COEFFICIENTS OF UNIT MOMENT

FIG. 24.—SOLUTION OF A RIGID FRAME

Other "coefficients of unit moment" or "torque splits" are found in a similar manner.

The writer objects strongly to the term "torque split" for the reason that, in a structural analysis, the word "torque" is associated with twisting action, causing primarily shear stresses in a member. Moreover, the design of structures often incorporates the analysis of noncoplanar members, in which a moment acting at the joint may be resisted partly by the bending of some members and partly by the twisting of the other members. The term "torque split" would apply more consistently to the analysis of a spandrel girder receiving a twisting moment when this moment is split in unequal amounts to two segments of the girder; but, for the sake of clearness as well as uniformity in engineering literature, it would be advisable to stay within the customary definitions of bending and twists.

To distribute a moment to a frame of the general type (that is, a frame with a sidesway and variable moment of inertia) in a single operation, it is necessary to determine "true frame characteristics" or "true moment coefficients." At the designer's discretion, there are several optional methods of computing the "true moment coefficients." The following discussion does not infer that it presents the only procedure available but, rather, that it offers the simplest and the most systematic treatment of the problem. The true moment coefficients due to a unit moment m_{BC} may be derived as follows:

TABLE 8.—COMPUTATION OF INFLUENCE ORDINATES

Moments	COEFFICIENTS OF UNIT MOMENT, FOR POSITIVE UNIT VALUES OF:						INFLUENCE ORDINATES FOR MOMENT[a]		
	m_{BC}	m_{CB}	m_{BC}	m_{CB}	m_{BC}	m_{CB}	$M_{Bf} = -2.18$	$M_{Cf} = 0.44$	Total (kip-ft)

[a] Ordinates of the influence line for moment (in kip-ft) caused by a unit load at the quarter points of beam BC.

1. Compute the torque split ("coefficients of unit moment") shown in Fig. 24;

2. Compute "beam coefficients" due to $m_{BC} = +1$ on the assumption that no sidesway exists and record them in Col. 2, Table 8 (this step is the equivalent of the author's procedure outlined in Section 13);

3. Find the horizontal reaction R_{mB} due to m_{BC}, which prevents the translation of the joints ($R_{mB} = -\frac{1}{6}(0.273 + 0.545 - 0.186 - 0.093 + 0.032 + 0.016 - 0.003 - 0.001) = -0.097$ kips);

4. Compute sidesway moments in the frame due to $H = 1$, as shown in Table 9;

5. Find "sidesway coefficients" due to $-R_{mB}$, and record them in Col. 4, Table 8; and

6. Find the "true moment coefficients" due to m_{BC} by adding the values of Cols. 2 and 4, and record them in Col. 6, Table 8.

TABLE 9.—Sidesway Moments Caused by Various Fixed-End Moments

Sidesway moments	$M_{AB} = 1$ and $M_{BA} = 1$	$M_{DC} = 3$ and $M_{CD} = 3$	$M_{FE} = 3$ and $M_{EF} = 3$	$M_{HG} = 1$ and $M_{GH} = 1$	$H = -1.793\ k$	$H = +1\ k$
M_{AB}	0.727	0.093	− 0.016	0.001	0.805	− 0.448
M_{BA}	0.455	0.186	− 0.033	0.003	0.611	− 0.341

The Germundsson charts were used for the computation of beam constants, or the elastic properties of members which are independent of the framed structure. These computations are shown in Table 10. Steps 1 and 2 are computed by slide rule.[30] Computations for step 4 are similar to those for step 2. The sidesway moments from any horizontal force applied at the top of columns are found first. These values are reduced to moments generated by the force $H = 1$, as shown in Table 9.

TABLE 10.—Computation of Beam Constants

Members	a	b	$Z = r$	C	$S = C_s\, I/L$ [a]
BC and EG	2.4/12 = 0.2	1/5.83 = 0.171	0.641	0.588	4.25/12 = 0.354
CE	3.6/18 = 0.2	2/17.55 = 0.114	0.664	0.56	4.48 × 2/18 = 0.498
AB and HG	....	....	0.5	0.75	4/6 = 0.667
DC and EF	....	....	0.5	0.75	4 × 3/6 = 2.0

[a] In this formula the symbol C_s is a constant that can be read from the design charts.[30]

Thus far the discussion has been limited strictly to the computation of the "true moment coefficients" due to $m_{BC} = +1$. True moment coefficients will be changed, of course, with the point of application of a unit moment, but for any new position, such as will be defined by the subscript of the unit moment m_{CB}, the additional work recorded in Cols. 3, 5, and 7, Table 8, is negligible. After the sixth step, it is possible to distribute a moment to the frame in a single operation. Nevertheless, because the derivation of these coefficients may be divided into two distinct operations—an analysis of a frame without sidesway and evaluation of sidesway corrections—it would be more correct to describe the analysis as moment distribution in two operations. Thus, for a two-story frame, there will be two sidesway corrections, and the analysis will require three distinct operations. A rigid frame with N sidesway forces will have N corrections and $N + 1$ distinct operations.

---

[30] *Transactions*, Am. Soc. C. E., Vol. 111 (1946), p. 430.

For practical purposes, contrary to the author's opinion, the writer still believes that the design of structures for moving loads is rendered much easier by influence lines than by any other method. This will be even more true of a structure that must be designed for various conditions of loading; but any important structure may be expected to have a set of design conditions. Even in a preliminary design of a continuous beam, the author's formulas could scarcely compete with the old fixed-end moment formulas, because, in the former, as a result of a series of abstract computations, the chances for mistakes are innumerable, and there is no way to "feel" the errors. However, in the latter the maximum limit of moments is given at once, and the values of the exact moments, depending on the end fixity, may be correctly estimated without the complete analysis. It will now be shown how simple moments due to a unit load placed, say, at the quarter point of beam BC may be determined. The fixed-end moments from this load will be: $M_{Bf} = - 0.182 \times 12 = - 2.18$ kip-ft; and $M_{Cf} = 0.037 \times 12 = 0.44$ kip-ft.

These moments multiplied by the values of Cols. 6 and 7, Table 8, will yield the products recorded in Cols. 8 and 9, respectively. Summation of Cols. 8 and 9 in Col. 10 gives the final distributed moments and, at the same time, the values of influence ordinates. If the computations of Cols. 8, 9, and 10 were repeated for a unit load placed at the center line and three-quarter point of the span, the complete values of the influence ordinates, for a load on beam BC, would be obtained. From a practical standpoint, these load positions were found to be entirely satisfactory for the accurate construction of influence lines. The writer, at least, has never had occasion to use more points than those suggested herein.

The definitions of "normal" and "reverse," as applied to bending moments, are definitely inferior to the brief and simple definition: "Clockwise moments are positive." The value of this simpler definition may be realized and appreciated to the greatest extent by one familiar with an analysis of frames in three dimensions, such as the twist analysis of a dam or the analysis of a structure on an elastic foundation. How difficult it would be to perform these analyses with the definitions proposed by the writer may be realized by consideration of the equation of joint equilibrium, which would be stated as follows: The summation of normal bending and clockwise twisting moments, minus reverse bending and counterclockwise twisting moments, plus or minus an externally applied couple at the joint, is equal to zero. In contrast to this phraseology is the simplicity of the commonly adopted statement of joint equilibrium, namely: "The summation of moments is equal to zero; clockwise moments are positive." Contrary to the author's opinion, the old definition of "clockwise moments are positive" fits the analysis of beams radiating in all directions exceptionally well—especially when many loading conditions must be investigated. The old definition fixes the sense of the bending moment in such a manner as to avoid confusion.

The author's statement (Section 13) that "One distribution also is sufficient for all purposes, including live-load and dead-load moment distribution, wind moments, and sidesway * * *" is not clear. Because the allowable unit stresses, as a rule, vary with the particular combination of loadings, a separate distribution should be made for each of the aforementioned loads.

Of incidental interest, but nonetheless important, is the question of nomenclature. Every new paper on this subject yields its own set of nomenclature and abbreviations. If writers would take full advantage of the commonly accepted symbols and restrict the introduction of new symbols to the absolute minimum, they would render the engineering profession a priceless service as well as facilitate the task of education. For example, there are only three really important structural concepts that need to be known for analysis of structures. They have been established previously and again are presented in this paper but, being differently derived, are given new definitions and symbols. Excluding foreign sources, the equivalent symbols for these concepts are known as follows: Transmission coefficient C equals carry-over factor f equals coefficient of unit moment Z'; torque split t equals distribution factor d equals coefficient of unit moment K; and moment split m equals joint moment coefficient J.

It is not clear why the span of a simple structure should be designated by three symbols such as 1BC, and why the same subscript should be needed to define the bending moment. In most structural analyses in two dimensions, two letters (or two subscripts in the case of a moment) are sufficient. If the first subscript were always selected to designate the location, the term M_{AB} would define the moment at point A in span (or member) AB. The same system would hold true for shear, angle, deflection, and twisting moment. In the case of an angle, two subscripts will be needed only when the efficiency of a joint is less than 100%. For isolated members, or for single spans, the second subscript, of course, would be omitted because the first subscript completely defines the location of the point. A similar system of lower-case letter subscripts could be adopted for the description of other properties of members. The selection of lower-case letters, although not absolutely necessary, would facilitate recognition of apparently equal terms, such as S_{AB} and S_{ab}, at a glance. The first term would refer to the shear and the second to the stiffness at point A of member AB. The transmission coefficient, or the exact carry-over factor with the subscript ab in the same system, would signify the exact moment at point A due to a unit moment at point B, which, evidently, would be contrary to the author's notation.

Sometimes a distinction may need to be made between hinged, fully fixed, or partly fixed, end conditions. In such cases the writer suggests the use of lower-case letters o, f, and p, respectively, for the third subscript. This appears to be a contradiction of the foregoing statement, but in reality it is not, because in the latter case three independent structures are being analyzed. Instead of verbal descriptions, a simple subscript is utilized for this distinction. For example, M_{ABf} would define the fixed-end moment at point A of member AB. Were one or both of the capital subscripts missing, M_f would still be recognized as a fixed-end moment. Not all the three subscripts o, f, or p would have to be retained in the same analysis; the predominating subscript might be omitted at the discretion of the designer.

For analyzing multistoried frames, with many members and joints, a grid pattern of numbering may be used to advantage. In this pattern, a joint is defined by the intersection of two lines and, therefore, one letter and one number will be needed for identification. The grid pattern of numbering will not be in conflict with the foregoing described system of abbreviations, if it is remembered that the first two subscripts define the point and the third subscript, the direction. For instance, M_{1BC} will define the moment at point 1B in the member BC.

Frederick S. Merritt,[31] Assoc. M. Am. Soc. C. E.—Inevitably, in practice, simplifications of theoretical solutions will occur to the designer. Such simplifications of Professor Brumfield's method, made by the writer as a result of experience with practical design problems, have been so numerous that only the basic assumptions have been untouched. For the present discussion Professor Brumfield's "transmission coefficients" may be compared with the writer's "moment ratios."[32]

The action of a beam in a continuous structure depends upon its shape and size relative to the remainder of the structure. Constants evaluating these relative shape and size characteristics may be selected and defined almost at will; but, of course, if they are to be of practical value, they should be few in number and sufficiently descriptive of the action of the member. For the purpose of this discussion, three fundamental constants—K, $m^F{}_R$, and $m^F{}_L$—will be used. Clockwise end moments and end rotations will be considered positive and counterclockwise moments and rotations negative.

Consider an unloaded member removed from a monolithic structure and simply supported instead. Then, K is the moment that must be applied at one end of this beam to produce unit rotation at the other end. Now, fix the right end of the member and apply a unit moment at the left end. For this condition, the moment that will be produced at the right, or fixed, end is $1/m^F{}_R$. Similarly, the carry-over ratio for a fixed end at the left is $1/m^F{}_L$. For beams of constant moment of inertia, $m^F{}_R = m^F{}_L = 2$ and $K = 6\,E\,I/L$.

The coefficients K and m^F are sufficient to describe the action of this member when it is once again returned to its position in the continuous structure. Stiffness s of the end of an unloaded beam in a monolithic structure is defined as the moment producing a rotation of unity at the end where it is applied, when the other end of the beam is restrained against rotation by other members of the structure. For an unloaded member of a continuous structure the moment ratio m is defined as the ratio of the moment introduced at one end of the span to the moment carried over, or transmitted, to the other end.

Then, the stiffness of the right end of a beam can be shown to be:

$$s_R = \frac{K}{m^F{}_R - \dfrac{1}{m_L}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (71a)$$

---

[31] Editorial Asst., *Engineering News-Record*, New York, N. Y.

[32] "Moment Ratios Simplify Continuity Analysis," by Frederick S. Merritt, *Engineering News-Record*, November 1, 1945, p. 112 and November 15, 1945, p. 102.

Similarly, the stiffness of the left end is:

$$s_L = \frac{K}{m^F{}_L - \dfrac{1}{m_R}} \quad \text{(71}b\text{)}$$

For beams of constant moment of inertia:

$$s_R = \frac{K}{2 - \dfrac{1}{m_L}} \quad \text{(72}a\text{)}$$

and

$$s_L = \frac{K}{2 - \dfrac{1}{m_R}} \quad \text{(72}b\text{)}$$

Eqs. 71 and 72 should be compared with Professor Brumfield's stiffness index formulas (Eqs. 3).

The restraint r at the end of an unloaded beam at a joint is defined as the moment applied at that end to produce a unit rotation in all the members of the joint.

Since, by definition of continuity, the end rotations of all the members of a joint are equal, restraint of the member under consideration is equal to the sum of the stiffnesses of the adjacent ends of the other members of the joint. Furthermore, the moment induced in any of these other members bears the same ratio to the applied moment as the stiffness of the member does to the restraint. Consequently, end moments are distributed at a joint in proportion to the stiffnesses of the members. These relationships should be compared with Professor Brumfield's restraint index formulas, moment splits, torque splits, and technique of distribution (Eqs. 9, 39, 40, and 41).

Moment ratios can be computed in terms of K and, through r, the moment ratios of preceding spans. It can be shown that:

$$m_R = m^F{}_R + \frac{K}{r_R} \quad \text{(73}a\text{)}$$

and

$$m_L = m^F{}_L + \frac{K}{r_L} \quad \text{(73}b\text{)}$$

For beams of constant moment of inertia,

$$m_R = 2 + \frac{K}{r_R} \quad \text{(74}a\text{)}$$

and

$$m_L = 2 + \frac{K}{r_L} \quad \text{(74}b\text{)}$$

These formulas should be compared with Professor Brumfield's formulas for transmission coefficients (Eq. 5).

End moment formulas may be given in terms of moment ratios as follows:

$$M_R = -\frac{K\,(m_L\,\phi_R + \phi_L)}{m_R\,m_L - 1} \quad \text{(75}a\text{)}$$

and

$$M_L = -\frac{K\,(m_R\,\phi_L + \phi_R)}{m_R\,m_L - 1};\ldots\ldots\ldots\ldots\ldots\ldots(75b)$$

in which ϕ is the end rotation under load considering the member as simply supported. Fixed-end moments may be obtained by setting the moment ratios in Eqs. 75 equal to $m^F{}_R$ and $m^F{}_L$, respectively. These formulas, also, should be compared with the corresponding ones given in the author's paper (Eqs. 14 and 27).

When the suggested comparisons are made, it may be seen that in several of the formulas the use of moment ratios decreases the number of arithmetical steps involved, particularly for the cases of variable moment of inertia. There is no arithmetical advantage in using transmission coefficients, which are reciprocals of moment ratios, since multiplication is as easy as division. Similarly, computation of stiffness as the ratio of two factors involves no more steps than that of stiffness index, which is the product of two factors. However, calculation of restraint as the sum of stiffnesses is considerably easier than that of restraint index as the reciprocal of the sum of reciprocals of stiffness indexes. Furthermore, there is a considerable advantage in moment distribution in using K, s, and r, instead of Q, i, and R, respectively, because the former bear direct relationships to the properties of the structure, the latter reciprocal. Thus, much work may be saved and a better visualization of structural action obtained by changing the reciprocal terms used by Professor Brumfield to direct ones.[32]

Alfred B. Heiser,[33] M. Am. Soc. C. E.—For a number of years the writer has searched among the indeterminate stress theories such as the Cross method and the method of fixed points to find a quick and comparatively easy method for computing indeterminate stresses; but disappointment seemed to result from these excursions until he encountered Professor Brumfield's theory as described in the present paper. Few, if any, of the theories make it possible to place loads definitely in order to obtain the maximum moments or shears either at the supports or at intermediate points in the span. It is also very difficult to decide by these theories just which spans must be loaded to obtain the maximum results. Professor Brumfield's paper fills this need. His method permits the effects at any point of a load or group of loads to be summed up, readily, at any other point throughout the entire structure however complicated the structure or grouping of loads may be.

Does this seem impossible? Not if one peruses the full theory developed by Professor Brumfield since his system has been developed to cover wind stresses, sidesway, beams of any type and shape, arches, and, best of all, structures having spans that are noncoplanar.[3] He has conquered stress analysis through three-dimensional space. The writer has personally checked many of the formulas for this advance theory and has found that, although they are complicated, they are workable.

In all cases, these formulas cover the general as well as the special cases. As the span member or load conditions are simplified, the equations are reduced to forms familiar to all—that is, the formulas used in ordinary beam design.

---

[33] Chf. Draftsman, Am. Can Co., New York, N. Y.

T. B. Rights,[34] Assoc. M. Am. Soc. C. E.—This method is not new or untried. The Cooper Union, in New York, N. Y., has offered this course for graduate credit, since 1938. Professor Brumfield filed his paper, "Moving Loads on Beams with Restrained Ends," in the Engineering Societies Library in 1937. The task of placing a moving load for maximum moment at any point on a restrained beam is quite difficult by older methods. In the Hardy Cross method,[2] it meant that unit loads must be placed successively across the beam and their influence calculated, which is quite time consuming. By the use of Anger's tables,[35] it is comparatively simple to select positions for maximum moment. These tables are for uniform cross sections, however, and any haunching would affect the results. Values for the usual range of span lengths in two, three, and four spans are given, but any unusual span ratios would prevent the use of these tables. Furthermore, these tables, having been printed in Germany, are not available in the United States. The tables by Walter Ruppel, Assoc. M. Am. Soc. C. E., should also be mentioned.[36]

It would be interesting if the author would show how his method, applied to tall building frames, gives a fast and accurate solution to this difficult problem.

Once this method is mastered, it will be found to be a quick solution for most indeterminate stress analyses. The writer can set up a three-span or a four-span problem faster by the Cross method; but, for any problems of involved conditions, the Brumfield method is faster because the moment at the joint is only "transmitted once." For moving loads on a continuous span, this method is a "must."

Phil M. Ferguson,[37] M. Am. Soc. C. E.—In so far as the writer knows, this paper is the first presentation in English of an analytical method for locating moving loads so as to cause maximum moment. That the criteria developed are not simple does not in any way detract from the definite advance in thought that this method represents. The key to this advance lies in certain advantages inherent in designating the location of wheels in a load system in terms of distances from the resultant of the system, or, as the author states, from the center of gravity. The writer regards this as a development of considerable importance, even if it is, as now presented, limited strictly to beams of uniform section.

The use of Professor Brumfield's criteria does not require adoption of the author's general procedure for frame analysis. The criteria (Eqs. 29, 32, 33, 34, and 35) involve loading constants and the so-called transmission factors C_L and C_R. Only C_L and C_R involve the author's method of frame analysis. However, these transmission factors are identical with the "modified carry-over factors" introduced by T. Y. Lin,[38] Jun. Am. Soc. C. E., and, of course, are related to the fixed points that are usually determined graphically. Hence, the methods are also available in connection with the loading criteria.

[36] *Transactions*, Vol. 90 (1927), p. 167.

[37] Chairman, Civ. Eng., Univ. of Texas, Austin, Tex.

[38] "A Direct Method of Moment Distribution," by T. Y. Lin, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 561.

The development of the criteria for the position of loads might not have resulted from any other approach to frame analysis than that of the author. Nevertheless, the writer considers this particular approach to the direct method of moment distribution definitely inferior to the Lin method in several respects and would urge that the author's excellent ideas be used for moving loads applying either the Brumfield or the Lin idea of the direct method of moment distribution (basically the same method) and that the author's method of calculating the frame constants be discarded entirely.

The writer has three basic criticisms of the author's method of frame analysis:

1. A new vocabulary of specialized terms is required, most of which are not essential to this type of analysis and the remainder of which could be clarified by correlation with the basic Cross nomenclature;
2. As given, the method is not directly applicable to members of variable section, and such adaptation would seem to require extensive alterations; and
3. The method abandons the principle that has been most productive in American methods of frame analysis—namely, the use of fixed-end moments for the initial step.

In addition, the writer feels that the system of subscripts used by the author is nonspecific enough to create unnecessary difficulty for the student of this method.

The author prefaces his paper (see heading, "1. Definitions and the Nomenclature of Unusual Terms") with the statement:

> "Inherent in the usefulness of the paper * * * are certain symbolisms peculiar to the method itself, and the nomenclature needs to be understood clearly to grasp the full import of the paper."

This nomenclature is an unnecessary handicap because it is truly an entirely new vocabulary. Several symbols represent concepts applicable only to this method. A new symbol Q is even introduced to designate the reciprocal of the stiffness K—apparently only because it looks simpler to write Q than to write $\frac{1}{K}$ or $\frac{L}{I}$. In contrast, Mr. Lin has presented an equivalent method of distributing moments to a frame in a single operation utilizing only one new symbol and two "modified" terms—modified stiffness and modified carry-over factor—both closely related to the original moment distribution terms developed by Hardy Cross,[2] M. Am. Soc. C. E. Since it may be presumed that American engineers will first know something of Professor Cross' basic method, notation related to it will always be preferable in introducing new ideas in moment distribution. Not only does Mr. Lin's[38] method involve simpler notation, but it is applicable, without modification, to members of variable sections.

In addition to a new terminology, the author introduces a notation difficult to follow in that subscripts are not self-explanatory and are not uniform. For example, the rather definite form of subscript used in C_{AB} (Eqs. 3*a* and 3*b*) is dropped in favor of the indefinite form C_1 and C_2 for other members, and becomes C_L and C_R in connection with moments in loaded beams. There are no subscripts to identify the particular R to be used in Eqs. 5 and 8. With such uncertain notation it is difficult to picture the author's process properly as it is gradually developed. As a result, close study of Sections 10 and 13, near the end of the paper, is required to clarify Section 2.

Mr. Lin develops essentially the same method of moment distribution from short proofs based upon the original moment distribution process. The frame-constant equations in the Lin method are stated for comparison as follows:

K_{ab} is the relative stiffness of member AB (Fig. 25) based upon rotation of end A when end B is fixed. When the member has uniform section K_{ab} equals I/L.

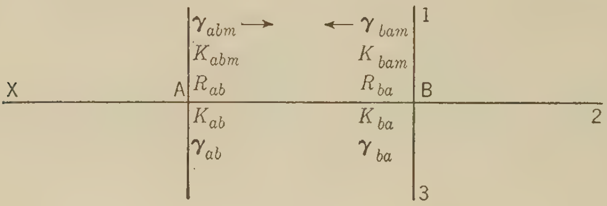

FIG. 25

K_{abm} is the modified relative stiffness of member AB based upon rotation of end A when end B is considered restrained only by the remainder of the frame.

γ_{ab} is the carry-over factor from end A to end B when end B is fixed (0.5 when beam has uniform section).

γ_{abm} is the modified carry-over factor when end B is considered restrained only by the remainder of the frame. Factor γ_{abm} is identical with the author's C_{AB}.

R is a ratio defined by the expression:[39]

$$R_{ba} = \frac{K_{ba} + K_{b1m} + K_{b2m} + K_{b3m}}{K_{ba}} \qquad (76)$$

R_{ba} is infinite if end B is fixed, and is unity if end B is pinned.

Mr. Lin derives the following relations:

$$K_{abm} = K_{ab}\left(1 - \frac{\gamma_{ab}\,\gamma_{ba}}{R_{ba}}\right) = K_{ab}\left(\frac{R_{ba} - \gamma_{ab}\,\gamma_{ba}}{R_{ba}}\right) \qquad (77a)$$

and

$$\gamma_{abm} = \gamma_{ab}\left(\frac{R_{ba} - 1}{R_{ba} - \gamma_{ab}\,\gamma_{ba}}\right) \qquad (77b)$$

For members of constant section, $\gamma_{ab} = \gamma_{ba} = 0.5$, and these equations become simply:

---

[39] "A Direct Method of Moment Distribution," by T. Y. Lin, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), Eq. 1, p. 562.

$$K_{abm} = K_{ab}\left(\frac{R_{ba} - 0.25}{R_{ba}}\right); \dots\dots\dots\dots\dots\dots (78a)$$

and

$$\gamma_{abm} = 0.5\left(\frac{R_{ba} - 1}{R_{ba} - 0.25}\right) \dots\dots\dots\dots\dots\dots (78b)$$

The quantities in parentheses in Eq. 78*a* and Eq. 78*b* are susceptible to simple tabulation for various values of R, but the equations are also simple to use with the slide rule. It should be noted that R in Mr. Lin's paper is not the same as that in the Brumfield paper, but is to be evaluated from Eq. 76.

Since R_{ba} at a fixed end B is infinity and at a pinned end B is unity (and at other terminals can be estimated), it is easy to use Eqs. 78 or Eqs. 77 to find K_{abm} and γ_{abm} at the opposite or inside end of any terminal member. The resulting value of K_{abm} and similar modified stiffness values of other terminal members meeting at joint A can then be used in Eq. 76 to find R_{ax} in the next interior member AX; and R_{ax} is used in turn to find the modified stiffness carry-over factor at end X of member AX. It must be kept in mind that the sequence of subscripts used with carry-over factors indicates the direction in which the carry-over moment is being transmitted—that is, γ_{ab} or γ_{abm} indicates that the direction is from end A to end B.

FIG. 26

To illustrate the sequence of these frame-constant calculations, the Lin constants for the frame in Table 1 of the Brumfield paper are developed in Fig. 26. The arrows indicate the sequence of calculations, not the direction of carry-over factors. Some constants not needed by the author's problem are omitted, but are indicated by dotted lines. Since the constants are tabulated with the same arrangement at each joint, no table is needed. Each constant is tabulated at the joint corresponding to its first subscript letter—that is, K_{ab} is tabulated at joint A. The K-values for beams of uniform stiffness are I/L-

ratios and are the reciprocals of the author's Q-values. Except to maintain a form suitable for variable sections, there is no need to tabulate, separately, K_{ab} and K_{ba} or γ_{ab} and γ_{ba}. For members of variable section, the unmodified K-values and γ-values would be calculated for fixed ends, exactly as in the basic moment-distribution method, and then used in Eqs. 77. No modification of the Lin method is needed for these members of variable section.

The Lin modified carry-over factor γ_{abm} can be substituted directly for its equivalent C_R in the author's criteria for the location of loads; and likewise γ_{bam} can be substituted for C_L. Fixed-end moments for the critical position of loading can then be calculated and used with the regular Lin method. This method begins with the equivalent of the author's torque split applied to fixed-end moments. The Lin method proceeds to calculate the numerical terms that would make up the restraining moments used by the author, but Mr. Lin does not segregate and label these as such.

It is also possible to calculate the restraining moments from formulas and thus eliminate the first steps of the Lin method. This would agree with the author's procedure. To develop such formulas, the moment-distribution method (Fig. 27) can be used. Let M_F represent the fixed-end moment. The distribution factor or torque split for this moment at joint A is

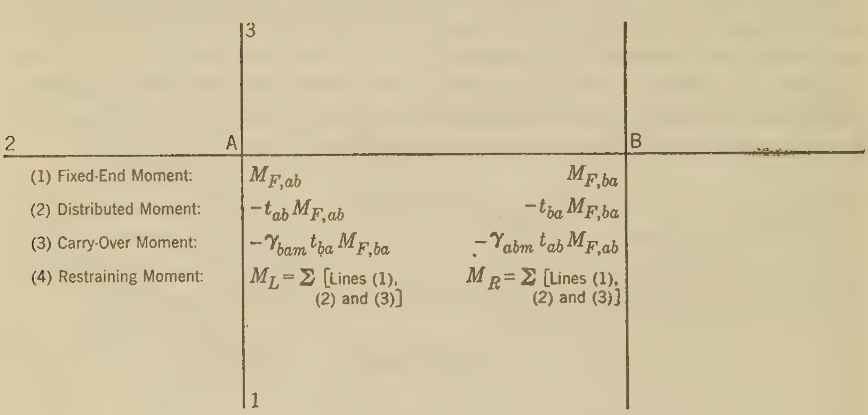

FIG. 27

$$t_{ab} = \frac{K_{abm}}{\Sigma K_{anm}} \quad \text{.........................(79)}$$

in which ΣK_{anm} represents the summation of modified stiffness for all members meeting at joint A. The distribution and carry-over terms in Fig. 27 can be written into formulas for M_L and M_R:

$$\begin{aligned} M_L &= M_{F,ab} - t_{ab}\, M_{F,ab} - \gamma_{bam}\, t_{ba}\, M_{F,ba} \\ &= M_{F,ab}\,(1 - t_{ab}) - M_{F,ba}\,\gamma_{bam}\, t_{ba} \quad \text{..............(80a)} \end{aligned}$$

and

$$\begin{aligned} M_R &= M_{F,ba} - t_{ba}\, M_{F,ba} - \gamma_{abm}\, t_{ab}\, M_{F,ab} \\ &= M_{F,ba}\,(1 - t_{ba}) - M_{F,ab}\,\gamma_{abm}\, t_{ab} \quad \text{..............(80b)} \end{aligned}$$

In the Lin method, in the first distribution and carry-over step, this operation is performed by simple arithmetic rather than by algebra. Thereafter, there is no difference whatever between the Lin and the Brumfield procedures. Mr. Lin calculates the moment split to member A1 (without naming it) as $\frac{K_{a1m}}{\Sigma K_{am}}$ in which ΣK_{am} includes the modified stiffness of all members meeting at joint A except that of member AB, the member from which the moment originates.

Even if one does not accept the writer's thesis that a method more closely related to the basic moment distribution method, and already adapted to members of variable section, is preferable to the author's method, Eqs. 80 are still worthy of consideration. They are preferable to Eqs. 14, 16, and 17, because they permit the use of existing tables for M_F. For those who follow the author's method, C would be substituted for γ_m, as noted previously. The author's modified end-moment formulas written directly in terms of k seem necessary to develop criteria for placing loads, but seem unnecessarily complex for other purposes.

In conclusion, the writer again wishes to state that the treatment of moving loads in this paper is a most worthy one. Those who may have difficulty with the background method upon which it is based should be attracted by the relatively simple concepts of Mr. Lin's approach to the necessary frame constants. The Lin concepts are closely correlated with those used in the Cross method. The actual work involved in applying either the Brumfield method or the Lin method is not greatly different, but such difference as exists seems slightly in favor of the Lin procedure in that Mr. Lin does not use reciprocals of constants.

LEON BESKIN,[40] ASSOC. M. AM. SOC. C. E.—It is customary to make a distinction between "classical" and "modern" methods of solving statically indeterminate structures. The writer has attempted a comparison of these methods in a previous discussion,[41] and he feels that undue emphasis has been placed on "modern" methods. For this reason, it was especially gratifying to read Professor Brumfield's description of a "classical" method that had been developed for the special case of continuous beams and later was extended to frames. Regrettably, however, Professor Brumfield has omitted references to many of his predecessors—thus tending to obscure his personal contribution to the subject.

The concept of a transmission factor (also called nodal ratio, intercept ratio, or carry-over factor) was developed fully by O. Mohr and by Maurice Lévy [42] for continuous beams and by more recent authors, some of them previously indicated by the writer,[41] for frames. Formulas similar to Eqs. 5 and 43*a* can be found in these references—all defining relationships between transmission factors in adjacent spans. Eqs. 14, 16, and 17, defining moments at the supports of a continuous beam under the action of loads placed on a span with the abscissa corresponding to the maximum support moment, seem to have been first established by Weyrauch and by Mr. Lévy.[43]

---

[40] Design Specialist, Consolidated Vultee Aircraft Corp., Vultee Field, Calif.

[41] *Transactions*, Am. Soc. C. E., Vol. 111 (1945), p. 416.

[42] "La Statique Graphique, et Ses Applications aux Constructions," by Maurice Lévy, Gauthier-Villars & Co., Paris, France, 2d Ed., Vol. 2, 1886

Professor Brumfield extends the formula defining the abscissa corresponding to the maximum support moment to combination loads, which leads to the introduction of concepts of radius of dissymmetry, span-distribution ratio, and dissymmetry-span ratio. These results represent a definite contribution to the theory of continuous beams and frameworks; they can be generalized and could be applied as well to the case of distributed loads or to combinations of concentrated and distributed loads.

However, their practical value appears somewhat limited, because great care should be exercised when applying the formulas established by the author because they seldom define true maxima. Consider, for instance, the simple case of two concentrated loads. Depending on the ratio of distance to length of the span, the maximum moment on a support may be obtained either when the two loads are on the same span or when they are on the two sides of a support. Professor Brumfield's formulas are valid only in the first case, and the restriction is extremely inconvenient because no criterion is given to determine when the formulas are not valid. This important limitation is not mentioned by the author. In the special case of two equal loads, placed on a continuous beam with spans of equal stiffness ("*K*-value"), the author's formulas are valid only if $a_1 = a_2 < 0.37$ (see Fig. 4).

Another limitation results from the fact that, in general, diagrams for several loads are longer than the length of one span. Professor Brumfield's method cannot be applied in this case, since the effects of loads acting on one span only are considered. In addition, the method may be misleading even if the loading diagram is shorter than the span, because it may lead to such a location of the diagram that some of the loads are in the adjacent span. In this case, the formula gives an analytical maximum that has no physical significance.

Thus, contrary to the statement, "Eqs. 29 apply to all kinds of loads, with the exception of a pure couple," Professor Brumfield's method seems to have a very limited field of application. The writer feels that the method applies principally to the design of girders for overhead cranes, because the loads are generally distributed on a short length (small a-constants). For this case, however, very complete tables are available, which make any general method superfluous.

BRUCE JAMEYSON,[44] ASSOC. M. AM. SOC. C.E.—The paper dealing with a method of solution for continuous rigid frames composed of prismatic members and with criteria for moving loads is of academic value only because (1) the usual case of moving loads occurs in bridge design and involves frames composed of nonprismatic and often unsymmetrical members; (2) the paper does not fully include the effect of broken loads on adjacent and other spans; (3) the author's method already seems complicated and would become unduly so if modified to apply to frames composed of nonprismatic members; and (4) better and more general methods of approach to the problem are available.

---

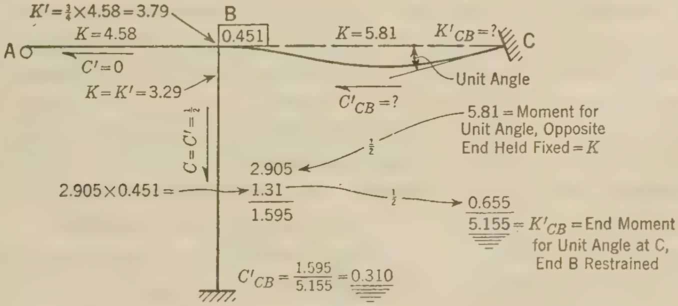
[43] "La Statique Graphique, et Ses Applications aux Constructions," by Maurice Lévy, Gauthier-Villars & Co., Paris, France, 2d Ed., Vol. 2, 1886, pp. 187 and 282.

[44] Prof., Civ. Eng., Univ. of California, Berkeley, Calif.

The writer considers one-cycle moment distribution, the method advanced by T. Y. Lin,[38] Jun. Am. Soc. C. E., more general and superior to any other method yet proposed, for this particular case of one-story rigid continuous frames carrying moving loads. In fact, a considerable part of the author's procedure is very similar to the Lin method—that is, his "transmission coefficients" and his "methods for distributing the moment to the frame in a single operation." The author has taken the difficult way to develop and explain this procedure. Since the loads may be broken loads, influence lines are necessary if high accuracy is expected.

The author's "transmission coefficient," "moment split," and "torque split" ("frame characteristics") are not new but are simply carry-over factors and joint distribution factors of moment distribution for the general case of any end condition of members. It would have been better to have used this latter nomenclature since it is in general use. For the same reason, the well-known stiffness-factor symbol K should have been used rather than the reciprocal, the author's Q-value. Moment distribution becomes a more powerful tool if these terms, carry-over factors (C'), stiffness factors (K'), and distribution factors, are considered as modified factors applying to members with end conditions as they exist in the structure—that is, with fixed, restrained, or free ends. Formulas and diagrams have appeared in recent literature[8,38,46] for these modified factors and have been used for some years in bridge design in conjunction with one-cycle balance of moment distribution.[38]

In addition to the final one-cycle balancing by moment distribution, the writer prefers to obtain the foregoing modified factors by moment distribution rather than by formulas or diagrams regardless of whether or not the frame is composed of prismatic members. The method is probably faster. Fig. 28 indicates this procedure and is self-explanatory to any one familiar with moment distribution. The modified carry-over factor ($C' = 0.310$) checks the author's value of the "transmission coefficient" in Table 1. Continuing



$K' = \frac{3}{4} \times 4.58 = 3.79$
B
$K = 4.58$
0.451
$K = 5.81$
$K'_{CB} = ?$
C
A
$C' = 0$
Unit Angle
$K = K' = 3.29$
$C'_{CB} = ?$
5.81 = Moment for Unit Angle, Opposite End Held Fixed = K
$C = C' = \frac{1}{2}$
$\frac{1}{2}$
2.905
$2.905 \times 0.451 =$
1.31
$\frac{1}{2}$
0.655
1.595
5.155 = K'_{CB} = End Moment for Unit Angle at C, End B Restrained
$C'_{CB} = \frac{1.595}{5.155} = 0.310$

[46] "Theory of Modern Steel Structures," by L. E. Grinter, The Macmillan Co., New York, N. Y., Vol. 2, 1936–1937, p. 192.

to the right and then proceeding back to the left in a similar manner, all values of C' and K' are found for the actual end conditions of the members in the structure. Distribution values follow from the K'-values. The distribution constants are better shown in a diagram than in a table, as the author has done, since more than one set may be required at a joint. For example, at joint B four sets are obtained, one set for each possible combination of members. These are shown for joint B in Fig. 29 and can be identified for use at a glance

Any one fixed-end moment is now balanced in one cycle throughout the structure using the modified carry-over factors (C') and distribution factors. One precaution must be taken—a fixed-end moment is balanced into all members at a joint whereas a moment carried over is the final correct end moment. This final moment must remain unchanged and therefore is balanced into only the remaining members at the joint, which explains why different sets of distribution factors are obtained for each joint. Some of these sets may never be used, however, depending upon the loading and where the fixed-end moments originate.

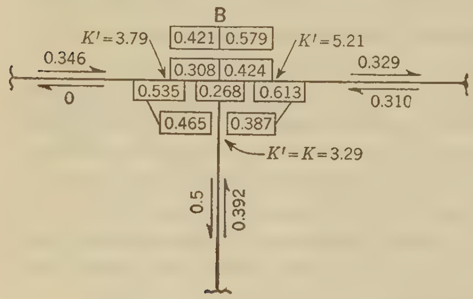

Fig. 29

Should the structure be composed of nonprismatic members, the K-values and C-values, for fixed ends and for most types and shapes of members used in practice, can readily be obtained from excellent tables or diagrams well known to structural engineers. Using these values the modified values are obtained in the simple, quick, and understandable manner outlined herein. The fixed-end moments are also taken from these tables or diagrams. One-cycle moment distribution then yields final end moments. Sidesway corrections, if necessary, follow. Influence lines may then be computed and plotted. This method is exceedingly rapid since the modified carry-over factors, stiffness values, and the distribution factors are independent of the loading and remain unchanged. This method is as "exact" as any other.

A clear knowledge of the fundamental definition of "stiffness factor" and "carry-over factor" as applied to any end condition is really all that is needed for an understanding of this method. In moment distribution the stiffness factor should never be defined as I/L even for a prismatic member.

The author's statement that moment distribution "can be shown to be a special case" of his method is not supported by his explanation of only a part of the moment-distribution concept. The Cross method of moment distribution is based upon fundamental concepts, independent of other methods; is more general than the Brumfield method which is involved with criteria, and, in its broader application, is a powerful tool of analysis. When the subject matter pertaining to criteria is separated from the Brumfield procedure, there remains the valuable part of this article—that part which is very similiar to the method of direct moment distribution.[38]

CHARLES W. DOHN,[46] JUN. AM. SOC. C. E.—The art of designing statically indeterminate structures, including the determination of maximum moments caused by concentrated loading groups on continuous frame structures, has been advanced materially by the publication of this paper. Although a new method may simplify the design of a great number of statically indeterminate structures, there is always some resistance to its adoption, particularly if it is not widely recorded, discussed, and understood. Design agencies that could use such a method are limited by their respective authorities, usually governmental, to widely published and accessible methods which have been accepted and applied, more or less, as office standards. In one instance, known to the writer—which involved bridge cranes operating on rigid-frame bents with haunched beams, and with a trussed jib that had a variable-section upper chord—the Brumfield method of transmission coefficients[4] was rejected in favor of the Cross method of successive approximations (moment distribution)[2] because: (1) Time would not permit teaching, organizing, and instituting a new method; and (2) the clients wanted the design made by a widely known method that could be accepted quickly, and could be checked and approved in successive steps by a number of other engineers, at different times and places.

When many designs and detailed investigations of the statically indeterminate type must be made for a great many different loadings and loading conditions, the method of transmission coefficients holds some advantages over those of conventional moment distribution. The busy design office handling a multitude of such investigations cannot afford to ignore its advantages. On the other hand, a design agent or office, which handles only a limited number of statically indeterminate investigations and designs, may well prefer the conventional moment-distribution method.

Computations can be expedited using transmission coefficients in conjunction with computing devices to determine frame characteristics, and to distribute moments, according to the procedure developed by Professor Brumfield. His method is well-adapted to machine computation, and the mechanics of calculation could thus easily be done by a group of computers working under the supervision of a design engineer. The speed of applying the method to any particular design could be increased greatly merely by employing more computers and machines. Furthermore, the method tends to relieve the design engineer of the arduous tasks involved in changes in design and loadings; and it allows him more time and inducement to change the design to a more efficient one, whatever the purpose. The value of the method in redesigns and investigations will also be apparent.

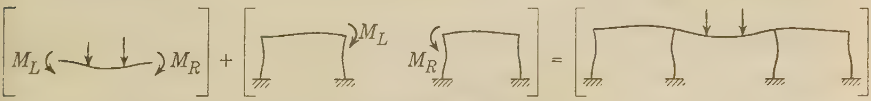

FIG. 30.—OUTLINE OF THE BRUMFIELD METHOD OF ANALYSIS

In the method of transmission coefficients, the only artificially restrained joints are those at the ends of the loaded span and these are only partly locked or restrained. At the beginning (see Fig. 30) the condition can best be pictured as that of a loaded span removed from the structure, with artificial restraint applied at each end of an amount equal to that which would have existed had the loaded span not been removed from the structure. Equal and opposite artificial restraints are then applied to the structure at joints corresponding to the application of the artificial restraints at the ends of the loaded span. The loaded span is then inserted in the structure and the analysis is complete. The method is "exact" and will give the same result as other accepted methods.

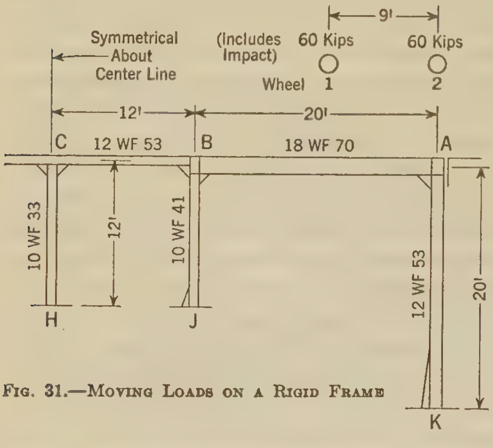

FIG. 31.—MOVING LOADS ON A RIGID FRAME

Moving Loads on a Rigid Frame.—To support a fair appraisal of the method of transmission coefficients, the writer presents, herewith, the solution of a frame with moving loads (Fig. 31). The problem is treated by the Brumfield method and, for comparison, by the Cross method of moment distribution.

By Moment Distribution.—The formal distribution of unit, fixed-end moments at joints A and B, Fig. 31, is presented in Table 11. By a similar procedure, unit ordinates are computed (for the construction of influence lines) of 1-kip loads placed successively at each fifth-point beginning at end A.

Table 12 contains a summary of the results, for negative moment, as applied to beam AB, Fig. 31. The maximum negative moment M_A (see Fig. 32(*a*)) equals $-0.81 \times 60 - 0.70 \times 60 = -90.6$ ft-kips. Similarly (see Fig. 32(*b*)), the maximum negative moment M_B equals $-1.46 \times 60 - 1.40 \times 60 = -171.6$ ft-kips. The final step is the preparation of influence lines for positive moment, from data in Tables 11 and 12. For successive positions of wheel 1 the positive moments (see Fig. 32(*c*)) are:

Fifth-point	Computation	Ft-kip
0.2 L	$\frac{1}{20} \times 60 \times 16 \times 4 - \frac{4}{20} \times 0.82 \times 60 - \frac{16}{20} \times 0.81 \times 60$	143
0.4 L	$\frac{1}{20} \times 60 \times 12 \times 8 - \frac{8}{20} \times 1.55 \times 60 - \frac{12}{20} \times 1.01 \times 60$	215
0.6 L	$\frac{1}{20} \times 60 \times 12 \times 8 + \frac{8}{17} \times \frac{1}{20} \times 60 \times 17 \times 3 - \frac{12}{20} \times 60\,(0.62 + 1.86) - \frac{8}{20} \times 60\,(0.66 + 0.79)$	236
0.8 L	$\frac{1}{20} \times 60 \times 4 \times 16 + \frac{4}{13} \times \frac{1}{20} \times 60 \times 13 \times 7 - \frac{16}{20} \times 60\,(1.46 + 1.40) - \frac{4}{20} \times 60\,(0.39 + 1.02)$	122

The maximum ordinate (Fig. 32(*c*)) is 239 ft-kips. Similarly, for successive positions of wheel 2, the positive moments are:

Fifth-point	Computation	Ft-kips
0.2 L	$\frac{1}{20} \times 60 \times 16 \times 4 + \frac{4}{13} \times \frac{1}{20} \times 60 \times 7 \times 13 - \frac{4}{20} \times 60\,(0.82 + 1.83) - \frac{16}{20} \times 60\,(0.81 + 0.70)$	172
0.4 L	$\frac{1}{20} \times 60 \times 12 \times 8 + \frac{8}{17} \times \frac{1}{20} \times 60 \times 3 \times 17 - \frac{8}{20} \times 60\,(1.55 + 1.20) - \frac{12}{20} \times 60\,(1.02 + 0.28)$	247
0.6 L	$\frac{1}{20} \times 60 \times 8 \times 12 - \frac{12}{20} \times 1.86 \times 60 - \frac{8}{20} \times 0.79 \times 60$	202
0.8 L	$\frac{1}{20} \times 60 \times 4 \times 16 - \frac{16}{20} \times 1.46 \times 60 - \frac{4}{20} \times 0.39 \times 60$	117

The maximum ordinate in this case (Fig. 32(*d*)) is 248 ft-kips, when load 2 is at a distance of 10.74 ft from joint B.

By Transmission Coefficients.—The computation of frame characteristics is presented in Table 13. The next step is to compute the maximum negative moments at the supports in span AB (Fig. 33) caused by the moving loads. By Eq. 28, $A_R = \frac{0.165}{1 - 0.165 \times 0.268} = 0.173$; and, similarly, $A_L = \frac{0.268}{0.956}$

TABLE 12.—UNIT MOVING LOADS ON MEMBER AB, FIG. 31; SUMMARY OF COMBINED UNIT MOMENTS

Description	1-KIP LOAD AT THE FOLLOWING POINTS (FROM END A):									
	0.8 L		0.6 L		0.5 L		0.4 L		0.2 L	
	M_B	M_A	M_B	M_A	M_B	M_A	M_B	M_A	M_B	M_A
Fixed-end moment, unit moving load...	2.56	0.64	2.87	1.92	2.50	2.50	1.92	2.87	0.64	2.56
Distributed unit load combined with:										
Rotation effect, end A[a].........	0.12	0.19	0.36	0.57	0.47	0.75	0.55	0.86	0.49	0.76
Rotation effect, end B[a].........	1.34	0.20	1.50	0.22	1.31	0.19	1.00	0.15	0.33	0.05
Combined unit moment, moving load and end rotation..................	1.46	0.39	1.86	0.79	1.78	0.94	1.55	1.01	0.82	0.81

[a] From Table 11, 1 kip at end A yields $M_A = -0.298$ and $M_B = -0.190$; and 1 kip at end B yields $M_A = -0.078$ and $M_B = -0.521$.

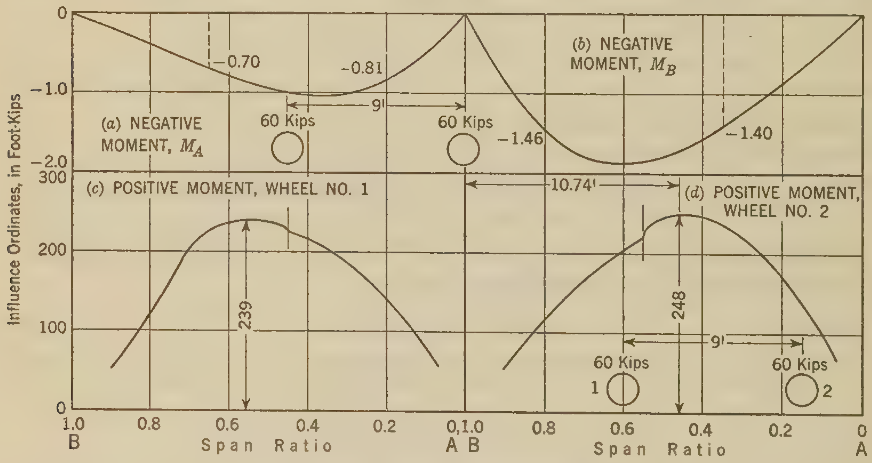

FIG. 32.—INFLUENCE LINES FOR MAXIMUM MOMENTS

TABLE 13.—BRUMFIELD METHOD OF COMPUTING FRAME CHARACTERISTICS

$$Q = \frac{L}{I}; \quad R = \frac{i^2}{1 - i^2/i^3}; \quad C = \frac{1}{2 + R/Q}; \quad m = \frac{R}{i}; \quad t = \frac{1}{1 + i/R}$$

BC	0.337 (2 − 0.319)	0.568	0.275	0.355	CB	0.633	0.407	CB	0.328
Joint C:									
CB	0.337 (2 − 0.355)	0.556	0.382	0.319	BC	BC	0.50	0.69	..
CH	0.842 (2 − 0.5)	1.263	0.273	0.430	HC	0.31	HC	0.31	..
CD = CB	0.337 (2 − 0.355)	0.556	0.382	0.319	DC = BC	0.69	0.50	DC	..

= 0.282. The span distribution ratio $\lambda = \frac{r}{L} = \frac{4.5}{20} = 0.225$. The remainder of the solution yields:

Quantity	Left	Right
C	0.165	0.268
K	0.455	0.555
B	0.29	0.29
D	0.30	0.28
M	−170	−90

—in which: K, for maximum moments M_L and M_R, is selected from Fig. 6; B and D are selected from Fig. 5; and M_L and M_R, respectively (in foot-kips), are computed from Eqs. 27. The dissymmetry span ratio ϵ is zero in this case because the modulus of dissymmetry of the particular loading group used is zero.

The foregoing values compare favorably with those obtained by the Cross method (see Figs. 32(*a*) and 32(*b*)).

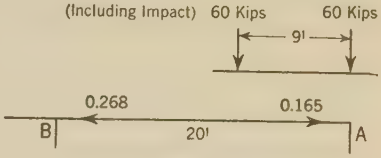

FIG. 33

The maximum negative moments having been computed, the maximum positive moment under the moving loads in the span AB is computed as follows: By Eq. 32, $q_1 = 0.165 + 2 \times 0.165 \times 0.268 + 0.268 = 0.522$; and $q_2 = 0.268 + 0.165 \times 0.268 = 0.312$. Eqs. 33 then yield: $f_3 = 4 \times 0.522 = 2.088$; $f_2 = 3\left(\frac{4.5 \times 0.522}{20} - 4 \times 0.312\right) = -3.339$; and f (Eq. 33*c*) $= 6 \times 0.522 \times 0.225^2 + 0.312\left(6 - \frac{6 \times 4.5}{20}\right) + 2\,(3 \times 0.268 - 0.165 \times 1) = -0.112$.

The application of the foregoing equations, as shown, gives the value of κ for use in placing the loads to produce maximum positive moment. Substituting in Eq. 34: $\bar{\kappa} = 2 \times 0.268 - 1 + 0.225\,(1 + 0.165) + 0.312\,(6 \times 0.225^2 - 2 \times 0.225) - 0.522 \times 3 \times 0.225 \times 0.225^2 = -0.339$. Finally, by Eq. 35, $\kappa = 2.088 \times -0.339^3 - 3.339 \times -0.339^2 - 0.112 \times 0.339 = -0.312$. This represents the ratio of the distance of the mass center of the loading group from the left support. Hence, wheel 2 is $0.312 \times 20 + 4.5 = 10.74$ ft from joint B for maximum positive moment. As in the determination of maximum negative moment the remainder of the solution, with $\lambda = 0.225$, yields:

Quantity	Left	Right
C	0.165	0.268
κ	0.312	0.312
B	0.24	0.24
D	0.25	0.25
M	−142	−70

in which, as before, B and D are selected from Fig. 5, and M_L and M_R, respectively (in foot-kips), are computed from Eqs. 27. The composite maximum moment is computed by applying the laws of statics, as: $\frac{60 \times 10.74 \times 9.26}{20} + \frac{60 \times 1.74 \times 18.26}{20} \times \frac{9.26}{18.26} - \frac{142 \times 9.26}{20} - \frac{70 \times 10.74}{20} = 246$ ft-kips. This value compares favorably with $M = 248$ ft-kips as computed by the Cross method (see Figs. 32(*c*) and 32(*d*)).

Summary of Comparisons.—The actual design of the bent illustrated in Fig. 31 was better proportioned to resist the moments with minimum excess of material, which was an important requirement of the design. Hence, haunched beams and columns were proportioned to resist the moments as indicated by the preliminary investigation, and another investigation was made. Sidesway was neglected in the preliminary design since the column sections were large and there were enough of them to keep sidesway effect to a minimum in any case. Another condition of loading—a horizontal thrust—required bracing in the interior bay for the final design. The exterior columns were also increased 50% in section for other reasons, chiefly impact on the column itself.

Although the Brumfield method has a short distribution, it requires comparable work in order to obtain the frame characteristics. The Cross method requires little more than a pencil and something to write on. It can be applied any time and anywhere. The Brumfield method with its formulas, constants, and charts is better adapted to advanced design work in a well-established office.

One great advantage of using the Cross method rather than the Brumfield method in the analysis of moving loads should not be overlooked—the principle of separately distributing an assumed fixed-end moment of, say, 1,000 ft-kips at each end of all loaded spans. It is then only necessary to multiply the distributed moments by the ratio of the actual fixed-end moment to the assumed fixed-end moment. The influence lines can then be plotted; maximum and minimum moments for any loading are obtained therefrom. The influence lines are a useful part of any analysis using live loads, and an American design engineer would not want to analyze any involved structural design problem without their aid.

The method of using influence lines will be preferred as the "picture" can be applied to different loading conditions with ease. The Brumfield method can be used to determine influence lines also, although not with the same ease and convenience as the Cross method; the latter requires only two distributions for any number of loadings and corresponding fixed-end moments in any one span (see the foregoing example of moving loads).

In any actual continuous structure subjected to moving loads, the loads outside the span as well as the loads in the span must be considered for maximum and minimum moments. For most practical problems, influence lines are the best guide to the placing of loads for maximum and minimum moments due to loads both within the span and outside the span. Hence, except as in the special case of the span in question loaded and all other spans unloaded (the dead load remaining, nevertheless), there is no point in determining the maximum moments within a span of a restrained beam, especially when the loading group occupies more than two spans. Most actual maximum moments in design work are due to loadings both inside and outside the span in question. Hence, influence lines must be used, and the Cross method is probably the best adapted to their use.

The Brumfield method is not so complicated as might appear. It is probably a bit difficult to assimilate and apply at first. With constant practice, the operations become automatic, and the time and effort necessary for each step gradually diminish. It might be well to note that the frame characteristics are constants. In standard multiple designs they are similar and hence, once calculated, they can be used over and over again for all different conditions of loadings, for secondary stress investigations, and for sidesway, settlement of supports, temperature stress, degree of fixity, erection, damage, replacement, modification, alteration, and conversion.

The Hardy Cross method is more easily recalled to use after long periods of disuse. It requires quite an extensive review to apply the Brumfield method after a long lapse of time. Furthermore, practically minded designers will question the niceties of this method. It is probably only in the unusual problems, or in the case where detailed investigation is required, and where otherwise it is unnecessary to obtain influence data, that the Brumfield method is most applicable. The method is also helpful as a check or alternative method to the Cross method.

In the study and application of moment-distribution methods, the individual designer will usually evolve tables, curves, and nomographic charts as an aid to computation. Several of these have been published, and their usefulness should not be overlooked. It might be possible to construct a nomograph to read M_L and M_R and a maximum positive moment directly based on Professor Brumfield's equations and constants. One of the factors in this nomograph could be fixed-end moments.

The similarity of some of the factors used in determining the "frame characteristics" to equations of electrical circuits suggests that perhaps it would be possible to set up an electronic computing device for "frame characteristics." Then all one would need to do would be to press some buttons and read the frame characteristics on a dial, enter a nomograph, and read M_L, M_R, positive M_{max}, and make a simple distribution on prepared forms. By another electronic computing device it might also be possible to draw influence lines if necessary.

In the hands of the unenlightened, this method, and other useful tools of engineering, can become "sledges" to drive engineers deeper into the mud of tedium. However, in the hands of enlightened direction, with sufficient care in distributing the labor of computation over a large group of people, working short daily hours under healthful working conditions with adequate compensation, and with sufficient rest periods, something worthwhile can be accomplished without straining humanity.

Moment distribution is but one step in the design procedure for any continuous structure. To illustrate the proportionately small but nevertheless important part that moment analysis occupies in an engineering organization doing continuous-frame structural work, a simplified organizational chart is presented in Fig. 34. Sections where moment analysis and the Brumfield method may be applied are indicated as the "Preliminary Design" section in division I and the "Structural Analysis" section in division II. The design organization illustrated is one engaged in preparing both contract and working plans, as well as supervising and inspecting construction. In an organization engaged only in preparing contract plans, moment analysis assumes a proportionately larger part of the organization.

FIG. 34.—ORGANIZATION CHART FOR ENGINEERS ENGAGED IN THE DESIGN AND CONSTRUCTION OF CONTINUOUS FRAMES

CLIFFORD PETERSEN,[47] JUN. AM. SOC. C. E.—It would be well to state that Professor Brumfield's method is flexible to the utmost and is readily applicable to the solution of problems in rigid frames outside the scope of conventional rectangular building frames. Also, once a basic understanding of the method has been absorbed, it is possible to pick up the method and employ it on a short notice even if a considerable interval has passed since last it was used.

The writer first became familiar with the method during his undergraduate days. In the succeeding years he has been engaged entirely in the aeronautical engineering field and has had no occasion to apply the method to building frames. There have been a few isolated yet important instances, however, where it has been necessary for the writer to investigate moving air loads and other loads in the design of multiangular frames which occur so often in aircraft structures. After the briefest perusal of Professor Brumfield's mimeographed notes,[3] the method was applied successfully to the exact solution of the problems with a considerable over-all saving in time and effort. The saving in time resulted primarily from the fact that, once the characteristics of the frame were determined, it was a comparatively simple and rapid process to evaluate the effect of the many different loading conditions.

---

[47] Aeronautical Research Engr., Univ. of Southern California, Los Angeles, Calif.

A. A. EREMIN,[48] ASSOC. M. AM. SOC. C. E.—The distribution moments in continuous frames by the Brumfield method is similar in many respects to the procedure for distributing moments graphically. Therefore, the author's method can be simplified easily by introducing graphical constructions.

For illustration consider a member AB with a constant section and with the ends restrained by the continuity of members. The member AB is subjected to a concentrated load P as shown in Fig. 35. The distances, a and b, to the inflection points in member AB, are

$$a = \frac{C_{AB}}{1 + C_{AB}} \times L \ldots (81a)$$

and

$$b = \frac{C_{BA}}{1 + C_{BA}} \times L \ldots (81b)$$

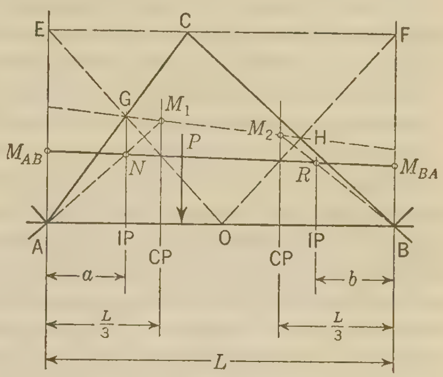

FIG. 35

The constants C_{AB} and C_{BA} are determined from Eq. 4. The moments in member AB may be determined by the graphical construction as shown in Fig. 35. Draw the verticals from the inflection points and from the central points at the third-points of span AB. Line EF is drawn through the vertex C of the M-diagram of span AB, as shown. Connect the points E and F with the mid-span point O. Draw line GH through the points cut on the M-diagram. Line GH gives the central moments M_1 and M_2 at the third-points. The closing line of the final moments M_{AB} and M_{BA} is drawn through the points cut by lines AM_1 and BM_2.

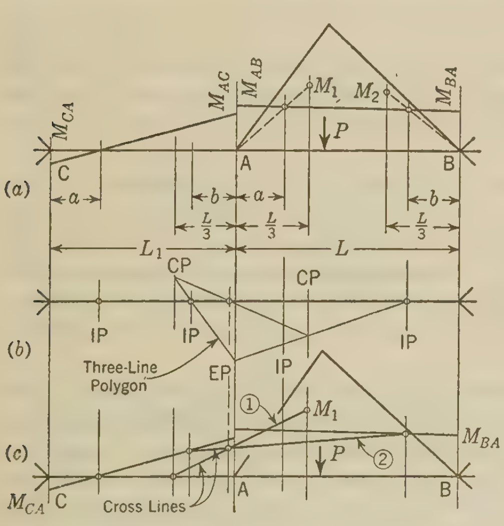

FIG. 36.—GRAPHICAL DISTRIBUTION OF MOMENTS

Fig. 36 illustrates the solution of a continuous beam CAB with a constant section and with the ends restrained by continuity of members. The span AB and the loading are the same as those shown in Fig. 35. At point A the beam is supported on a rigid column. The moments in span CA may be determined either by the author's moment-split factors, Eq. 39, or by the cross lines as shown in Fig. 36(*c*). The location of the inflection points in span CA are determined by Eq. 40. The location of the elastic-point vertical is determined[49] by the three-line polygon as shown in Fig. 36(*b*). The central moments in span CA are each zero; therefore, line 1 of the cross lines is drawn through the third-point in span CA and M_1 in span AB. Line 2 of the cross lines is drawn through the closing point on the inflection-point vertical in span AB and the point cut by line 1 on the elastic-point vertical. The intersection point of line 2 and the inflection-point vertical in span CA give the closing point at that span, thus deriving the points by which the closing line of moments M_{CA} and M_{AC} are constructed.

[48] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

In calculating the maximum moment Professor Brumfield has placed the moving load on one span only. It is known that the maximum moment near a support is produced by a moving load placed on two or more spans; and it would be valuable to have Professor Brumfield demonstrate his method for this type of loading. Evidently the method of influence lines is still the simplest for computing such moments. The graphical procedure illustrated by Figs. 35 and 36, in conjunction with Eq. 4 of the paper, is a time-saving method of drawing influence lines. Therefore, it is gratifying that Professor Brumfield has developed the algebraic formulas for the physical properties of structures which may also be applied in the graphical distribution of moments.

R. C. Brumfield,[50] M. Am. Soc. C. E.—It will not be possible to comment in detail on all the questions raised in discussion. Some were asked by more than one discusser. The writer will accordingly try to answer first those which are frequently duplicated and then proceed to comment on the individual discussions.

At the start the writer wishes to express his sincere appreciation for the many complimentary statements. Compensation for the time and effort of developing the type of material represented by the paper must of necessity be more or less spiritual in character. No small part of such compensation is the knowledge that others have benefited from the effort involved. It is gratifying, therefore, to read that the principles developed have been found useful in practice.

The writer was somewhat puzzled by the number of discussers who stressed terminology and nomenclature and by others who devoted their comments to the subject of moment distribution. Difference in viewpoint may account for this insistence on discussing subjects which were considered only auxiliary to the main purpose of the paper—the handling of moving loads on restrained beams. Accordingly, it seems desirable to give a brief history of the development of this material in the hope of somewhat clarifying the diversity of viewpoint. Nomenclature and moment distribution will then each be commented on separately.

The essential part of the material on moving loads, which is contained in the paper, was developed about 1925–1926 and has been available since that time together with the nomenclature which accompanied it. About 1930 the material on moment distribution, in its elementary form as it appears in the paper, was added and the whole, with additional material on sidesway and secondary stresses in trusses, was published in mimeographed form, in 1933.[3] The procedure has been taught continuously to both undergraduate and graduate students at The Cooper Union in New York, N. Y., from then to the present time. The methods were adapted to beams of variable section and to curved beams about 1936. The material was republished in photo-offset form in 1941.[4] Since that time it has been extended to include beams of noncoplanar frames.

---

[49] "Analysis of Continuous Frames by Graphical Distribution of Moments," by A. A. Eremin, Sacramento, Calif., 1943 Ed.

[50] Associate Prof., Civ. Eng. Dept., The Cooper Union, New York, N. Y.

Nomenclature and terminology, in technical writing, bear some analogy to the language of ordinary speech or written material. It is natural that each reader should desire to read in his own language, since less effort is involved. It would also be a courtesy on the part of the writer to express his material so as to accommodate the greatest number, even though the truth is the same expressed in any nomenclature. Unfortunately, basic nomenclatures dealing with beams are as diverse as are the textbooks from which the engineer learns fundamentals in mechanics of materials.

The writer therefore has no apologies for the nomenclature used in the paper; it was fully embedded, in the method presented, long before such papers as that by Hardy Cross,[2] M. Am. Soc. C. E., and most of the others cited were published. From the standpoint of serving the majority, the nomenclature performed that service, as far as the discussers were concerned, since more than half of them were men who had previously studied the writer's courses in indeterminate structures. Also, a writer should not be closely restrained in his choice of nomenclature. Since he is responsible for accuracy of statement, he is most likely to meet this requirement when thinking and writing in a familiar language—his own nomenclature.

Some of the discussers chose to comment on the method of distribution of bending moment, and several introduced, briefly, methods of their own, for comparison. These are interesting, of course. It is significant that the methods are not alike, which indicates that preferences in the methods of distribution of moment to a frame are likely to be determined to a large extent by the habits and prejudices of the individual. Few men are sufficiently familiar with all available methods through practice to be qualified to make a fair comparison of their merits. Although the writer has a bowing acquaintance with some of those cited, he confesses to a lack of the necessary intimate familiarity to make profitable comparisons on the bases of convenience and serviceability. Again, the writer gave only the essentials of his method of distribution, and so stated in the paper. In fact, in the method actually used for extensive frames, the frame characteristics developed are only a means to an end and do not appear as such in the final method. Messrs. Rolsma and Gieseking touch briefly on the more general method in their discussion. Since space is not available for introducing the method here, the writer must refuse various invitations to make comparisons in methods of moment distribution and confine his closing comment closely to the matter of moving loads.

Mr. Stewart makes the observation that the method is not applicable to beams of variable section. This is true of the formulas shown in the paper since they have been adapted to the special case of beams of uniform section throughout the span. The method has been adapted to members of variable section, however, giving formulas which reduce to those for members of uniform section when the nonuniformity of the beam disappears. Thus, the formulas in the paper are special cases of the more general ones which apply to nonuniform beams, and the nonuniform beam formulas in turn are special cases of those which apply to curved beams. In fact, a paper was filed in the Engineering Societies Library in 1936 which contained many of the formulas that apply to beams of nonuniform section.

Mr. Brodkin has transformed the formulas of the paper to apply to the computations of fixed-end bending moments at beam ends. Mr. Strauss also does essentially the same thing. These are interesting applications and no doubt will be useful to engineers interested in fixed-end moments. Mr. Brodkin also brings out the fact that angular rotations at the supports may readily be computed from the B-values and the D-values. This is an interesting comment on a matter not included in the paper.

Professor Hickerson speculates as to whether or not it might be easier to determine the position of load for the maximum bending moment and the value of the maximum bending moment by influence lines, rather than by the formulas of the paper. At least one other discusser raised the question as to the difference between the method of influence lines and the formulas of the paper. Considering them as separate methods of handling moving loads, there should be no argument possible. This is true since Eqs. 14*a* and 14*b* are exact formulas for influence lines at the two supports, caused by a single load, when the value of W is unity. Similarly, Eqs. 25*a* and 25*b*, as well as Eqs. 27*a* and 27*b*, are formulas for combined influence lines when the value of W is unity, the unit load being considered as distributed on the span in any manner chosen, as dictated by λ^2 and ϵ^3. Since the equations of the paper are in essence those of influence lines, it would seem strained to attempt to make the distinctions cited.

Mr. Strauss has suggested that it would be more convenient to use the reciprocals of Q, i, and R, rather than the symbols in the paper. Mr. Merritt makes essentially the same suggestion. In support of his suggestion, Mr. Strauss states that, in computing the R-values of Table 1 from the i-values of Col. 3, this procedure would avoid taking the reciprocals of the i-values before adding them to obtain the R-value needed in Eq. 40. The writer readily admits that this is true and commends the suggestion to those who compute R-values in this way. In his own work, however, he has always followed the suggestion made in connection with the transformed Eq. 42. In Eq. 42, there is no conscious addition of the i-values at all, but rather ratios of i-values are taken on the slide rule and unity is added mentally. Thus, the entire computation of a R-value, from any number of component i-values, consists of a single continuous slide-rule operation leading to the final result.

Mr. Mackenzie illustrates the use of the frame characteristics in the paper for distribution of fixed-end moments, indicating an interesting combination of the methods of the paper and the concepts of the Cross approach to the problem of rigid frames.

The comments of Mr. Schaffner on the use of the methods of the paper in practical engineering should be of interest to those not familiar with them, since the procedure must be judged on such testimony. The practical illustrations given by Mr. Kalb and Messrs. Rolsma and Gieseking are further examples of such testimony, and are particularly valuable in showing adaptations to studies on unusual frames and the flexibilities obtained with the methods. Messrs. Rolsma and Gieseking touch briefly on the general method which the writer uses for distribution of bending moment but it is not likely that the explanations, because of their brevity, will be clear to the uninitiated.

Mr. Schure gives the analysis of a five-span continuous beam. It appears that Eqs. 61*a* and 61*b* are identical to Eqs. 14*a* and 14*b* of the paper. The curve in Fig. 22 is identical with the outer curve ($\lambda = 0$), in Fig. 5 of the paper. Mr. Schure also suggests the use of a table of reciporocals in computing frame characteristics. This is in line with the suggestions made by Messrs. Strauss and Merritt and the same answer applies. If reciprocals are to be taken in the computation, the suggestion of Mr. Strauss had better be followed and the inversions of Q, i, and R used.

Mr. Dodge makes considerable effort to show that the supports A_1 and E_1, in Fig. 12, will permit uplift and that hence the frame characteristics computed are invalid. He also states that sidesway would result in any case and that this would render inaccurate the solution given for the frame and loading. He buttresses these observations with the statement that, if the supports were pins, no lateral movement would be permitted and thus expansion due to temperature would be impossible.

The writer has long been familiar with the fact that most textbooks on the mechanics of materials, from which engineers obtain their first concepts of beams, deal only with the fixed support and free support as being the two limiting cases of a large group of restrained supports. For mathematical purposes, the free support is defined as one which permits no translation but does allow perfect freedom of rotation. Although this is an idealized definition, it serves mathematical purposes very well. In this sense the writer used the definition of free support in the paper. With such a definition, of course, there is no question of sidesway or uplift. In fact, the very symbol, used in the paper to designate the support, is the one ordinarily used in textbooks to show a free support conforming to this definition.

Again, if it be granted, in deference to the practical man, that such supports must permit lateral motion to provide for expansion, it must at the same time be granted that the practical man would design his support to prevent uplift, to avoid hammer, just as is done at the anchor pier of a cantilever bridge. Such a provision would render the frame characteristics accurate. Since only one such support is required to care for expansion, sidesway is eliminated by fixing the other support against lateral motion. The writer has no desire to avoid the question of sidesway; but, since it was not covered in the paper, he feels it would be presumptuous to introduce it in the discussion.

Mr. Dodge's distinction between the terms "beam class" and "frame class" is obscure. Since beams are the units from which all frames are built, no distinction would appear to be justified. Whether the frame is to be analyzed with or without sidesway, the fundamental approach to the problem of the beam is the same as to that of the frame. Mr. Dodge also states that, as presented by the writer, the computation for the effects of a pure couple involves a concept that is different from those for other loads. This is not true as may be verified from the paper. The formulas for the couple expressed by Eqs. 36 were obtained directly from Eqs. 14*a* and 14*b*, and hence have the same underlying concept.

Mr. Dodge "objects strongly to the term 'torque split'" to designate the division of resisting bending moment among the receiving members of a joint which is actuated by an artificial couple. The writer used this term to distinguish such moment from similar bending moment induced in the members, when the joint is actuated by a bending moment transmitted to it by one of the radiating members. Mr. Dodge would reserve the term torque split for those cases where "primarily shear stresses" are caused in the members.

The term "primarily" is not defined. Primarily may not refer to the order of induction since, when both shear and bending moment are induced in a member, their induction is simultaneous. It may perhaps then be inferred that Mr. Dodge means that shear must be the greatest or predominating influence and the bending influence must be lesser in numerical value. Even this interpretation is difficult to make consistent. In such a case as that of a shaft, which has by long usage been associated with the term torque, when torsion is applied by some procedure such as a belt and pulley, the question of whether bending moment or torsion predominates in the shaft is wholly a matter of distribution of bearings, pulley-size belt pull, and so forth. Similarly, in a noncoplanar frame if some members become quite short, it is entirely conceivable that shear may predominate in amount. Thus, accepting Mr. Dodge's criterion, it would seem that the use of terms is somewhat relative and a matter of individual taste.

The writer regrets that space does not permit a full explanation of the meaning of his statement (see Section 13) that: "One distribution is sufficient for all purposes, including live-load and dead-load moment distribution, wind moments, and sidesway * * *." Mr. Dodge suggests that a separate distribution is required for each operation. Under the writer's procedure this is not the case. Although separate collections or partial collections are made for the various purposes they all follow from one distribution. The discussion by Messrs. Rolsma and Gieseking touches very briefly on this question.

The testimonies of Messrs. Rights and Heiser as to the usefulness of the method and its flexibility and versatility in practice are most gratifying coming from men actively engaged in a broad field of general engineering practice.

The writer appreciates the complimentary comments of Professor Ferguson. The confusion which Professor Ferguson feels in the terminology and nomenclature would seem to arise from unfamiliarity and perhaps from the too brief explanations which must accompany a short paper. For many years, the writer has taught these concepts, expressed in this terminology, to undergraduate engineering students and has noted no confusions. It is harder to supplant a familiar nomenclature with a new one than to become familiar with the new one from the start, which may account for some of Professor Ferguson's difficulty.

Mr. Beskin suggests that the writer has omitted reference to his predecessors. The writer is most conscious of the duty to give credit where credit is due. However, he confesses total lack of knowledge of the writings of O. Mohr and Maurice Lévy[42] which are stated to have been published about 1886. As for the other references cited, they all appeared after the methods of the paper were complete. The writer has a general familiarity with most of them but they had no influence on any procedures in the paper.

Messrs. Beskin, Eremin, and Jameyson all mention, in one way or another, the opinions that the equations for moving loads are not valid when the load occupies more than one span and that therefore this is a distinct limitation on their use. Mr. Beskin particularly refers to the fact that the greatest bending moment at the common support of two contiguous spans occurs when load lies in each of them. This is true and the equations cover this case.

A continuous beam of six spans is shown in Fig. 37. A load W is shown, which is too extensive to be contained wholly in span CD. It then becomes a "broken load," in Professor Jameyson's terminology, with a part W_1 lying in span CD and a part W_2 lying in span DE. There are two statements to be made in connection with this case. The first is that such a load is not in general the most suitable type for use as a criterion to determine the maximum bending moment at a given point—say, the right end of span DC. If the loads W_1 and W_2 are fixed in spacing with respect to each other, it is obvious that one of them, say, W_1, may be placed, by Fig. 6 or Eq. 29*a*, in position to produce maximum bending M_{DC}. It is also evident that the load W_2 in span DE will occupy any companion position dictated by the fixed spacing. Although, fortuitously, this could also be the position that would produce maximum bending moment M_{DE}, it is likely to be some position that will produce less than maximum at the left end of span DE. Thus, it can obviously be concluded that a fixed-space loading that occupies more than one of two contiguous spans simultaneously may not ordinarily produce as great a bending moment at the common support as would the two sections of the load if they were free to move independently of each other and that, in any case, the bending moment produced may not be greater than the one that would be produced by the independent movement of the two sections. This leads to the conclusion that loads which may not be wholly contained within a span should not be used as criterions for maximum bending moment.

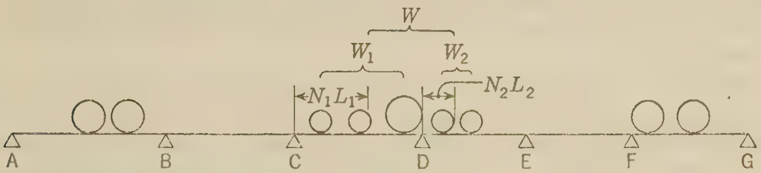

FIG. 37

The second statement to be stressed is that if, in spite of the undesirability of fixed-space loads too widely spaced to be contained in the span as criterions, it is necessary to use such loads, the procedure may be as follows: Referring to Fig. 37, let the major part of the load be placed in the span which has the greatest product of $L\ A$ (see Eq. 27), in position for maximum in its own span at the common support—W_1 in Fig. 37. Then, W_2 will lie in span DE in whatever position the fixed spacing dictates. The maximum bending moment at point D due to W_1 and the simultaneous bending moment due to W_2 will ordinarily be all that is required. If greater accuracy is desired, a few other bending moments may be computed from Eqs. 27*a* and 27*b* in a trial-and-error location of an absolute maximum. The equations are those of combined influence lines and this is exactly the procedure that would be required with influence lines.

It may be stated in passing that the writer has derived exact equations for this case; but, since these formulas involve the characteristics of both spans and hence are quite complicated, they have not been considered practical.

Fig. 37 also illustrates the possibility of placing the load in distant spans for maximum at a given point. In addition to bending moment M_{DC} induced from the loads in the adjacent spans CD and DE, loads placed in spans AB and FG in positions for maximum at point B and point F will also contribute to the maximum M_{DC} in greatest possible amount. Mr. Dohn has referred to this condition.

Commenting on the opinion of Professor Jameyson that the method would be impossibly complicated when applied to beams of variable section, the writer can state that, on the contrary, it is quite as simple for these cases as for those outlined for beams of constant section and the formulas for beams of variable section reduce directly to those of straight section when the nonuniformity disappears.

The observation by Mr. Petersen that he has found the methods useful in airplane structures is quite interesting, indicating practicability in fields outside those ordinarily considered structural.

In closing the writer again wishes to express his appreciation of the privilege of reading the extended comment on his paper and of presenting a topic of interest to structural engineers.

SEDIMENTATION AND THE DESIGN OF SETTLING TANKS

BY THOMAS R. CAMP,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. NORVAL E. ANDERSON, R. A. MULHOLLAND, P. CHARLES STEIN, LYNN PERRY, E. SHERMAN CHASE, ROLF ELIASSEN, AND THOMAS R. CAMP.

SYNOPSIS

Sedimentation has been used for generations to clarify liquors and to concentrate solids in many widely diversified fields. It is the most commonly used process in the field of water and sewage treatment. The investments for settling tanks in this field are probably about one third of the total capital investment for treatment. Despite the importance of the process, current understanding of the principles involved has progressed so slightly that there is as yet no such thing in practice as the economic design of tanks from a functional viewpoint. The dimensions of most settling tanks are fixed on the basis of standard detention periods recommended by state health departments. This practice prevails in disregard of the fact that evidence was presented as early as 1904[2] that removal of suspended matter depends upon surface area and not upon tank volume. The settling characteristics of the suspensions to be clarified are rarely considered in the design of settling tanks.

The purpose of this paper is to collect in one compendium the known principles of sedimentation essential to the development of design theory, and to present the theory of design developed to a stage which will permit its use in practice. The paper is divided into ten interrelated topics. Much of the subject matter is the work of others, and due credit is given by means of references. The use of the theory is illustrated by a number of practical examples. It has been necessary to omit a discussion of the design of inlets and outlets because of lack of space.

Notation.—In so far as they apply, the letter symbols used in this paper conform essentially to American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942) prepared by a Committee of the American Standards

1. Settling Velocities of Individual Particles

When a particle is released in a still fluid it will move vertically due to gravity if its density differs from that of the fluid. The particle will accelerate until the frictional "drag" of the fluid approaches the value of the impelling force, after which the vertical velocity of the particle with respect to the fluid at rest will be substantially constant. The terminal velocity is known as the "settling velocity" of the particle and it is of great importance in sedimentation.

The law for drag was first proposed by Sir Isaac Newton[3] on the assumption that the drag is due to inertia only and hence is proportional to the square of the velocity. Newton's law is now usually written:

$$F_D = C_D\, A\, \frac{\rho\, v^2}{2} \quad \ldots\ldots\ldots\ldots (1)$$

in which: F_D = the drag force; C_D = a dimensionless number called the "drag coefficient"; A = the projected area of the body in the direction of motion $\left(\frac{\pi}{4} D^2 \text{ for spheres}\right)$; v = the relative velocity between the body and the fluid; $\frac{\rho\, v^2}{2}$ = the dynamic pressure; and ρ is the mass density of the fluid. Instead of being constant, as Newton assumed, the drag coefficient C_D has been found by experiment to vary widely. Experiments demonstrate, however, that when geometric similarity exists, as in the case of objects of similar shape, similarly oriented, the drag coefficient is a function of the Reynolds number, as shown in Fig. 1.[4,5]

The general equation for the settling velocity of spheres of diameter D in terms of the drag coefficient may be obtained by equating the impelling force to the drag, from which the settling velocity is

$$v = \sqrt{\frac{4}{3}\,\frac{g}{C_D}\,\frac{(\rho_1 - \rho)\, D}{\rho}} \quad \ldots\ldots\ldots\ldots (2)$$

in which g is the gravity constant and ρ_1 is the mass density of the sphere. The solution of settling velocity problems by means of Eq. 2 and experimental values of C_D from Fig. 1 requires trial computations involving the Reynolds number $\mathbf{R} = \frac{v\, D}{\nu}$ in which ν is the kinematic viscosity of the fluid. To avoid trial calculations, the curve of Fig. 1 has been replotted in Fig. 2 in terms of

[5] "Nomograph for the Settling Velocity of Spheres," by Hunter Rouse, *Report of the Committee on Sedimentation for 1936–1937*, National Research Council, Div. of Geology and Geography, Washington, D. C., 1937, p. 57.

$\frac{C_D}{\mathrm{R}}$ and $C_D\,\mathrm{R}^2$ as ordinates against R as abscissas.[6] It will be noted from Eq. 2 that

$$\frac{C_D}{\mathrm{R}} = \frac{4}{3}\,\frac{\rho_1 - \rho}{\rho^2}\,\frac{g\,\mu}{v^3} \quad \text{(3a)}$$

and

$$C_D\,\mathrm{R}^2 = \frac{4}{3}\,\rho\,(\rho_1 - \rho)\,\frac{g\,D^3}{\mu^2} \quad \text{(3b)}$$

in which μ is the absolute viscosity of the fluid. For obtaining the diameter in terms of a measured settling velocity, $\frac{C_D}{\mathrm{R}}$ may be computed from Eq. 3*a* and R can be obtained from the curve; D is then computed from the value of R taken from Fig. 2. Similarly, for computing the settling velocity of a sphere of size D, $C_D\,\mathrm{R}^2$ is calculated from Eq. 3*b* and the corresponding value of R is taken from Fig. 2; v is then computed from R.

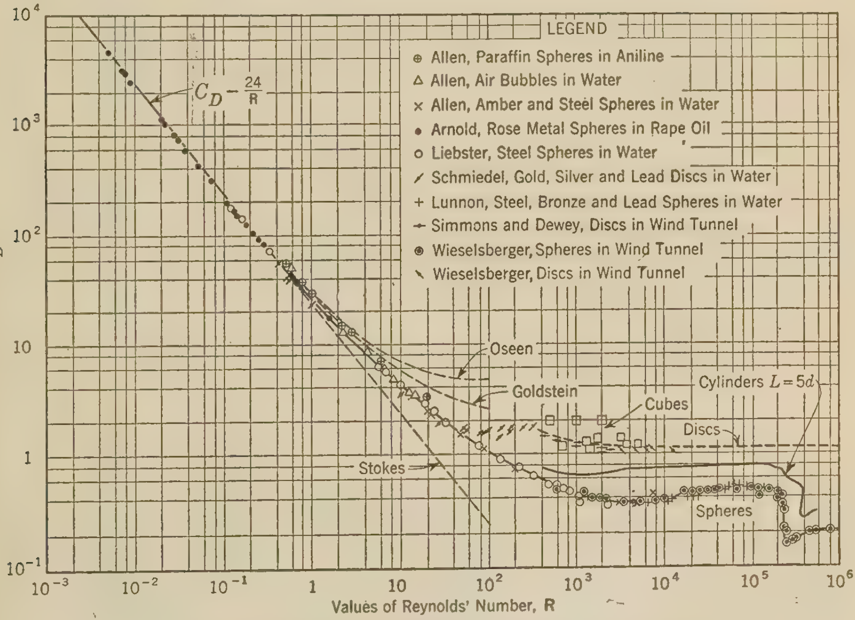

FIG. 1

The drag for a small sphere in an incompressible viscous fluid of infinite extent was first developed by Sir G. G. Stokes,[7] completely neglecting the inertia forces, as follows:

$$F_D = 3\,\pi\,\mu\,D\,v \quad \text{(4)}$$

---

[6] "Principles of Chemical Engineering," by W. H. Walker, W. K. Lewis, W. H. McAdams, and E. R. Gilliland, McGraw-Hill Book Co., Inc., New York, N. Y., 1937, p. 299.

[7] "On the Theories of the Internal Friction of Fluids in Motion, and of the Equilibrium and Motion of Elastic Solids," by Sir G. G. Stokes, *Transactions*, Cambridge Philosophical Soc., Vol. VIII, 1845, p. 287; also in "Mathematical and Physical Papers," by Sir George Gabriel Stokes, Univ. Press, Cambridge, England, Vol. I, 1880, p. 75.

Comparison of Eq. 4 with Eq. 1 reveals that, in the region of viscous settling, the drag coefficient is $\frac{24}{R}$. The corresponding settling velocity is given by Stokes' law:

$$v = \frac{1}{18}\frac{g}{\mu}(\rho_1 - \rho)\, D^2 \quad (5)$$

which has been verified experimentally by numerous investigators for fluids and

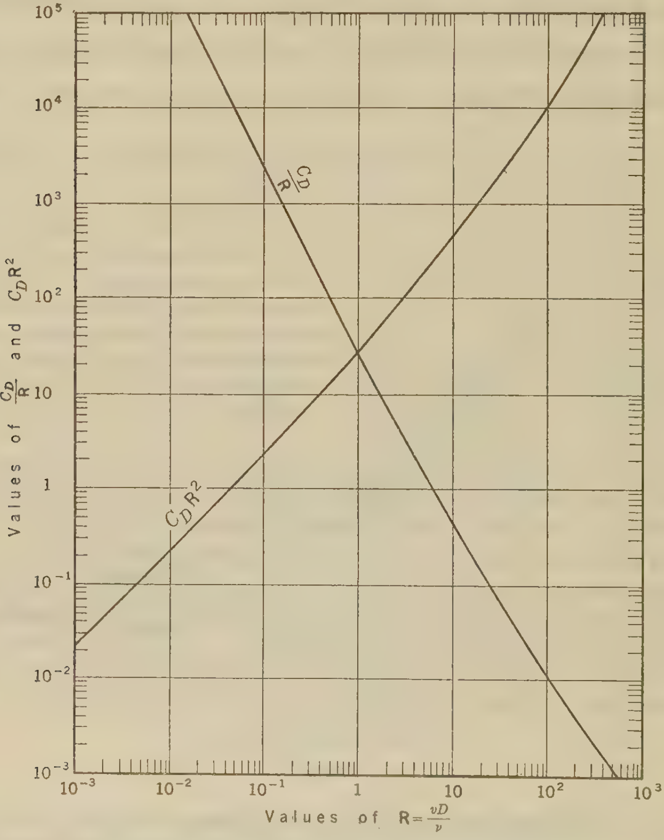

FIG. 2

spheres of various types. The data (see Fig. 1) are in good agreement with Stokes' law for values of R from 10^{-4} to about 0.5. Although Stokes' expression for the drag force, Eq. 4, was developed for incompressible fluids, the effects of compressibility are so small that the relation may be used safely with gases. In fact, the coefficient of drag throughout the entire range of Fig. 1 is not appreciably influenced by the compressibility of the fluid.

Particles to be removed from water and sewage by sedimentation are seldom truly spherical and are usually quite irregular in shape. The influence of irregularities in shape upon the drag is much greater as the velocity increases, as may be noted from Fig. 1, where size is taken in terms of the equivalent diameter of a sphere of equal volume.

A single particle settling in a container is subject to the influence of the walls at which the velocity of the fluid is zero. Empirical correction factors have been developed by A. W. Francis[8] for viscous settling and by H. S. Munroe[9] for turbulent settling. Computed values of the Francis and Munroe correction factors indicate that the influence of the wall is negligible if the diameter of the particle is less than 1% of the cylinder diameter.

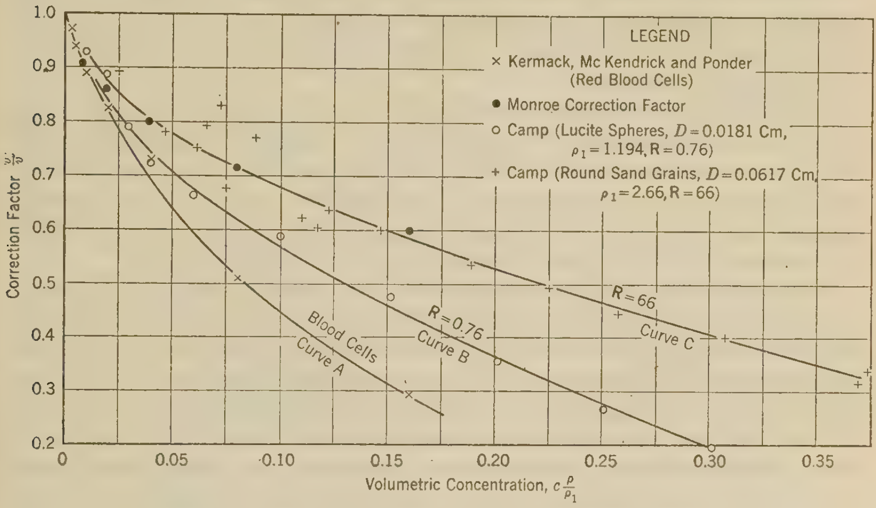

FIG. 3.—REDUCTION IN VELOCITY DUE TO HINDERED SETTLING

When a number of particles are settling in a fluid in close proximity, their velocity fields interfere and the settling is hindered. As in the case of a particle settling in a cylinder of limited cross section, there is an appreciable upward displacement of the fluid; and a correction factor analogous to the wall correction factor may be applied to estimate the "hindered" settling velocity. A theoretical analysis of the problem is lacking, however, and experimental data are not numerous.

The experiments of W. O. Kermack, A. G. McKendrick, and E. Ponder[10] on the hindered settling of red blood corpuscles are shown as curve A in Fig. 3, in which c is the concentration by weight. The writer's experiments on the viscous settling of lucite spheres in still water (curve B, Fig. 3) indicate that the correction factor $\frac{v'}{v}$, in which v' is the "hindered settling velocity," increases as the Reynolds number increases. No data are available for hindered settling in a still fluid in the transition region between viscous and turbulent settling, but A. M. Gaudin[11] has applied the Munroe correction factor as a rough approximation as shown in Fig. 3. The writer's experiments on round sand grains (curve C, Fig. 3) suspended in a tube of rising water may also be accepted as an approximation.

2. Nature of Settling Processes in Water and Sewage Treatment

The particles to be removed in water and sewage treatment plants consist of mineral and organic solids and grease with varying quantities of entrained water and occasionally gas. The settling velocity of a particle is controlled by its size and its net density ρ_1.

The suspended matter in turbid river water consists primarily of finely divided silica, clay, and silt. The density of the particles will range from about 2.6 for fine sand grains down to about 1.03 for flocculated mud particles containing 95% water. Water from wooded regions may contain suspended vegetable matter with particle densities ranging from about 1.5 down to about 1.0 depending upon the quantity of entrained and adsorbed water.

In water treated by coagulants in rapid filter plants, the suspended particles consist of precipitated Al_2O_3 or Fe_2O_3 floc with its adsorbed water and the enmeshed solids of the raw water. Alum or iron floc may contain as much adsorbed water as 20 mols per mol of oxide when freshly precipitated, the corresponding densities being 1.18 for $Al_2O_3 \cdot 20\,H_2O$ and 1.34 for $Fe_2O_3 \cdot 20\,H_2O$. The floc particles may also contain entrained water up to about 99% of the volume, with a corresponding reduction in density to about 1.002. The density of the floc particles is further modified by the amount and character of solids entrapped from the raw water. Clay and silt should increase the density, whereas entrapped organic coloring matter might reduce the density. The size of floc particles ranges from submicroscopic to 1 mm or more.

In softening plants where the water is treated with lime and soda ash, the suspended particles are composed principally of precipitated $CaCO_3$ crystals. Peter Homack,[12] Jun. Am. Soc. C. E., has shown that the pure precipitate is calcite having a density of 2.7 and a maximum crystal size of 15 to 20 microns. The curve of correction factors for hindered settling of these particles should be slightly above curve A, Fig. 3. A study of Lieutenant Homack's experiments on hindered settling of calcite indicates that the crystals settle in small clusters, about 0.1 mm in size, which contain about 75% water and have a net density of about 1.2. The indicated "free settling" velocity of these aggregates is about 0.06 cm per sec. Magnesium hydroxide, $Mg(OH)_2$, forms a flocculent precipitate and adsorbs water like alum floc. Hence, when the excess-lime process is used the density of the floc particles will be less as the relative amount of magnesium precipitate is increased. Calcium carbonate, $CaCO_3$, flocs are small, but floc particles composed partly of $Mg(OH)_2$ may be large because of the adsorbed water. Settling is less rapid when $Mg(OH)_2$ is present than when only $CaCO_3$ is present. Alum is sometimes used in lime softening plants treating turbid waters to speed flocculation and clarification. Alum floc Al_2O_3 is not formed in this case due to the high pH-value. Lieutenant Homack's experiments indicate that the effect produced is probably due to the flocculation of the negatively[13] charged colloidal calcite crystals by the Al^{+++} ions forming large aggregates.

[12] "A Study of the Precipitates Formed in Lime Softening," by Peter Homack, thesis submitted to Mass. Inst. Tech., Cambridge, Mass., in 1941 in partial fulfilment of the requirements for the degree of Master of Science.

In American type grit chambers for sewage treatment it is desired to remove heavy granular material such as sand in order to protect pumps, inverted siphons, or treatment units from undue abrasion and heavy deposits. Sewage grit may properly include coal dust, coffee grounds, fruit seeds, egg shells, and many other substances which are not subject to anaerobic decomposition. The density of these materials will vary from about 1.2 to 2.7. Practice indicates that chambers effectively removing sand 0.2 mm in size and larger (material retained on 65-mesh sieves) will usually perform the protective function satisfactorily. The settling velocity of 0.2 mm sand grains is from 2 to 2.4 cm per sec.

Some large sewage solids will also settle in a grit chamber, but because of their putrescibility they are not proper constituents of grit and should pass on to be disposed of with the other organic solids. Grit with no more than 3.5% washable organic matter[14] as measured by the "Dazey Churn" test can usually be disposed of as fill without nuisance, but washed grit with less than 1% washable organic matter can be obtained with careful design and operation. Washable putrescible solids may be separated from grit by "bed-load" movement in the grit chamber, by means of a mechanical "classifier" which washes the organics out as the grit is removed, or by grit washers.

Sewage organic suspended solids to be settled in primary tanks consist mainly of proteins and fats with some cellulose and varying amounts of entrained water and some gas. Thus, the net density of these particles will vary from less than 1.0 to perhaps 1.2. De-emulsified soaps, oils, grease, and some fatty particles tend to rise and form scum, carrying with them some proteins and cellulose. In chemical precipitation plants these sewage solids are combined in flocs with the chemicals used for coagulation. Suspended sewage particles range in size from colloidal to several centimeters.

In final settling tanks for trickling filters or activated sludge, the suspended particles consist of gelatinous flocs composed of a zoogleal matrix, numerous living bacteria and microorganisms, and some undecomposed organic matter. The particles settle rapidly despite their low density.

All the aforementioned suspended particles except grit flocculate during settling. Two particles that coalesce during settling lose their original settling velocities and thenceforth settle at another velocity characteristic of the combined particle which is usually faster than the original velocities. In a suspension of discrete particles, such as grit, each particle maintains its individuality and characteristic settling velocity during sedimentation; and an analysis of the suspension in terms of settling velocities may be used to predict removal and design basins. This is not the case in a suspension of flocculating particles, however, since settling velocities are changing continually.

[13] "Theoretical Limits of the Lime-Soda Method of Water Softening," by T. E. Larson and A. M. Buswell, *Industrial and Engineering Chemistry*, Vol. 32, 1940, p. 132.

[14] "Grit Removal from Sewage," by W. A. Kivell and N. B. Lund, *Water Works & Sewerage*, Vol. 87, 1940, pp. 176–185.

From Fig. 3 it appears that the volumetric concentration of suspended solids must exceed about 0.5% before there is an appreciable reduction in settling velocity due to hindered settling. This is comparable to from 1,000 to 5,000 ppm of silt in a turbid river water, about 2,000 ppm of $CaCO_3$ in a lime-softening plant, and about 1,000 ppm of sewage suspended solids. Hence, sedimentation in all these processes may be considered "free settling" without appreciable error.

In the final tank of the activated sludge process, however, the suspended solids content will range from less than 800 to about 5,000 ppm, and the volumetric concentration of the floc particles is so great that the initial subsidence is a process of hindered settling. The particles are so close together and so flocculent that they appear to settle as a blanket, all going down at about the same velocity at the start and leaving a clear supernatant above the top of the sludge blanket. There is doubtless some free settling above the top of the sludge blanket of small floc particles which escaped entrapment in the blanket; but in tanks that are functioning well the concentration of these particles should be small enough to permit withdrawal of the supernatant from almost any place at the liquid surface beyond the inlet zone. The nature of the settling of activated sludge is illustrated in Fig. 4.

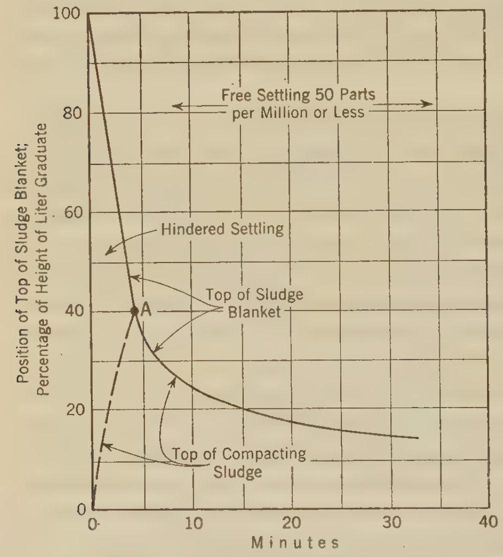

FIG. 4.—SETTLING AND COMPACTING OF TYPICAL ACTIVATED SLUDGE MIXED LIQUOR WITH AN INITIAL SUSPENDED SOLIDS CONTENT OF ABOUT 2,000 PPM

The initial subsidence of the activated sludge blanket is a process analogous to upward filtration through the sludge such as occurs in the Spaulding "Precipitator" and other similar units in which the sludge is virtually at rest with respect to the tank, being held in position by the drag of the water which flows upward between the particles. In the settling of activated sludge, however, the liquid is virtually at rest with respect to the test container as regards vertical motion and the sludge blanket moves downward. As the particles in the lower part of the blanket reach the bottom, others above settle upon these particles, and so on progressively until all floc particles in the sludge are supported upon the particles below. The supported particles do not come to rest when they make contact with the particles below, however. The weight of the sludge accumulating above distorts and compresses the supporting particles, slowly squeezing the liquid out of the sludge in an upward direction. The process is one of "sludge compacting" in which each particle above the bottom subsides at a decreasing velocity. In most existing final settling tanks the influent mixed liquor flows as a "density current"[15] along the bottom of the tank, and the process described takes place within this current.

A study of experiments[16] made by W. Rudolfs, M. Am. Soc. C. E., and I. O. Lacy indicates that the hindered settling velocity of activated sludge conforms fairly well with curve B of Fig. 3. The volumetric concentration of good activated sludge in a mixed liquor containing 2,000 ppm of suspended solids appears to be about 10%, indicating 98% water in the floc particles and a net density of about 1.005. The experiments of Messrs. Rudolfs and Lacy indicate that the hindered settling velocity, at room temperature, of a 20,000 ppm sludge is from 0.08 to 0.15 cm per sec. Fig. 3 indicates a free settling velocity of from 0.14 to 0.27 cm per sec for these particles. The equivalent diameter of the floc particles is about 1 mm.

3. Settling Analyses of Suspensions

A settling analysis of a suspension is a laboratory-scale test of its settling qualities made for the purpose of predicting removals or subsidence rates in a plant-scale settling tank. The rate of subsidence in a settling tank is a function of both the settling quality of the suspension and the hydraulic characteristics of the tank. Settling tests made for design purposes or for checking settling tank performance should yield analyses which are characteristic of the suspension when it is subjected during settling to only such tank influences as are readily reproducible in the test container.

The tank characteristics that may be reproduced approximately in a properly designed settling test container are:

(1) Flocculation due to differences in settling velocity of flocculent particles;
(2) Retardation in settling due to turbulence;
(3) Flocculation due to velocity gradients in the liquid; and
(4) Scour from the bottom.

Geometric models of plant-scale tanks cannot be adapted to reproduce these effects, but are quite useful in the measurement of hydraulic short-circuiting. Settling analyses may be corrected for short-circuiting to predict performance in plant-scale settling tanks.

A quiescent analysis of a suspension of discrete particles will yield results that are characteristic of the suspension only. A quiescent settling analysis of a suspension of flocculent particles will yield results which include the effects of flocculation due to differences in particle settling velocity. Stirring is required to reproduce tank characteristics (2), (3), and (4).

To obtain reliable quiescent settling analyses, the following precautions should be taken:

---

[15] "Stratified Flow in Reservoirs and Its Use in Prevention of Silting," by Hugh S. Bell, *Miscellaneous Publication No. 491*, U. S. D. A., September, 1942.

[16] "Settling and Compacting of Activated Sludge," by Willem Rudolfs and I. O. Lacy, *Sewage Works Journal*, Vol. VI, No. 4, 1934, p. 647.

1. The sample should be representative of the suspension to be settled and should be collected in the test container in a manner least likely to change its character. Since settling and flocculation are continuous processes, the time interval between the collection of the sample and the start of the settling test must be small enough to be a negligible factor in the result. With flocculent suspensions, the collection process must not subject the floc particles to greater velocity gradients than prevail in the mother suspension lest they be broken up. Settling analyses of delicate floc are best made in the container in which the floc is formed. Settling analyses made on sewage samples collected from a sewer are of little value for predicting removal in primary tanks if the sewage must first pass through comminutors or meters or be pumped to the tanks.
2. The settling sample should be kept at a constant temperature throughout the depth of the sample by means of a water bath in order to minimize convection currents.
3. If practicable, the settling analysis should be made in a sample whose depth is equal to or greater than the depth of the tank. If the process is largely sludge concentration, a depth equal to the depth of the settling tank is preferable. Settling analyses made in shallow containers are useful in predicting performance in deep tanks, but the predictions are based on extrapolations.

For convenience, a hypothetical settling tank in which settling takes place in exactly the same manner as in a quiescent settling container of the same depth will be referred to as an "ideal basin." In an actual tank settling will differ from the quiescent analysis because of short-circuiting, eddies due to turbulence, bed-load movement or scour, faster flocculation, convection currents, and other causes. Most of these factors retard settling but faster flocculation will promote faster settling. Hence the performance of an actual settling basin will differ from that of the ideal basin, and the removal may be greater or less depending upon the relative magnitude of the disturbing factors.

Quiescent settling tests of the type here advocated have not been used widely in general practice. The Imhoff cone test has long been used in sewage plant operation, but it is inadequate for design. Another test now commonly used for the control of the activated sludge process is the quiescent settling of the "mixed liquor" in liter graduates. A liter of mixed liquor is permitted to settle and the position of the top of the sludge blanket is noted at intervals during a period of 30 min or more. The results of such a test are shown in Fig. 4.

If readings are made at more frequent intervals at the start of settling, this test may be used to make approximate predictions of settling of activated sludge in deep tanks, although a deep container is preferred in order to avoid extrapolations. In the example given in Fig. 4, the slope of the line at the start of settling is a measure of the velocity of hindered settling of the particles in the top of the sludge blanket. Hindered settling is complete at point A, Fig. 4. The rate of compacting thereafter, in terms of the ratio of the volume occupied by the sludge blanket, seems to be little influenced by the depth of the sludge or the temperature, according to the experiments by Messrs. Rudolfs and Lacy.[16] Experiments indicate that sludge compacting begins at a concentration of from 4,000 to 7,000 ppm for good activated sludge. The foregoing principles can be illustrated by two examples, as follows:

Example 1.—For the mixed liquor of Fig. 4, how long will it take for hindered settling to be complete in an ideal tank 10 ft deep, and what will be the depth of the sludge blanket and the solids concentration at the end of this period?

Since the height of the liter graduate in which the test is made is about 40 cm, the velocity indicated is about 0.11 cm per sec. In a 10-ft tank, the settling period corresponding to point A, Fig. 4, is $\frac{10 \times 30.48}{40} \times 3.6 = 27.5$ min. The depth of sludge is 4 ft and the average concentration of suspended solids in the sludge is $\frac{2,000}{0.4} = 5,000$ ppm.

Example 2.—For the same mixed liquor, and the same tank as in Example 1, what settling period is required to produce a sludge with a suspended solids content of 12,500 ppm?

The corresponding volume is $\frac{2,000}{12,500}$ or 16% of the initial volume, and the time required to reach this volume in the test (Fig. 4) was 25 min. Because of the greater depth, however, there is a time lag of 27.5 − 3.6 = 23.9 min for the completion of hindered settling. Hence a settling period of 25 + 23.9 = 48.9 min is required.

Quiescent settling analyses of suspensions of either discrete or flocculent particles may be made in a container of the type illustrated in Fig. 5. The temperature of the water bath should be the same as that of the sample; and at the start of the analysis the suspension should be distributed with a minimum of residual disturbance as uniformly as possible throughout the depth of the container. The interpretation of the analysis and its application to settling tank studies are much simplified if the initial concentration is constant throughout the depth. The analysis consists of determining the initial concentration of suspended matter and the concentration at one or more depths at measured time intervals throughout a period of settling in excess of that required in the settling tank.

Fig. 5.—Apparatus for Quiescent Settling Analyses

The concentration of suspended matter may be measured in terms of suspended solids, turbidity, iron, alumina, calcium, hardness, color, biochemical oxygen demand (B.O.D.), or any other index that is reduced by settling. Fig. 5 indicates means for removal of portions for concentration tests. Portions may be withdrawn quite safely for tests for iron, alumina, calcium, hardness, suspended solids, total solids, and B.O.D.; but this method cannot be used when the turbidity test is used and the results are doubtful with color determinations. Turbidity and color may be measured directly in the settling container by photoelectric or comparator methods. When portions are to be withdrawn for analysis the size of the portion required depends upon the test used and accuracy desired. The cross-section area of the settling container should be large enough to permit withdrawal of all necessary portions without lowering the water surface excessively.

The method to be used for collecting samples in the settling container must be determined for each problem, and considerable ingenuity may be required to obtain satisfactory results. In some cases, the mother suspension may be used as the water bath. If the mother suspension or a representative sample of it can be directed through the water bath so that the concentration is substantially uniform with depth, the test sample may be collected by lowering a bottomless cylinder vertically through the water bath to the bottom, thus trapping the sample within the cylinder.

TABLE 1.—QUIESCENT SETTLING ANALYSES OF SUSPENSIONS

Point[a]	Settling Time, in Minutes[b]												
	0	15		30		45		60		90		180

[a] Sampling points in Fig. 5. [b] The depth below the surface in centimeters, as shown in Fig. 5, is represented by h; and c_r is the ratio of measured concentration to initial concentration. At 0 minutes c_r is equal to 1.

Table 1(*a*) shows a hypothetical settling analysis of a suspension of discrete particles such as would result with unhindered settling and ideal test conditions. The concentration has been recorded for each sampling point and each settling period as the ratio c_r of the measured to the initial concentration. The depth h recorded for each portion is the depth below the surface just before the first portion of the set is withdrawn. To minimize error, portions should be withdrawn in sequence from top to bottom and as rapidly as possible at the end of the measured time interval. Each portion withdrawn comes from a bulb-shaped region as shown at point 5, Fig. 5. The suspension above, except in the immediate vicinity of the sampling point, is drawn down vertically a distance corresponding to the volume removed, with practically no change in the relative position of the suspended particles. Hence the values of h for any period are less than the previous values by an amount corresponding to the volume of all portions withdrawn at the end of the previous period.

Each portion contains no particles whose settling velocities are high enough to carry them from the surface past the sampling point during the settling period. Hence the maximum settling velocity v for each portion is approximately $\frac{h}{t}$, in which t is the settling period. The values of v thus computed for the top samples are correct, but values for the other portions are slightly in error because the values of h do not represent the actual distance settled by the largest particles. The error is greatest for the last sample taken at the lowest sampling point. In the example, the actual distance settled for the last portion taken (point 5 at 180 min, Table 1(a)) is 352.4 cm instead of 350 as recorded.

Since the initial concentration was uniform from top to bottom, the concentration c_r of all particles in a sample whose settling velocities are less than v is the same as the initial concentration. Therefore a "settling velocity curve" may be plotted as a characteristic of the suspension. Fig. 6 represents the data in Table 1(a), the points marked with crosses and circles corresponding to samples from points 2 and 4, respectively. It will be noted that the curve may be drawn from data obtained at only one sampling point, but that data from all sampling points fall on the same curve.

Under ideal test conditions with unhindered settling, if flocculation is taking place, particles that coalesce will thenceforth settle at other velocities, usually faster. This results in more rapid clearing near the bottom than with discrete particles. A hypothetical settling analysis of a flocculent suspension is shown in Table 1(b). A settling velocity curve cannot be drawn for flocculent suspensions because the particles do not retain constant settling velocities. If an attempt is made to draw a settling velocity curve, a separate curve will result for each sampling point. An examination of the tabulated data from a settling analysis to determine if the values of c_r are about the same for all portions having the same value of v will reveal whether the suspension is discrete or flocculent.

4. Clarification Theory for an Ideal Basin

Since an "ideal basin" has been defined as a hypothetical settling tank in which settling takes place in exactly the same manner as in a quiescent settling container of the same depth, an "ideal rectangular continuous flow basin" for unhindered settling has the following characteristics:

1. The direction of flow is horizontal and the velocity is the same in all parts of the settling zone (hence, each particle of water is assumed to remain in

the settling zone for a time equal to the detention period—namely, the volume of the settling zone divided by the discharge rate);

2. The concentration of suspended particles of each size is the same at all points in the vertical cross section at the inlet end of the settling zone; and

3. A particle is removed from suspension when it reaches the bottom of the settling zone.

Any continuous flow basin may be considered as being comprised of four zones (see Fig. 7) according to function as follows: (1) An inlet zone in which the suspension is dispersed uniformly over the cross section of the basin; (2) the settling zone in which all settling takes place; (3) an outlet zone in which the clarified liquid is collected uniformly over the cross section of the basin and directed to an outlet conduit; and (4) a sludge zone at the bottom. The present discussion is confined to the settling zone.

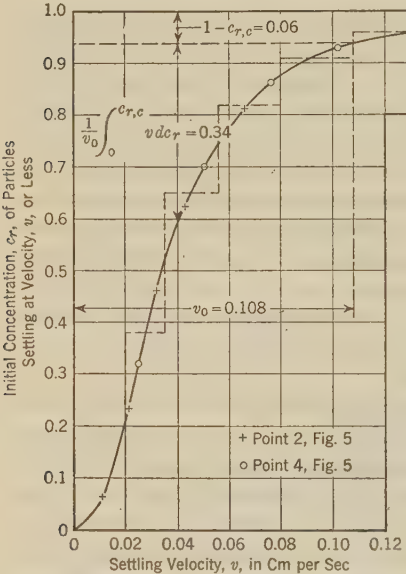

Fig. 6.—Settling Velocity Analysis of Suspension of Discrete Particles (Illustrating Example 5)

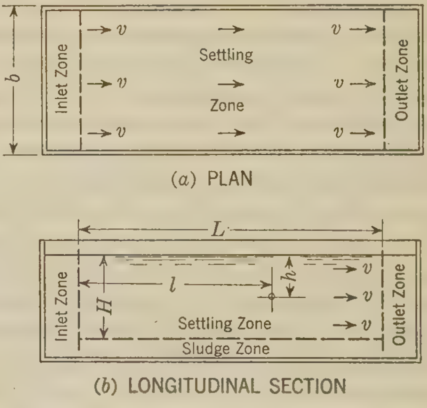

Fig. 7.—Ideal Rectangular Settling Basin

The concentration of suspended matter in any vertical column in an ideal basin will be distributed in precisely the same manner as in the quiescent settling analysis after an equal period of settling. Hence the settling analysis may be used to predict the concentration at any point in the settling zone, in accordance with the following example:

> *Example 3.*—What will be the concentration of suspended matter at a depth of 194 cm in an ideal basin after 60 min of settling of the suspension represented by Table 1(*a*); also of the suspension represented by Table 1(*b*)?
>
> Referring to Table 1, the concentrations are 73% and 21%, respectively, of the original concentration.

In the vertical cross section through any point in an ideal basin the concentration of suspended matter will be distributed vertically as indicated by the values of c_r in the analysis after an equal settling period; and the average concentration is approximately equal to the arithmetical average of the values of c_r throughout the depth H. Therefore, the residual concentration and the removal for any period of settling may be estimated from the analysis, as follows:

> *Example 4.*—What will be the removal in the settling zone of an ideal basin after 60 min of settling of the suspension of Table 1(*a*) if the depth is 390 cm; also if the depth is only 150 cm?
>
> For a depth of 390 cm, the average concentration from Table 1(*a*) is about 0.60; and the removal is therefore 40%. For a depth of 150 cm, the average concentration is about 0.26 and the removal is 74%.

It is evident therefore that a depth and settling period may be selected to secure any removal within the limits of the settling analysis of the suspension. In design the length L and depth H of the settling zone are determined from the removal required. The distribution of solids along the bottom may be estimated by computing the removal in partial lengths l.

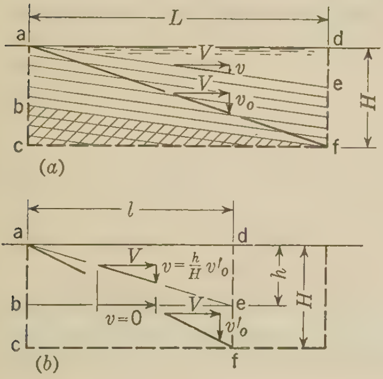

FIG. 8

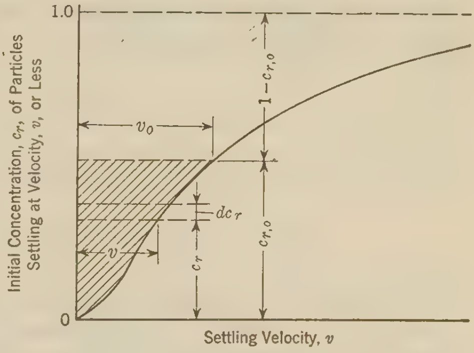

FIG. 9.—TYPICAL SETTLING VELOCITY ANALYSIS CURVE OF SUSPENSION FOR DISCRETE PARTICLES

Any particle settling in a moving liquid will move in a direction and at a velocity, with reference to the basin, which is the vector sum of its own settling velocity and the velocity of the surrounding liquid. In an ideal basin, the settling paths of discrete particles may be used to develop a clarification theory that is helpful in grit-chamber design and in understanding settling phenomena. In an ideal rectangular basin the paths of all discrete particles will be straight lines, and all particles with the same settling velocity will move in parallel paths as illustrated by lines parallel to ae in Fig. 8(*a*). Moreover, the settling pattern will be the same in all longitudinal sections of the settling zone and any longitudinal section, as shown in Fig. 8(*a*), may be considered in a study of the process.[17,18] All particles having settling velocities equal to or greater than v_o will settle out; but the removal of particles having any settling velocity v which is less than v_o will be equal to the ratio $\frac{\overline{\mathrm{bc}}}{\overline{\mathrm{ac}}}$. From similar triangles, this removal ratio is

$$r_r = \frac{v}{v_o} = \frac{b\,L\,v}{Q} \quad \text{(6)}$$

in which $b\,L =$ the surface area of the settling zone of width b and length L; $Q =$ the rate of discharge; and $v_o = \frac{Q}{b\,L} =$ the "overflow rate" or the discharge per unit of surface area of the settling zone.

Eq. 6 appears to have been discovered by the late Allen Hazen,[2] M. Am. Soc. C. E. The area $b\,L$ is the surface area only for basins with vertical side-walls. For basins with sloping walls, $b\,L$ is the average area of horizontal sections throughout the depth of settling.

If the settling velocity analysis of the original suspension is represented by a curve such as Fig. 9, the value of c_r (here designated as $c_{r,o}$) corresponding to the overflow rate v_o of the basin may be read from the curve. Since all particles which settle faster than v_o will be 100% removed, the removal of such particles in terms of the total suspension will be $1 - c_{r,o}$. The removal of particles having any settling velocity v which is less than v_o is given by Eq. 6; and, since the ratio of such particles to the total suspension is dc_r, the removal in terms of the total suspension is

$$r_r\,dc_r = \frac{1}{v_o}\,v\,dc_r \quad \text{(7a)}$$

The total removal of all particles is, therefore,

$$r_r = 1 - c_{r,o} + \frac{1}{v_o}\int_0^{c_{r,o}} v\,dc_r \quad \text{(7b)}$$

It is not necessary to assign an equation to the velocity analysis curve in order to solve for the removal. The last term of Eq. 7b is the average vertical distance from the curve (Fig. 9) to the horizontal line for $c_r = c_{r,o}$. It is the shaded area in Fig. 9 divided by v_o.

The concentration of suspended matter at any point in the settling zone, such as point e, Fig. 8(b), is the initial concentration of all sizes whose settling paths are such as to permit them to reach the point. The only particles that can reach point e are those whose settling velocities are between zero and $\frac{h}{H}\,v'_o$, in which v'_o is the overflow rate for the length l. Therefore, the concentration at point e is c'_r, the value of c_r corresponding to the velocity $\frac{h}{H}\,v'_o$, which may be read directly from the settling velocity analysis curve.

---

[17] "A Study of the Rational Design of Settling Tanks," by Thomas R. Camp, *Sewage Works Journal*, Vol. VIII, No. 5, September, 1936, p. 742.

[18] Discussion by Thomas R. Camp of "Sedimentation in Quiescent and Turbulent Basins," by J. J. Slade, Jr., *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 306.

The foregoing theory also applies to the settling of discrete particles in ideal radial flow basins, in which case the basin velocity V varies inversely as the radial distance, and consequently the paths of the particles are curved. The application of Eq. 7*b* is demonstrated by Example 5, as follows:

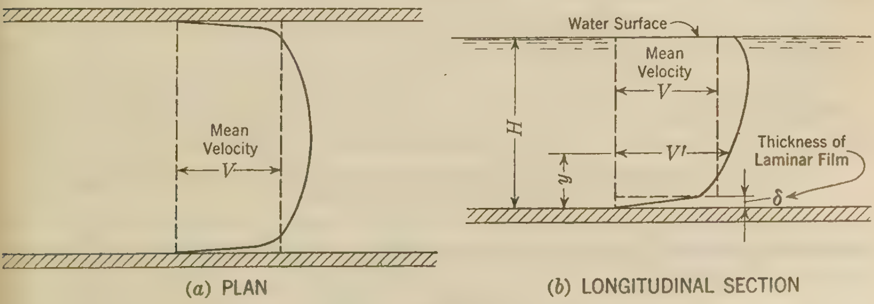
> *Example 5.*—By means of Eq. 7*b*, estimate the removal in the settling zone of an ideal basin after 60 min of settling of the suspension of Table 1(*a*) and Fig. 6 if the depth is 390 cm.
>
> The overflow rate, v_o, of the basin is $\frac{390}{60 \times 60} = 0.108$ cm per sec, and the corresponding value of $c_{r,o}$ from Fig. 6 is 0.94. Since the value of the last term of Eq. 7*b*, from Fig. 6, is about 0.34, the removal is $1 - 0.94 + 0.34 = 0.40$, or 40% as in Example 4.

As a consequence of the foregoing theory (Eqs. 6 and 7), the following conclusions may be drawn with respect to settling of discrete particles in an ideal basin:

1. For any given discharge, the removal is a function of the surface area and is independent of the depth of the basin; or, the removal is a function of the overflow rate and, for a given discharge, is independent of the detention period; and
2. The concentration of suspended matter at any cross section in the settling zone increases with the depth below the surface, and decreases with the proximity of the cross section to the outlet end of the basin. The settling path of a particle of settling velocity v from the surface at the inlet end of the settling zone is a line of equal concentration, the concentration being the corresponding value of c_r from the settling velocity analysis curve of the suspension. Hence, lines of equal concentration intersect at the surface at the inlet end, are straight lines for rectangular basins, and are curved lines for radial flow basins.

5. Tractive Force and Bed-Load Movement

In an actual settling basin the velocity is not uniform over a cross section as assumed for an ideal basin. In a rectangular tank with the best of conditions the distribution will approximate that shown in Fig. 10. The value of the Reynolds number $\frac{VR}{\nu}$, in which R is the hydraulic radius, will in most cases



(*a*) PLAN (*b*) LONGITUDINAL SECTION

Fig. 10

greatly exceed 500. Hence, in most settling tanks the flow will be turbulent. If the walls are smooth, it may be assumed that the flow in a thin "laminar film" of thickness δ, adjacent to the walls and floor, will be streamlined.

If the bottom is covered with a leveled sand bed, A. Shields[19, 20] reasoned that the turbulent flow theory as developed by J. Nikuradse, L. Prandtl, and Theodor von Kármán, M. Am. Soc. C. E., should be applicable to the beginning of bed-load movement. Accordingly, he developed the following relation:

$$\frac{T_c}{(\gamma_s - \gamma)\,D} = \phi\left(\frac{D}{\delta}\right) = \beta \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which T_c is the critical tractive force required to produce motion along the bottom of particles of diameter D and specific weight γ_s, γ is the specific weight of the liquid, and $\phi\left(\frac{D}{\delta}\right)$ is some function of $\frac{D}{\delta}$ which may be assumed equal to a constant β without great error.

The results of experiments by Mr. Shields and others on the critical tractive force of unigranular materials of varying specific gravity are plotted in Fig. 11 in accordance with Eq. 8. For the beginning of bed-load movement, the experiments show that

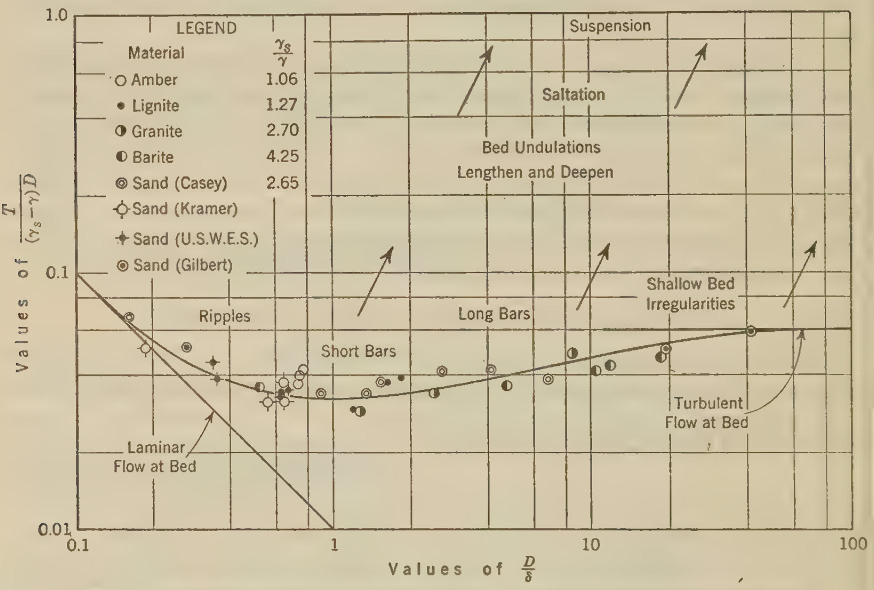


FIG. 11.—BEGINNING OF BED-LOAD MOVEMENT AS A FUNCTION OF GRAIN DIAMETER AND BOUNDARY-LAYER THICKNESS

$$T_c = \beta\,(\gamma_s - \gamma)\,D \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

---

[19] "Anwendung der Aehnlichkeitsmechanik und der Turbulenz forschung auf die Geschiebebewegung," by A. Shields, *Mitteilungen der Preussischen Versuchsanstalt für Wasserbau und Schiffbau*, Heft 26, 1936, Berlin.

[20] "An Analysis of Sediment Transportation in the Light of Fluid Turbulence," by H. Rouse, Sedimentation Div., U. S. D. A., Washington, D. C., July, 1939.

in which the value of β, or $\phi\left(\frac{D}{\delta}\right)$, is about 0.04. For nonuniform material or for sticky and flocculent material, the value of β may be larger. Fine nonuniform sands tend to exhibit two values[21] for the critical tractive force, a lower value (β equal to about 0.04) for impending motion from smooth beds and a higher value (β equaling from 0.10 to 0.25) for impending motion from sand ripples formed from the smooth bed; the values of β, in both cases, corresponding to the mean grain size.

It is evident that the average value of the tractive force T in a unit length of open channel is $\gamma R h_f$, in which R is the hydraulic radius and h_f the head loss. Since, from the Weisbach-Darcy formula,

$$h_f = \frac{f}{4R}\frac{V^2}{2g} \qquad (10)$$

in which f is the well-known friction factor and V is the mean velocity in the channel, it follows that:

$$T = \frac{f}{8}\frac{\gamma V^2}{g} \qquad (11)$$

From Eqs. 9 and 11, the channel velocity required to start motion of particles of size D is

$$V_c = \sqrt{\frac{8\beta}{f} g (s-1) D} \qquad (12)$$

in which s = the specific gravity of the particles.

Eq. 12 indicates that the velocity required to start scour is independent of the size and depth of tank; and that it depends only on the friction factor and the mean particle size and specific gravity. Actually, the value of the tractive force T in Eq. 11 is the mean value around the wetted perimeter. It is constant only for circular pipes flowing full. In open channels, the tractive force is greater at the invert than on the sides, and hence its value at the bottom is influenced by the shape of the cross section. The maximum velocity that may be used in a settling tank to avoid scour is given by Eq. 12.

Eq. 12 is of value in the investigation of sewage grit chambers. Both grit and some organic matter will reach the bottom, but since organic solids are lighter than grit the chamber acts as a "classifier" to separate the organics by bed-load movement. The greater the difference in specific gravity the better is the separation. An application of Eq. 12 is as follows:

Example 6.—Estimate the limiting velocity in a grit chamber to avoid scour of sand particles 0.2 mm in size. What size sand will be started in motion if the velocity is 1.0 ft per sec? What is the relative size of sand and organic matter (assume $s = 1.2$) that will be scoured?

If β is taken at 0.06 and f is assumed to be 0.03, the value of V_c for sand ($s = 2.65$) 0.2 mm in size, from Eq. 12, is 0.75 ft per sec. If V_c is

---

[21] *Paper No. 17*, U. S. Waterways Experiment Station, Vicksburg, Miss., January, 1935.

1.0 ft per sec, the sand size $D = \left(\frac{1.0}{0.75}\right)^2 \times 0.2 = 0.36$ mm. The critical size of organic matter is $\frac{2.65 - 1}{1.2 - 1}$ or eight times as large as the sand.

Eqs. 8 and 12 yield no clue as to the quantity of sediment moved by traction, nor upon the vertical distribution of material picked up from the bottom. As the tractive force is increased more material is thrown into suspension, as shown by Fig. 11; and if the tractive force is great enough all the material appears to be in suspension, as in the case of a clean sewer. Transportation in suspension is not of itself an equilibrium condition. For the concentration in suspension to remain constant at any depth, the rate of pickup from the bottom must equal the rate of settling on to the bottom. If all particles are fixed in position or removed when they reach the bottom, the stream will eventually clarify.

The effect of turbulence on settling of material already in suspension is independent of scour and may or may not be accompanied by bed-load movement.

6. Effects of Turbulence on Sedimentation

The turbulent mixing process works in a manner similar to diffusion. The rate of transport of any substance or fluid property is proportional to the space rate of change in concentration or magnitude of the substance or fluid property, the flow being in the direction of decreasing concentration or magnitude. In the transfer of suspended matter due to mixing, the rate of upward transport at a point y above the bottom (Fig. 10(*b*)) is $-\epsilon\frac{dc}{dy}$, in which $-\frac{dc}{dy}$ is the concentration gradient in the direction of y and ϵ is the mixing coefficient.

The intensity of shear is zero at the water surface and is distributed vertically in two-dimensional open channel flow according to the expression,

$$\tau = T\left(1 - \frac{y}{H}\right) \quad \text{(13)}$$

Therefore, the assumptions made by Prandtl[22] in deriving the theory of turbulent mixing will yield the following relation:

$$\epsilon = \frac{\frac{\tau}{\rho}}{\frac{dV'}{dy}} = \frac{T}{\rho}\,\frac{1 - \frac{y}{H}}{\frac{dV'}{dy}} \quad \text{(14)}$$

in which V' is the velocity at height y. This expression was not expected by Prandtl to hold at the boundaries or at the center of a full pipe where it yields a value of zero for ϵ. Mixing is known to take place across the axis of a full pipe and a finite value for ϵ at the bed seems necessary to start scour.

---

[22] "Bericht über Untersuchungen zur ausgebildeten Turbulenz," by L. Prandt., *Zeitschrift für Angewandte Mathematik und Mechanik*, Vol. 5, No. 2, 1925, p. 136.

The value of ϵ for any depth y in the intermediate zone between bottom and water surface may be estimated by means of Eq. 14 from the slopes of measured velocity distribution curves. The trend of ϵ from Nikuradse's measurements of velocity distribution in both smooth and rough pipes is shown[20] by curve A of Fig. 12. If a logarithmic velocity distribution is assumed, the resulting trend of ϵ is shown by curve B. A more complex expression as developed by Professor von Kármán is shown by curve C,[20] Fig. 12. A parabolic velocity distribution results in a constant value of ϵ throughout the depth:

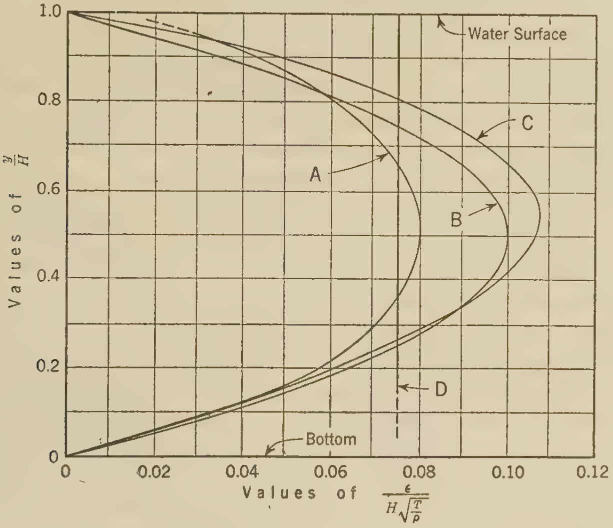

FIG. 12

$$\epsilon = 0.075\, H \sqrt{\frac{T}{\rho}} \quad \text{(15)}$$

as shown by curve D, Fig. 12. The constant 0.075 results in a parabola which approximates Nikuradse's measured velocity distribution from the pipe axis to within 0.9 of the radial distance to the wall. The assumption of a parabolic velocity distribution simplifies computations; but this approximation cannot be used for studying turbulence near the wall since it implies a finite wall velocity.

If the rate of scour from the bed is at equilibrium with the rate of settling in steady uniform flow, the suspended load transport at any height y above the bed is also at equilibrium with settling as follows:

$$\epsilon \frac{dc}{dy} = -v\,c \quad \text{(16)}$$

v being the settling velocity of the particles, and c the concentration of the particles at height y. Integration of Eq. 16 results in an expression for the relative concentration at height y with respect to any other height a:

$$\log_e \frac{c}{c_a} = -v \int^{y} \frac{dy}{\epsilon} \quad \text{(17)}$$

The validity of Eq. 17 has been verified experimentally by Hunter Rouse,[23] M. Am. Soc. C. E., and by W. E. Dobbins,[24] Jun. Am. Soc. C. E., for constant values of ϵ by means of vertical cylindrical tanks equipped with mechanical agitators designed to produce a constant intensity of mixing throughout the depth. It has also been verified by Vito A. Vanoni,[25] Assoc. M. Am. Soc. C. E., for open channel flow with a value for ϵ as shown by curve B, Fig. 12. If a parabolic velocity distribution is assumed as an approximation of the logarithmic distribution in which ϵ may be determined by Eq. 15, and if a is assumed very small compared with H, computed values of $\frac{c}{c_a}$ are substantially correct at 0.4 H. They reach a maximum deviation at 0.1 H and 0.7 H, being too large at 0.1 H and too small at 0.7 H.

In a settling tank the equilibrium condition postulated by Eq. 16 is approached by only those particles which are scoured after they reach the bottom. Eqs. 16 and 17 provide the means, therefore, of estimating the vertical distribution of discrete particles thrown into suspension by bed-load transportation. The equations permit computations of only relative concentrations.

Most of the particles settling in a tank are undisturbed after they reach the bottom, and the effect of turbulence on the settling of these particles is limited to a delaying action. This effect may be investigated for discrete particles with two-dimensional flow in a rectangular tank by studying the concentration changes at a point in the tank such as m, Fig. 13.

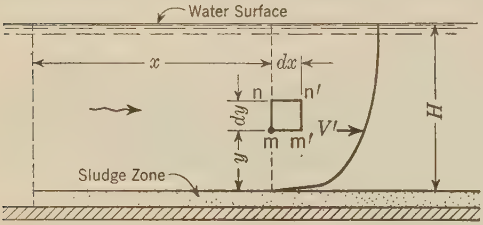

FIG. 13

For the steady state in which the concentration at a fixed point in the tank remains unchanged with time, Ensign Dobbins[24] found that

$$V' \frac{\partial c}{\partial x} = \epsilon_y \frac{\partial^2 c}{\partial y^2} + \left(v + \frac{\partial \epsilon_y}{\partial y} \right) \frac{\partial c}{\partial y} + \epsilon_x \frac{\partial^2 c}{\partial x^2} \quad \text{(18)}$$

in which ϵ_x is the mixing coefficient in the direction of x. No solution of Eq. 18 has been obtained in its general form. Before a solution can be found, V', ϵ_y, and ϵ_x must be expressed as functions of y. The equation can be greatly simplified by making certain approximations. If the assumptions are made that $\epsilon_x \frac{\partial^2 c}{\partial x^2}$ is zero and that both V' and ϵ_y are constant throughout the depth H, Eq. 18 is reduced to

[24] "Effect of Turbulence on Sedimentation," by William E. Dobbins, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 629 (condensed from "A Study of the Effect of Turbulence on Sedimentation," presented to Mass. Inst. Tech., Cambridge, Mass., in partial fulfilment of the requirements for the degree of Doctor of Science, October, 1941).

[25] "Experiments on the Transportation of Suspended Sediment by Water," by Vito A. Vanoni, Sedimentation Div., U. S. D. A., Washington, D. C., September, 1940.

$$V \frac{\partial c}{\partial x} = \epsilon \frac{\partial^2 c}{\partial y^2} + v \frac{\partial c}{\partial y} \qquad (19)$$

Now, if the point m is assumed to move in the direction of x at velocity $V = \frac{\partial x}{\partial t}$, the time rate of change in concentration at m is

$$\frac{\partial c}{\partial t} = \epsilon \frac{\partial^2 c}{\partial y^2} + v \frac{\partial c}{\partial y} \qquad (20)$$

Eq. 20 also expresses the rate of change in concentration at any point m in a settling container in which turbulence of uniform intensity is imposed throughout.

A solution for Eq. 20 has been obtained by Ensign Dobbins[24] and has been verified experimentally. Since no solution has been found for the general form of the differential equation as given by Eq. 18, it is necessary to use Ensign Dobbins' solution of Eq. 20 to obtain an approximation of the effect of turbulence in retarding settling. This integration is also a solution for Eq. 19 and corresponds with the assumption of uniform concentration at the inlet end and constant values for ϵ and tank velocity throughout the tank. For the case of no scour, the writer[26,27] has transformed Ensign Dobbins' solution so that the results are given in terms of the removal as follows:

$$r_r = 1 - 8 \left(\frac{v\,H}{2\,\epsilon}\right)^2 e^i \sum_{n=1}^{\infty} \frac{\alpha^2{}_n\, H_n\, e^j}{\left[\left(\frac{v\,H}{2\,\epsilon}\right)^2 + \alpha^2{}_n + 2\,\frac{v\,H}{2\,\epsilon}\right]\left[\left(\frac{v\,H}{2\,\epsilon}\right)^2 + \alpha^2{}_n\right]^2} \qquad (21)$$

in which $\alpha_1, \alpha_2, \alpha_3, \cdots, \alpha_n$ are the successive real positive roots of the transcendental equation

$$2 \cot \alpha = \frac{\alpha}{\frac{v\,H}{2\,\epsilon}} - \frac{\frac{v\,H}{2\,\epsilon}}{\alpha} \qquad (22)$$

H_n is $+1$ when α is in the first and second quadrants and -1 when α is in the third and fourth quadrants; v_o is the overflow rate; and to simplify typography

$$i = \frac{v\,H}{2\,\epsilon} \qquad (23a)$$

and

$$j = -\,(i^2 + \alpha^2{}_n)\,\frac{v}{2\,i\,v_o} \qquad (23b)$$

---

[26] "The Effect of Turbulence in Retarding Settling," by T. R. Camp, *Bulletin 27*, *Proceedings*, 2d Hydraulics Conference, Iowa Inst. of Hydr. Research, Univ. of Iowa, Iowa City, 1942, p. 307.

[27] *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 660.

The removal in Eq. 21 is expressed as a function of only three variables, $\frac{v\,H}{2\,\epsilon}$, α_n, and $\frac{v}{v_o}$, all of which are dimensionless. Fig. 14 is a dimensionless plot for the graphical solution of Eq. 21. The successive values of α required for each computed point on this graph were determined to six decimal places by trial and error solutions of Eq. 22. Convergence of the series is rapid for low values of $\frac{v\,H}{2\,\epsilon}$, only one term being required for a value of 0.1; but fourteen terms were required for $\frac{v\,H}{2\,\epsilon} = 30$, and no solution could be obtained for $\frac{v\,H}{2\,\epsilon} = 100$.

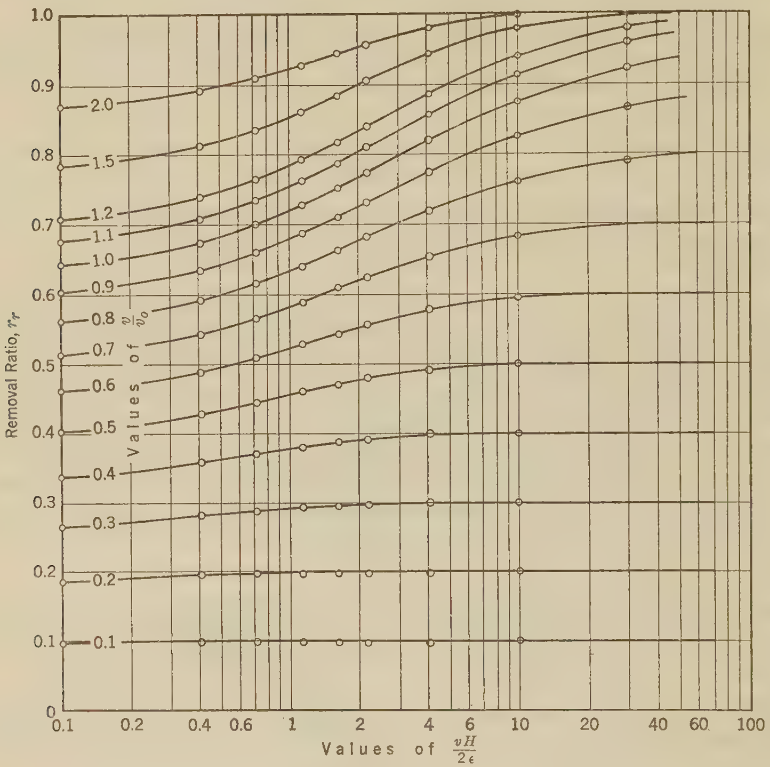

Fig. 14

In order to use Fig. 14 to estimate the removal in an actual settling tank with a free liquid surface, it is convenient to use values of ϵ arising from the assumption of parabolic velocity distribution as given by Eq. 15. With this value for ϵ and the friction factor f taken arbitrarily at 0.024:

$$\frac{v\,H}{2\,\epsilon} = 122\,\frac{v}{V} = 122\,\frac{v_o}{V}\,\frac{v}{v_o} = 122\,\frac{H}{L}\,\frac{v}{v_o} \ldots\ldots\ldots\ldots\ldots (24)$$

For values of $\frac{L}{H}$ ranging from about $\frac{2}{3}$ to 200 as they do in practice, and for values of $\frac{v}{v_o}$ from 0.1 to 2.0; Eq. 24 indicates a range from 0.06 to 81 for values of $\frac{v\,H}{2\,\epsilon}$.

The direct application of Fig. 14 in practice is limited to the determination of the length of grit chambers or other tanks settling discrete particles. The method of designing grit chambers on the basis of the simple theory of sedimentation for ideal basins (Eqs. 6 and 7*b*) has been described elsewhere.[28] An example of the application of Fig. 14 is as follows:

Example 7.—Determine the length of the settling zone of a grit chamber 4 ft deep which is required to effect a 95% removal of grit settling at 2 cm per sec when the chamber velocity is 1.0 ft per sec.

From Eq. 24, $\frac{v\,H}{2\,\epsilon} = 122\,\frac{v}{V} = 122\,\frac{2}{30.48 \times 1} = 8.0$. From Fig. 14 for 95% removal, $\frac{v}{v_o} = 1.3$ and $v_o = \frac{2}{30.48 \times 1.3} = 0.05$ ft per sec. Since $\frac{L}{H} = \frac{V}{v_o}$, the required length of the settling zone is $L = 40\,\frac{1.0}{0.05} = 80$ ft. If there were no retardation of settling by turbulence, $\frac{v}{v_o}$ would be 0.95 and the required length would be only 58.5 ft.

7. FLOCCULENT SUSPENSIONS

Flocculation in a settling tank is due to two causes:

1. Differences in the settling velocities of the particles whereby faster settling particles overtake those which settle more slowly and coalesce with them; and
2. Velocity gradients in the liquid which cause particles in a region of higher velocity to overtake those in adjacent stream paths moving at slower velocity.

In the ideal basin and in quiescent settling tests only the first cause is present. The degree of flocculation is difficult to measure except in terms of the effect on settling; but this effect may be measured by concentration tests at intervals of depth and time. Some experimental data,[17,18,29] mostly qualitative, are available.

Where flocculation occurs, settling velocities are usually increased. It is difficult to obtain a correlation between the rate of change of settling velocities and the rate of flocculation, because, when particles coalesce, size, density, and shape are all changed. The rate of flocculation is a function of the number of contacts between particles in unit time. Hence the number of contacts per unit time in unit volume may be used as a measure of the rate of flocculation, and where the rate is highest it may be assumed that the effect on settling is greatest.

---

[28] "Grit Chamber Design," by Thomas R. Camp, *Sewage Works Journal*, Vol. 14, No. 2, 1942, pp. 368–381.

[29] *Transactions*, Am. Soc. C. E., Vol. LIII (December, 1904), pp. 53 and 72.

In quiescent settling, a particle of diameter D_1 and settling velocity v_1 will contact in unit time all particles of diameter D_2 and settling velocity v_2 in a cylinder whose volume is $\frac{\pi}{4}(D_1 + D_2)^2(v_1 - v_2)$. If n_2 is the number of particles of diameter D_2 per unit volume, the number of contacts per unit of time per unit of volume with each 1-particle is $n_2 \frac{\pi}{4}(D_1 + D_2)^2(v_1 - v_2)$. If n_1 is the number of particles of diameter D_1 per unit of volume, the total number of contacts per unit of time per unit of volume due to settling velocity[30] is

$$N_s = n_1 n_2 \frac{\pi}{4}(D_1 + D_2)^2(v_1 - v_2) \qquad (25a)$$

If the consideration is limited to viscous settling, the Stokes law value of v from Eq. 5 may be substituted in Eq. 25*a* so that

$$N_s = n_1 n_2 \frac{\pi g (s - 1)}{72 \nu}(D_1 + D_2)^3(D_1 - D_2) \qquad (25b)$$

in which all particles have the same density.

It will be noted that there will be no union of particles having the same settling velocity, and that the rate of flocculation is proportional to the difference in settling velocities. The effect of flocculation will thus be more apparent near the bottom of deep tanks after a period of settling. Also it will be noted that since the rate of flocculation is proportional to the relative number of contacts, $\frac{N_s}{n}$ (in which n is the total number of particles per unit volume, and both n_1 and n_2 are proportional to n), the rate of flocculation is directly proportional to the concentration.

From a similar development,[30] the total number of contacts per unit of time per unit of volume due to a velocity gradient in the fluid is

$$N_v = n_1 n_2 \tfrac{1}{6} G (D_1 + D_2)^3 \qquad (26)$$

in which G represents the mean temporal velocity gradient in the fluid. Thus the rate of flocculation due to velocity gradient is directly proportional to the velocity gradient.

The velocity gradients in a settling tank are due both to the residual turbulence at the inlet and to the drag on the walls and floor. This discussion will be limited to velocity gradients caused by drag, the mean value of which can be evaluated as a function of tank shape and velocity as follows.

The shearing force on the opposite faces of an elementary cube of fluid in which the velocity gradient is $\frac{dv'}{dz}$ is $\mu \frac{dv'}{dz}\,dx\,dy$, and the work done per unit of time is $\mu \left(\frac{dv'}{dz}\right)^2 dx\,dy\,dz$. Hence, the work done by shear per unit of volume per unit of time[30] is

---

[30] "Velocity Gradients and Internal Work in Fluid Motion," by T. R. Camp and P. C. Stein, *Journal*, Boston Soc. of Civ. Engrs., October, 1943, p. 219.

$$W = \mu \left(\frac{dv'}{dz} \right)^2 \qquad (27a)$$

or

$$W = \mu G^2 \qquad (27b)$$

in which G is the root-mean-square velocity gradient throughout the fluid. The work done in a tank of length L in unit time, by drag, is

$$Q g \rho h_f = Q g \rho \frac{f L}{4 R} \frac{V^2}{2 g} = \frac{f L b H}{8 R} \rho V^3 \qquad (28)$$

from which the work done per unit of volume per unit of time is

$$W = \frac{f}{8 R} \rho V^3 \qquad (29)$$

Equating the values of W from Eqs. 27 and 29, the mean velocity gradient in the tank due to drag on the walls and floor is found to be

$$G = \sqrt{\frac{f}{8 \nu R} V^3} \qquad (30)$$

If this value of G is substituted in Eq. 26, the total number of contacts per unit of time per unit of tank volume due to velocity gradients is

$$N_V = \frac{n_1 n_2}{6} \sqrt{\frac{f}{8 \nu R} V^3} (D_1 + D_2)^3 \qquad (31)$$

From Eq. 31, it may be seen that the rate of flocculation due to velocity gradients is proportional to $V^{1.5}$ and inversely proportional to $\sqrt{R}$. Hence this type of coagulation is greatest for shallow tanks with relatively high velocities.

Computations by means of Eqs. 25*b* and 31 of the relative rates of flocculation due to settling and velocity gradients in water and sewage tanks indicate that:

(1) Flocculation in deep tanks at low velocity ($R = 20$ ft and $V = 1$ ft per min) is due almost entirely to differential settling velocities; and

(2) The rates of flocculation by the two processes are about the same in a tank 2 ft deep with a velocity of 10 ft per min.

The particles of flocculent suspensions are fragile and subject to rupture by shear, the shearing strength being less as the particle size increases. Although velocity gradients in the fluid bring small particles together to form larger ones, it is evident that there is a limiting size of particle which is determined by the mean shearing force and the strength of the floc. Since the mean shearing force is proportional to the mean velocity gradient, there is a limiting size corresponding to each value of the mean velocity gradient G; and the size is greater the smaller the velocity gradient. If the particles of a flocculent suspension entering the settling tank have not reached this limiting size, they will continue to coalesce until they have either reached this size or passed from the settling zone.

The flocculation of suspensions dealt with in water and sewage treatment is rarely complete when the particles enter the settling tanks, because they have been subjected to much higher velocity gradients during conveyance to the tanks. The additional flocculation caused by turbulence in the tanks may speed up the settling to a greater extent than turbulent mixing retards it. There is much qualitative experimental evidence that most of the suspensions are very much under-flocculated and that additional flocculation will greatly improve settling.

In a number of cases in the writer's studies in which two similar samples of iron floc were permitted to settle in liter graduates after a 30-min mixing period, one settling undisturbed and the other gently stirred, the stirred sample invariably clarified much more rapidly. In studying the flocculation and settling of iron floc in battery jars, Darrell A. Root[31] found that, with a total time of mixing and quiescent settling in excess of 75 min, any increase in mixing time at the expense of settling time up to 60 min of mixing would improve the settling.

In laboratory experiments on nine raw sewages from widely separated plants, A. J. Fischer, Assoc. M. Am. Soc. C. E., and A. Hillman have shown[32] that 20 min of self-flocculation prior to settling increases the removal of suspended solids after 60 min of settling by 4% to 36% over results obtained without flocculation, an average improvement of 20%. Plant-scale tests at Cedar Rapids, Iowa, and Sioux Falls, S. Dak., have demonstrated that the improvement expected from preflocculation can be obtained. Many primary sewage tanks have been built with provisions for preflocculation, and it is probable that this will become standard practice.

It is evident from the foregoing discussion that increased removal should be expected from tanks with higher velocities than are commonly used. In order to determine the optimum velocity and depth for a particular suspension, settling tests with turbulence superimposed are desirable. Already mechanical mixing grids have been used successfully to reproduce particular values of the mixing coefficient ϵ. It is quite likely that the dimensions, amplitudes, and mixing speeds of these devices can be adjusted so as to produce, at the same time, the desired values of ϵ and the mean velocity gradient G. The magnitude of G can be computed from the measured work input by Eq. 27*b*. Thus the effects of both turbulent retardation and coagulation can be taken account of in the settling tests.

8. OVERFLOW RATE, DETENTION PERIOD, VELOCITY, AND TANK DIMENSIONS

In the simple theory of sedimentation of discrete particles in an ideal basin it was demonstrated that the removal is a function of the overflow rate and is independent of the tank depth and the detention period. It follows from the simple theory that the most economical tank will have the least possible depth for the required overflow rate.

---

[31] "The Effect of Temperature Upon the Rate of Floc Formation," by Darrell A. Root, thesis submitted to Mass. Inst. Tech., Cambridge, Mass., in 1939, in partial fulfilment of the requirements for the degree of Master of Science.

[32] "Improved Sewage Clarification by Preflocculation Without Chemicals," by A. J. Fischer and A. Hillman, *Sewage Works Journal*, Vol. 12, No. 2, p. 280.

For a given overflow rate and fixed horizontal dimensions, the tank velocity varies inversely as the depth. Hence, the least possible depth is fixed by the maximum velocity that can be used without excessive scour. The magnitude of this velocity can be determined experimentally or estimated by Eq. 12, a relation which holds for either discrete or flocculent particles with the proper value of β.

The effect of turbulent mixing on these conclusions may be studied by means of Eqs. 21 and 24 and Fig. 14. It is evident from Eq. 24 that $\frac{v H}{2 \epsilon}$ is directly proportional to the depth, and since the removal is a function of $\frac{v H}{2 \epsilon}$ it is not independent of the depth as indicated in the simple theory. The effect of depth, however, is small. Fig. 14 indicates that a 50% decrease in depth will decrease the removal of discrete particles by not more than about 5% on the average; that is, a decrease in volume of 50% through a decrease in depth may be compensated for by a 5% increase in volume through increased surface area. For economy, therefore, the conclusion still holds that the depth should be made as small as is consistent with no scour.

Since flocculation in a settling tank produces a smaller concentration gradient, the retardation of settling due to turbulence will be even less than for discrete particles. Hence, from the standpoint of turbulent retardation of settling, shallow high-velocity tanks are more economical than deep tanks for both discrete and flocculent suspensions. Flocculation, however, also changes the settling velocity of the particles. With the data available, it is not possible to draw conclusions regarding the effect of flocculation upon removal, except that removal is generally increased. It is possible, however, to draw conclusions relating to the effect of depth upon flocculation and indirectly upon removal. Two limiting cases may be considered for argument—(1) deep tanks with low velocities in which coagulation is due entirely to differences in settling velocities; and (2) shallow tanks with high velocities in which the rates of coagulation by settling and velocity gradient are about equal.

Eq. 25*b* indicates that the rate of flocculation in deep tanks with low velocities is independent of the velocity or depth. If it is assumed that flocculation continues throughout the settling period (in other words, that the limiting size of particle is not reached), the amount of flocculation will be directly proportional to the detention period. Hence, an increase in depth for the same overflow rate will produce a proportional increase in the amount of flocculation. An increase in depth will thus increase removal; but it is not possible to state, without settling tests, whether the same increase in removal might not be obtained more economically by a decrease in overflow rate.

Eq. 31 indicates that the rate of flocculation due to velocity gradients is proportional to $\sqrt{\frac{V^3}{H}}$ in tanks whose depth is small compared to width. For the same horizontal dimensions V varies inversely with H. Hence, the rate of flocculation is proportional to $\frac{1}{H^2}$; and, assuming continuous flocculation, the amount of flocculation is inversely proportional to the depth. If the rates of flocculation by settling and velocity gradients are about equal, an increase in the amount of flocculation by velocity gradients due to a decrease in depth should be compensated for by a decreased flocculation due to settling. Therefore, for this case, the amount of flocculation should be independent of the depth for the same overflow rate. In shallow tanks with high velocities, removal of flocculent suspensions should be relatively independent of tank depth for the same horizontal dimensions and overflow rate, provided there is no scour, and provided the particles do not reach the limiting size. Hence, for economy, the same conclusion may be drawn, as with discrete suspensions, that the depth should be made as small as is consistent with no scour.

The minimum depth will result from the least practical value of the hydraulic radius. This economic value of R may be computed from Eq. 30 by using the optimum mean velocity gradient, G_o, which will yield the desired removal with the greatest overflow rate and the maximum velocity, V_c, which will not scour. The economic hydraulic radius is

$$R_e = \frac{\frac{f}{8\nu} V^3_c}{G^2_o} \qquad (32)$$

In a tank with a rectangular cross section, the hydraulic radius is, for a free water surface,

$$R = \frac{b\,H}{b + 2\,H} = \frac{\frac{Q}{V}}{\frac{Q}{V\,H} + 2\,H} \qquad (33a)$$

and, for a submerged cover,

$$R = \frac{b\,H}{2\,b + 2\,H} = \frac{\frac{Q}{V}}{\frac{2\,Q}{V\,H} + 2\,H} \qquad (33b)$$

It follows from Eqs. 33 that the economic tank depth is, for a free water surface,

$$H_e = \frac{Q}{4\,V_c\,R_e} - \sqrt{\left(\frac{Q}{4\,V_c\,R_e}\right)^2 - \frac{Q}{2\,V_c}} \qquad (34a)$$

and, for a submerged cover,

$$H_e = \frac{Q}{4\,V_c\,R_e} - \sqrt{\left(\frac{Q}{4\,V_c\,R_e}\right)^2 - \frac{Q}{V_c}} \qquad (34b)$$

It will be noted that Eqs. 34 yield unreal results if $\frac{Q}{2\,V_c}$ and $\frac{Q}{V_c}$ are greater than $\left(\frac{Q}{4\,V_c\,R_e}\right)^2$. This indicates the existence of a minimum or limiting discharge; and, if the actual value of Q is less than the limiting value, Eqs. 34

are not applicable. The limiting discharge is, for a free water surface,

$$Q_{\text{lim}} = 8\,V_e\,R^2_e \qquad (35a)$$

and, for a submerged cover,

$$Q_{\text{lim}} = 16\,V_e\,R^2_e \qquad (35b)$$

For this discharge the width of the tank is twice the depth for a free water surface and is equal to the depth for a submerged cover.

If the actual discharge is less than Q_{lim}, for best economy the width must be twice the depth for a free water surface and equal to the depth for a submerged cover. For this case, therefore, for a free water surface,

$$Q = 8\,V\,R^2 \qquad (36a)$$

and, for a submerged cover,

$$Q = 16\,V\,R^2 \qquad (36b)$$

in which V must be less than V_e, R must be less than R_e, or both V and R must be reduced. If V_e is maintained and R reduced, the optimum velocity gradient will be exceeded and the overflow rate must be decreased to obtain the required removal. If V is reduced and R_e maintained, the velocity gradient will be less than the optimum, and a decrease in overflow rate will be required. No decrease in overflow rate will be required if the optimum velocity gradient is maintained, but both V and R must be reduced. If the values of R from Eqs. 36 are introduced into Eq. 30, the value of V required to maintain the optimum velocity gradient is, for a free water surface,

$$V = \sqrt[7]{8\,Q\left(\frac{\nu}{f}\right)^2 G^4_o} \qquad (37a)$$

and, for a submerged cover,

$$V = \sqrt[7]{4\,Q\left(\frac{\nu}{f}\right)^2 G^4_o} \qquad (37b)$$

The corresponding values of R may be computed from Eqs. 36 with values of V given by Eqs. 37.

A direct procedure for the economic design of settling tanks for flocculent suspensions is to make settling analyses of the suspensions in containers equipped with stirring devices designed to produce any desired values of ϵ and G and to control the rate of scour from the bottom. If it is anticipated that a shallow high velocity tank can be used, the depth of container is not important. The method of designing stirring devices for this purpose has not yet been developed, but studies[33] with this objective have been made in the Sanitary Engineering Laboratory of the Massachusetts Institute of Technology, at Cambridge, Mass.

In the first series of tests, there should be no scour from the bottom and the magnitude of G should be increased progressively until a gradient is found that will produce the desired removal with the greatest overflow rate. The overflow rate is the depth of container divided by the time of settling. The values of ϵ to be used in this series may be computed by means of Eq. 15, and hence it is necessary to anticipate the approximate values of V and H. The stirring device may be calibrated for ϵ with a suspension of discrete particles of known settling velocity by means of Eq. 17.

---

[33] "Measurement of Work Input in Liquids by Reciprocating Mixing Devices," by K. A. Ignacio, thesis submitted to Mass. Inst. Tech., Cambridge, Mass., in 1943, in partial fulfilment of the requirements for the degree of Master of Science.

The next series of tests should be made at the optimum velocity gradient, G_o, previously found; or, if this value is too high, at the maximum practical value of G. In this series, scour from the bottom should be increased progressively until it just begins to reduce the removal. The amount of scour may be controlled by regulating the mean position of the stirring device relative to the bottom of the container. The device may be calibrated to determine the relation between incipient scour and tank velocity V by means of Eq. 12 and a bed of granular material of known size and density.

These settling tests should yield the best values of G and V, and the overflow rate v_o which is required for the desired removal. The tank dimensions may then be determined with the foregoing equations. The procedure is best illustrated by a number of examples, as follows:

Example 8.—Assume that settling analyses of a flocculent suspension at 10° C have resulted in the following test data for the required removal:

Velocity gradient G (sec^{-1})	Overflow rate v_o (gal per day per sq ft)	Non-scouring velocity V_e (cm per sec)
2.0	1,000	5.08
6.0	1,500	....
9.0	1,800	....
12.0	2,000	5.08
15.0	1,800	....
18.0	1,200	....

The problem is to determine the economic dimensions of the settling zone in rectangular tanks for (*a*) $Q = 30$ cu ft per sec $= 19.4$ mgd; and (*b*) $Q = 0.1$ cu ft per sec $= 64{,}600$ gal per day. The test data indicate that G_o is 12 sec^{-1} and that V_e is 5.08 cm per sec or $\frac{1}{6}$ ft per sec. Assuming that $f = 0.032$, the economic hydraulic radius, from Eq. 32, is: $R_e = \dfrac{\dfrac{0.032}{8 \times 0.01} \times 5.08^3}{12^2} = 0.366$ cm $= 0.144$ in. This value corresponds with tank depths of 0.14 in. and 0.28 in. for open and covered tanks, respectively, and it is obviously impracticable to construct such tanks. A tank of the tray clarifier type is indicated, however. Let it be assumed that the minimum depth of pass practical for construction and sludge removal is 6 in. (15.2 cm). Then R is about 7.6 cm and, from Eq. 30, the corresponding velocity gradient is

$$G = \sqrt{\frac{f}{8\,\nu\,R}\,V^3{}_e} = \sqrt{\frac{0.032}{8 \times 0.01 \times 7.6} \times 5.08^3} = 2.64 \text{ sec}^{-1}.$$

The test data indicate that, with this velocity gradient, the overflow rate must be reduced to about 1,000 gal per day per sq ft or 1.547×10^{-3} ft per sec to obtain the required removal.

(*a*) For $Q = 30$ cu ft per sec, $b = \frac{Q}{VH} = \frac{30}{\frac{1}{6} \times 0.5} = 360$ ft; and $L = \frac{V}{v_o} \times H = \frac{\frac{1}{6}}{1.547 \times 10^{-3}} \times 0.5 = 54$ ft. The width of pass for this discharge is obviously too great, and it is necessary to divide the discharge through a number of passes whose width is satisfactory for construction and sludge removal purposes. Let it be assumed that a width of 18 ft is satisfactory. There will then be twenty parallel passes, each 18 ft wide by 6 in. deep by 54 ft long and passing 1.5 cu ft per sec. For convenience, they may be stacked vertically in two tanks, each with ten trays. For each pass, from Eq. 33*b*: $R = \frac{18 \times 0.5}{2\,(18 + 0.5)} = 0.243$ ft, which is sufficiently close to the assumed value (7.6 cm = 0.25 ft) so that there will be no appreciable change in the computed value of the velocity gradient, 2.64 sec^{-1}. The detention period, $T = \frac{H}{v_o} = \frac{0.5}{1.547 \times 10^{-3}} = 323$ sec = 5.4 min.

(*b*) For $Q = 0.1$ cu ft per sec, the width of the tank will be much less than for $Q = 30$ cu ft per sec and will have an appreciable effect on R. If it is again assumed that 6 in. is the minimum practical depth, $b = \frac{0.1}{\frac{1}{6} \times 0.5} = 1.2$ ft.

From Eq. 33*b*, $R = \frac{1.2 \times 0.5}{2\,(1.2 + 0.5)} = 0.177$ ft = 5.4 cm, and from Eq. 30, $G = \sqrt{\frac{0.032}{8 \times 0.01 \times 5.4} \times 5.08^3} = 3.12\ \text{sec}^{-1}$. From the test data, the required removal can be obtained with an overflow rate of about 1,100 gal per day per sq ft ($v_o = 1.7 \times 10^{-3}$ ft per sec). Therefore, $L = \frac{\frac{1}{6}}{1.7 \times 10^{-3}} \times 0.5 = 49$ ft, and the detention period $T = \frac{0.5}{1.7 \times 10^{-3}} = 294$ sec = 4.9 min.

This tank may be made shorter by dividing the total length into a number of passes in series, stacked vertically or side by side.

It is not practical to use an open surface tank for this case because, to obtain the same velocity gradient, the depth would be only 3 in.

Example 9.—Assume that settling analyses of a flocculent suspension at 10° C have resulted in the following test data for the required removal:

Velocity gradient G (sec^{-1})	Overflow rate v_o (gal per day per sq ft)	Non-scouring velocity V_s (cm per sec)
0.2	200	....
0.5	400	....
1.0	600	3.81
1.5	400	....

Determine the economic dimensions of the settling zone in rectangular tanks for: (*a*) $Q = 30$ cu ft per sec = 19.4 mgd; and (*b*) $Q = 0.1$ cu ft per sec = 64,600 gal per day.

The test data indicate that $G_o = 1.0\ \text{sec}^{-1}$, $V_c = 3.81$ cm per sec, or $\frac{1}{8}$ ft per sec, and the overflow rate required is 600 gal per day per sq ft or 0.928×10^{-3} ft per sec. Assuming that $f = 0.032$, the economic hydraulic radius from Eq. 32 is $R_e = \dfrac{\dfrac{0.032}{8 \times 0.01} \times 3.81^3}{1^2} = 22.2$ cm $= 0.728$ ft.

(*a*) For $Q = 30$ cu ft per sec, $\dfrac{Q}{V_c R^2_e} = \dfrac{30}{\frac{1}{8} \times 0.728^2} = 453$. From Eqs. 34, H_e is about 0.73 ft for an open tank and 1.46 ft for a submerged cover. The corresponding widths are $\dfrac{30}{\frac{1}{8} \times 0.73} = 328$ ft and 164 ft. The tank with the free water surface is the cheaper because its length will be half that of the tank with the submerged cover. Therefore, $L = \dfrac{V_c}{v_o} \times H_e = \dfrac{\frac{1}{8}}{0.928 \times 10^{-3}} \times 0.73 = 98.3$ ft and the detention period is $T = \dfrac{H_e}{v_o} = \dfrac{0.73}{0.928 \times 10^{-3}} = 786$ sec $= 13.1$ min.

If it is desired to divide the width into parallel passes about 18 ft wide for sludge removal mechanism, there will be eighteen passes each with a discharge of 1.67 cu ft per sec. For each pass, $\dfrac{Q}{V_c R^2_e} = \dfrac{1.67}{\frac{1}{8} \times 0.728^2} = 25.2$. From Eq. 34*a*, $H_e = 0.8$ ft; and $b = 20.8 \times \dfrac{1}{0.8} = 16.65$ ft. Also, $L = \dfrac{\frac{1}{8}}{0.928 \times 10^{-3}} \times 0.8 = 108$ ft; and the detention period is $T = \dfrac{108}{7.5} = 14.4$ min.

(*b*) For $Q = 0.1$ cu ft per sec, $\dfrac{Q}{V_c R^2_e} = \dfrac{0.1}{\frac{1}{8} \times 0.728^2} = 1.51$.

It is evident that Q is less than Q_{lim}. Therefore, for economy, the velocity as given by Eq. 37*a* is $V = \sqrt[7]{8 \times 0.1 \times \overline{30.48}^3 \times \left(\dfrac{0.01}{0.032}\right)^2 \times \overline{1.0}^4} = 3.0$ cm per sec $= 0.0983$ ft per sec; and, from Eq. 36*a*, $R = \sqrt{\dfrac{Q}{8\,V}} = \sqrt{\dfrac{0.1}{8 \times 0.0983}} = 0.357$ ft. Finally: $H = 2 \times 0.357 = 0.715$ ft; $b = 2 \times 0.715 = 1.43$ ft; $L = \dfrac{V}{v_o} \times H = \dfrac{0.0983}{0.928 \times 10^{-3}} \times 0.715 = 75.8$ ft; and $T = \dfrac{75.8}{0.0983} = 772$ sec $= 12.8$ min.

Example 10.—Assume that settling analyses of a flocculent suspension at 10° C have resulted in the following test data for the required removal:

Velocity gradient G (sec^{-1})	Overflow rate v_o (gal per day per sq ft)	Non-scouring velocity V_c (cm per sec)
0.1	200	....
0.2	300	....
0.3	400	3.81
0.4	300	....
0.5	200	....

Determine the economic dimensions of the settling zone in rectangular tanks for: (a) $Q = 30$ cu ft per sec $= 19.4$ mgd; and (b) $Q = 0.1$ cu ft per sec $= 64{,}600$ gal per day. The test data indicate that G_o is 0.3 sec^{-1} and V_c is 3.81 cm per sec, or $\frac{1}{8}$ ft per sec, and that the required overflow rate is 400 gal per day per sq ft or 0.618×10^{-3} ft per sec. Assuming that $f = 0.032$, the economic hydraulic radius, from Eq. 32, is $R_e = \dfrac{\frac{0.032}{8 \times 0.01} \times 3.81^3}{0.3^2} = 247$ cm $= 8.1$ ft.

(a) For $Q = 30$ cu ft per sec, $\dfrac{Q}{V_c R^2_e} = \dfrac{30}{\frac{1}{8} \times \overline{8.1}^2} = 3.66$. It is evident that Q is less than Q_{lim}. Therefore, for economy, the velocity must be reduced as given by Eq. 37*a* to $V = \sqrt[7]{8 \times 30 \times \overline{30.48}^3 \times \left(\dfrac{0.01}{0.032}\right)^2 \times \overline{0.3}^4} = 3.41$ cm per sec $= 0.112$ ft per sec and, from Eq. 36*a*, $R = \sqrt{\dfrac{Q}{8\,V}} = \sqrt{\dfrac{30}{8 \times 0.112}} = 5.8$ ft. Finally: $H = 2 \times 5.8 = 11.6$ ft; $b = 2 \times 11.6 = 23.2$ ft; $L = \dfrac{V}{v_o} \times H = \dfrac{0.112}{0.618 \times 10^{-3}} \times 11.6 = 2{,}100$ ft; and $T = \dfrac{2{,}100}{0.112} = 18{,}800$ sec $= 5.22$ hr. The 2,100-ft length may be divided into a number of passes in series, placed side by side.

For this case it may be more economical to divide the 30 cu ft per sec between a number of parallel passes and thus reduce the depth and detention period. For example, if six passes are used, each with a discharge of 5 cu ft per sec, the dimensions of each will be: $H = 5.36$ ft; $b = 10.72$ ft; and $L = 754$ ft. The detention period will be reduced to 2.42 hr. The most economical number of passes can be determined only by considering the construction costs.

(b) For $Q = 0.1$ cu ft per sec, the discharge is again less than Q_{lim}, and, from Eq. 37*a*, $V = \sqrt[7]{8 \times 0.1 \times \overline{30.48}^3 \times \left(\dfrac{0.01}{0.032}\right)^2 \times \overline{0.3}^4} = 1.51$ cm per sec $= 0.0495$ ft per sec.

From Eq. 36*a*, $R = \sqrt{\dfrac{Q}{8\,V}} = \sqrt{\dfrac{0.10}{8 \times 0.0495}} = 0.502$ ft. Finally: $H = 2 \times 0.502 = 1.004$ ft; $b = 2 \times 1.004 = 2.008$ ft; $L = \dfrac{V}{v_o} \times H = \dfrac{0.0495}{0.618 \times 10^{-3}} \times 1.004 = 80.5$ ft; and $T = \dfrac{80.5}{0.0495} = 1{,}625$ sec $= 27.1$ min. The tank may be shortened by dividing the total length, 80.5 ft, into a number of passes in series placed side by side.

Comment.—A study of Examples 8, 9, and 10 reveals that the magnitude of the optimum velocity gradient G_o is of great influence on the type of tank required for economy. The possible range in values of G_o may be divided into three regions, each with a different method of tank design as follows:

(1) High values of G_o which result in values of R_e that are too small to be practicable. (The economic velocity V_c may be used, but it is impossible to

realize the optimum velocity gradient, and lower values must be used in design. Tanks of the tray clarifier type are indicated, and the depth H for each pass is dictated by construction and sludge removal requirements.)

(2) Intermediate values of G_o which can be realized in tank design with reasonable values of R_e and H_e. (Shallow tanks with free water surfaces are indicated.)

(3) Low values of G_o which are accompanied by values of Q less than Q_{lim}. (The optimum velocity gradient can be realized in tank design, but only by using values of V and R less than V_c and R_c. Tanks with a free water surface are indicated, with the width always twice the depth.)

There is a dearth of experimental data concerning the optimum values of G for the suspensions encountered in practice. A study of tank velocities used in practice will reveal the magnitudes of G in use. It has been common practice to limit the design velocity in settling tanks to about 3 ft per min. There is increasing evidence that higher velocities are accompanied by better removal, but it is doubtful whether any tanks have been built to operate at velocities and velocity gradients approaching V_c and G_o.

Reporting on a tunnel section with a flow velocity of 12 ft per min, W. F. Langelier[34] stated that settling had been unusually effective in removing turbidity and color from an alum-coagulated water. For this suspension it is evident that V_c was greater than 12 ft per min. Since a velocity of about 18 ft per min (0.3 ft per sec) is considered a minimum for baffled mixing chambers to avoid too much settling of floc in the chamber, it appears that 18 ft per min is greater than V_c for alum and iron floc.

The value of G for Langelier's tunnel computed by Eq. 30 is 0.96 sec^{-1}. Similar computations for baffled mixing chambers reveal that good floc is produced at values of G as high as 25 sec^{-1}. Hence, the value of G_o for alum and iron oxide floc is probably much higher than 1 sec^{-1}. The estimated value of G in the pore constrictions of a rapid sand filter during normal operating conditions is from 200 sec^{-1} to 400 sec^{-1}. This is too high to promote further coagulation of the fine floc particles within the bed, according to an unpublished paper on microscopic studies by P. C. Stein, Assoc. M. Am. Soc. C. E., but it is obviously not high enough to prevent the floc from sticking to the sand grains. The estimated value of G in the pore constrictions of slow sand filters is from 5 sec^{-1} to 40 sec^{-1}.

The primary tanks at the Detroit (Mich.) sewage treatment works[35] are designed for higher velocities than are in general use, the velocity at peak flow being 7.2 ft per min. The corresponding value of G is about 0.3 sec^{-1}. In view of the fact that preflocculation of sewage at velocity gradients of the same order of magnitude as those used for coagulation of water has shown marked improvement in settling, it seems likely that the values of G_o for sewage suspensions are much greater than the value of 0.3 sec^{-1} used at Detroit.

[34] "Shallow Sedimentation Basins," by Wilfred F. Langelier, *Journal*, A.W.W.A., Vol. 22, No. 11, 1930, p. 1484.

[35] "Report on Hydraulic Model Inlet Tests—Primary Sedimentation Tanks," by George E. Hubbell, Detroit Sewage Disposal Project, December 15, 1937.

Pending the development of methods of design of stirring devices to produce any desired values of ϵ and G in settling test containers, the parameters V_c, v_o, and the maximum practical value of G may be measured in a small continuous flow rectangular tank so designed that both depth and velocity may be changed between runs. This method of attack requires the construction and operation of a pilot treatment plant and, therefore, it is more costly than the aforementioned laboratory method. The pilot plant method, however, has the advantage that the pilot settling tank is an actual demonstration of the shape of tank required for best economy.

9. Short-Circuiting and Stability

Some of the fluid passes through the settling zone of a tank in less time than the detention period T. This "short-circuiting" is exhibited by all tanks and is due to differences in the velocities and lengths of stream paths. Short-circuiting is accentuated by mixing of the tank contents, by high inlet velocities, and by density currents.

A "density current"[15] is a flow of a fluid into a relatively quiet fluid having a different density. A density current that is heavier than the main body of fluid will sink and flow along the bottom of the tank at a relatively high velocity. If the density current is lighter it will flow along the top. Differences in density may be caused by differences in temperature, salt content, or suspended matter content. If the tank velocity is sufficiently great, density currents will mix with the tank contents with only slight effect on the flow pattern through the tank. Such a tank has a stable flow pattern. If density currents maintain their identity through a tank, the flow pattern is unstable.

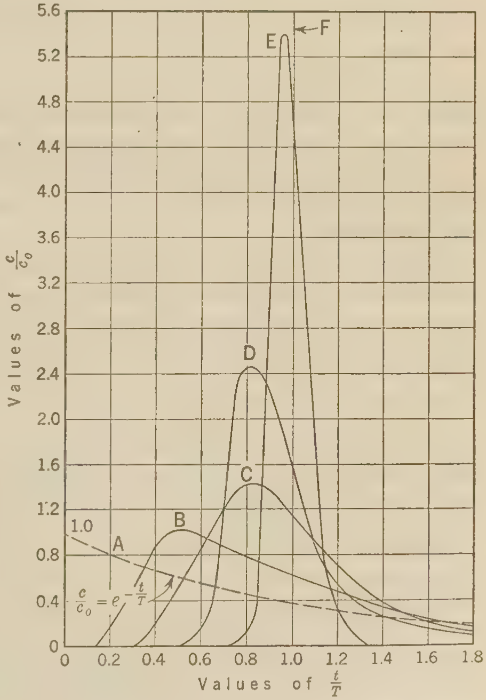

Fig. 15.—Typical Dispersion Curves for Tanks

Short-circuiting studies are usually made on model tanks operating in accordance with Froude's law. A dose of dye or salt solution is injected into the influent and the concentration of the added substance in the effluent is observed at the end of various time intervals until substantially all the substance has passed from the tank. From the data thus obtained a curve of concentration against time may be plotted. The shape of the dispersion curve is a measure of the flow pattern through a tank; and if these curves are plotted in dimensionless terms, as in Fig. 15, they are a means for comparing the hydraulic characteristics of different shapes of tanks or of the same tank at different rates of discharge.

If the flow pattern is relatively unstable, the density of the dye or salt solution must be sufficiently close to that of the water in the model to avoid the formation of a density current.

The abscissa for a point on the dimensionless curve is the relative time $\frac{t}{T}$—that is, the actual time t divided by the detention period T. The ordinate is the relative concentration $\frac{c}{c_o}$ computed by dividing the actual concentration c of salt or dye in the effluent by the concentration c_o which would be obtained if the dose were dispersed instantaneously throughout the tank volume. This type of plot is independent of the amount of dye or salt used and is independent of the detention period. If all the charge is accounted for in the effluent the area under the curve will be unity. If the flow pattern is stable and there are no dead spaces the value of $\frac{t}{T}$ to the center of gravity will also be unity.

If duplicate runs made under the same conditions yield dispersion curves which vary in shape, the flow pattern in the tank is unstable. A stable flow pattern is indicated when the same curve can be reproduced with fair precision. If a tank is not stable, short-circuiting studies will yield results which are not dependable and the performance of the tank in removing suspended matter will be erratic.

If there are dead spaces in a tank in which the liquid plays little or no part in the displacement through the tank, the effective tank volume is less than the true volume. The effective detention period will be less than the true detention period and the relative time to the center of gravity of the dispersion curve $\frac{t_G}{T}$ will be less than unity. If there is any interchange between the dead spaces and the main body of the liquid there will be flow through the dead spaces, but the resulting "tail" of the dispersion curve may be so long and the ordinates may be so small that the end of the tail will be lost and an apparent value of $\frac{t_G}{T}$ less than unity will result. If there are dead spaces, the recorded values of $\frac{c}{c_o}$ will be greater than the effective values and all ordinates to the dispersion curve will be increased in proportion to the decrease in $\frac{t}{T}$, such that the area will remain unity.

Since the relative time to the center of gravity is unity except for tanks with dead spaces, $\frac{t_G}{T}$ is an indicator of the amount of the dead space; but it is not a suitable index to short-circuiting in tanks with no dead spaces. The relative time to the center of area $\frac{t_A}{T}$ is usually less than unity and is smaller the worse the short-circuiting. Since half the particles of fluid pass in less time, t_A is the "probable flowing through time" of the fluid. The dispersion of the fluid is measured approximately by the time of initial appearance t_i of the charge in the effluent. The smaller the relative time $\frac{t_i}{T}$ the more rapid the dispersion. Small values of $\frac{t_i}{T}$ and $\frac{t_A}{T}$ indicate serious short-circuiting.

The shapes of dispersion curves found in practice for tanks without dead spaces will be intermediate to those characteristic of two limiting types of tanks: (1) The ideal dispersion tank, in which the influent is dispersed instantaneously and uniformly throughout the tank volume, characterized by curve A of Fig. 15; and (2) the ideal basin in which the velocity is the same throughout, characterized by a vertical line at $\frac{t}{T}$ equal to unity. The dispersion tank is the least efficient and the ideal basin the most efficient for settling. The dispersion curve for a cubical mixing chamber approximates curve A of Fig. 15.

Curves B, C, D, and E, Fig. 15, are characteristic of progressively better types of settling tanks. These curves are the results of measurements with models under stable flow conditions. Curve B is the dispersion curve for a radial-flow primary tank 200 ft in diameter proposed for the Detroit Sewage Treatment Works.[35] This curve represents the flow pattern with the conventional type of inlet and at the design detention period of 90 min. Curve C is the dispersion curve for the wide rectangular sedimentation basins at the Springwells Filtration Plant at Detroit.[36] Curve D is the dispersion curve[35] for the narrow rectangular primary tanks constructed for the Detroit Sewage Treatment Works in preference to the circular tanks characterized by curve B. Curve E is the dispersion curve for a model of a round-the-end type baffled mixing chamber with fifteen passes.[37] The velocity is too high in this chamber for ordinary settling, but the curve was inserted to indicate what might be expected of well-designed tray clarifiers. The significant data for the tanks represented by the curves of Fig. 15 are listed in Table 2.

TABLE 2.—HYDRAULIC CHARACTERISTICS OF TYPICAL TANKS

[36] "Sedimentation Basin Research and Design," by Arthur B. Morrill, *Journal*, A.W.W.A., Vol. 24, No. 9, 1932, p. 1442.

[37] "Comparative Studies of Shortcircuiting in Mixing Chambers by Means of Models," by Jorge Echarte, thesis submitted to Mass. Inst. Tech., Cambridge, Mass., in 1940, in partial fulfilment of the requirements for the degree of Bachelor of Science.

It has been shown previously by the writer[17] that the hydraulic characteristics of long narrow tanks are superior to those of wide low velocity tanks. This is indicated clearly by Fig. 15 and Table 2. The flow pattern is better for tanks with high values of Froude's number. Fig. 16 shows how the minimum and probable "flowing-through times" increase with higher values of Froude's number. It has also been shown by the writer[17] that tanks with high values of Froude's number are more stable. George E. Hubbell,[35] Assoc. M. Am. Soc. C. E., has shown that radial flow basins are characteristically unstable in their flow patterns. In the Detroit studies, stability was improved in the circular tank by directing the influent by inlet vanes to flow spirally around the tank for two or three circuits before the fluid reached the outlet weir. Since the velocity was thus increased the value of **F** for the circular tank was also raised. The value of $\frac{t_i}{T}$ was increased to 0.24 by this device and by other improvements in the design of the inlet.

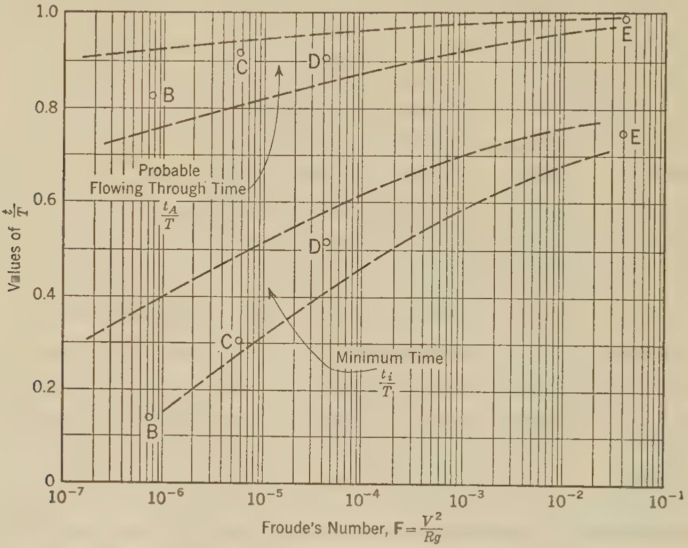

FIG. 16

A rough estimate of the effect of short-circuiting on removal may be had if it is assumed that the suspension is subjected to varying settling times, distributed as indicated by the dispersion curve. This method has been described previously by the writer.[38]

10. CONCLUSIONS

Fig. 17 illustrates the details for a tentative design of a primary settling tank based upon the principles developed in this paper. Each unit of this design is for a maximum discharge of 10 mgd, and provides a flocculation period of 60 min. The velocity of flow in the tray settling tank is 9.3 ft per min, the detention period is 10.8 min, the overflow rate is 667 gal per day per sq ft, and the mean velocity gradient is about 2 $\sec^{-1}$. Sludge and scum are scraped laterally from the trays. Gates must be provided at the sides of each tray which will prevent short-circuiting through the sludge compartments, and will open to permit the ejection of sludge and scum. In current practice, return bends in the flow path of primary settling tanks are generally frowned upon because of the turbulence set up by the bends. This objection is of minor importance if the length occupied by the bend is small as compared with the length of the passes.

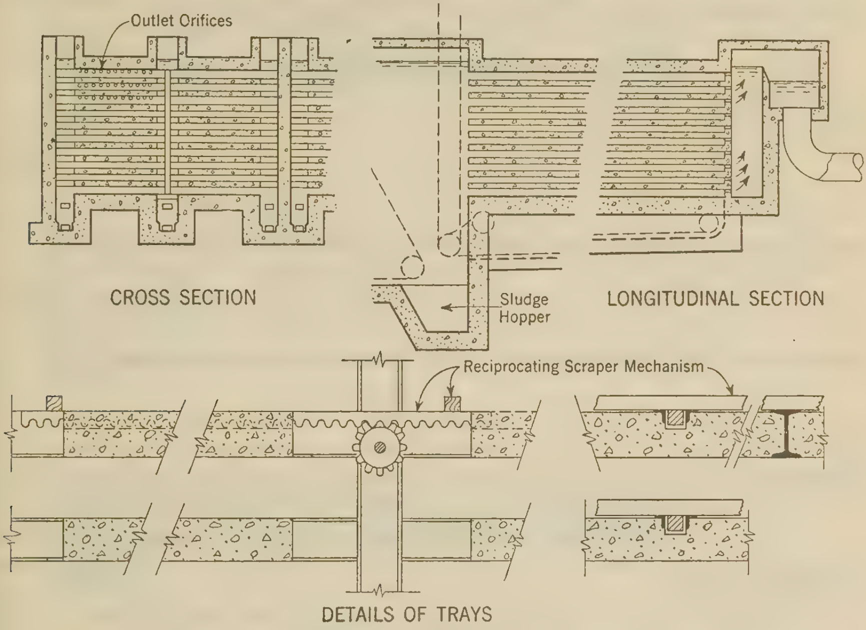

Fig. 17.—Details of Proposed Type of Tray Settling Tank

Fig. 18 illustrates current trends in the design of final settling tanks[39,40] for the activated sludge process. In many final settling tanks, the depth is so great and the mean velocity is so low that the mixed liquor falls at the inlet end as a density current and flows at high velocity toward the outlet end where it impinges on the end wall and rises as shown in Fig. 18(*a*). The flow is so rapid that hindered settling in the density current may not be complete until it reaches the end wall of the tank. The usual practice of withdrawing sludge from the bottom at the inlet end results in a mixture of fresh sludge short-circuited from the density current and stale sludge scraped from the effluent end. Short-circuiting of the sludge may be avoided if it is withdrawn from the outlet end as shown in Fig. 18. If the tank is made shallow and designed for a high velocity, the density current may be avoided and the sludge will settle as illustrated in Fig. 18(*c*). The hindered settling process will be completed at some point A which corresponds with point A of Fig. 4, and the re-

mainder of the length of the tank may be devoted to the task of concentrating the sludge.

In Fig. 18, the final settling tank is shown adjoining the aeration tank without connecting conduits. This is contrary to current practice, but is desirable in order to avoid high inlet velocities and the destruction of floc by excessive velocity gradients. The currents that usually prevail in final settling tanks, as illustrated in Fig. 18(*a*), produce the clearest liquor at the surface near the inlet. The effluent launders, which in early practice were placed at the effluent end of the tanks as with primary tanks, are now being extended toward the inlet end in order to pick up the clearer liquor. Weirs of great length are considered desirable to avoid high approach velocities and the danger of scour from the sludge blanket. Multiple V-notches are usually provided in these weirs to increase the head and assure uniform collection of the discharge.

FIG. 18.—CURRENT TREND IN THE DESIGN OF FINAL SETTLING TANKS FOR THE ACTIVATED SLUDGE PROCESS

ACKNOWLEDGMENT

The writer wishes to acknowledge the assistance of the many independent investigators whose work is collected to make up the bulk of this paper. Much of the original work published for the first time in this paper was done by the writer's students in the laboratories of the Massachusetts Institute of Technology. The writer is particularly indebted to his former associate, Ensign Dobbins, for the studies on the effect of turbulence, and to his associate, Mr. Stein, for the fundamental theory of flocculation, the concept of mean velocity gradient, the studies on short-circuiting, and for many helpful suggestions on other portions of the theory.

DISCUSSION

Norval E. Anderson,[41] M. Am. Soc. C. E.—The mathematical analyses presented by Mr. Camp should prove useful in further studies of settling tanks. Such theoretical analyses are informative. However, the "Conclusions" appear abrupt, since they imply recommendation of types of tanks for primary settling and for final settling of activated sludge, without reference to the available operating and experimental data on plant-size units and with little relation to the theory in the case of final tanks.

Multiple-tray settling tanks, similar in principle to the tank proposed by the author for primary settling, have been patented and promoted for many years. The author might have shown why these tanks have had such limited acceptance and in what way his proposed tank may be more acceptable.

Most of Mr. Camp's conclusions on final settling tanks for the activated sludge process may be questioned on the basis of an extensive study of plant-size experiments and operating data, some results of which were presented[42] by the writer in October, 1944.

It is doubtful if the statement in Section 10 that "Fig. 18 illustrates current trends in the design of final settling tanks[39,40] * * *" is based on a general view of the field.

The author's statements to the effect that density currents would be less with shallow tanks are not confirmed by actual velocity measurements. Experiments[42] on 126-ft diameter tanks at the Chicago (Ill.) Southwest Plant (allowing the sludge blanket to build up to various depths, thereby giving the effect of different tank depths) showed that the velocity of the density current was in an approximately inverse ratio to the flow depth. Also, relatively higher velocities of density current were found[42] in the rectangular final settling tanks at Columbus, Ohio, and at Wards Island, New York, where the ratio of length to depth is relatively large.

The author's argument for withdrawal of sludge at the effluent end of the tank is open to some question. He states (Section 10) that:

> "The usual practice of withdrawing sludge from the bottom at the inlet end results in a mixture of fresh sludge short-circuited from the density current and stale sludge scraped from the effluent end. Short-circuiting of the sludge may be avoided if it is withdrawn from the outlet end * * *."

Why should one avoid this so-called short-circuiting of fresh sludge when one of the most desirable features of a final settling tank is the withdrawal of fresh return sludge? The writer agrees[42] that activated sludge settles near the inlet of the tank. Thus, with a long rectangular tank and flight-conveyer-type sludge removal mechanisms as indicated in Fig. 18, the length of time that the dense sludge remains in the tank would be governed largely by the speed of the mechanism, resulting in sludge of greater average age than would be the case if the drawoff were near the inlet. With the drawoff near the inlet, the dense sludge is required to move a much shorter distance and only the lighter particles that settle at the effluent end need to move the full length of the tank. Also, it is possible that greater flocculation is obtained by withdrawing sludge near the inlet, since this causes the sludge to flow against the density current and affords more opportunities for contacts between particles, as stated by the author under "7. Flocculent Suspensions."

[41] Engr. of Treatment Plant Design, The San. Dist. of Chicago, Chicago, Ill.

[42] "Design of Final Settling Tanks for Activated Sludge," by Norval E. Anderson, *Sewage Works Journal*, January, 1945, p. 50.

Elimination of connecting conduits between aeration tanks and final settling tanks "in order to avoid high inlet velocities and the destruction of floc" may be practical in a small plant. However, in a large plant such an arrangement results in an uneconomical layout with sacrifice of flexibility in operation, as shown by layouts and studies of similar arrangements made by The Sanitary District of Chicago in 1933 for plants with 136-mgd capacity and more. Furthermore, it appears that "destruction of floc by excessive velocity gradients" (last paragraph of Section 10) is not an important factor with aeration tank effluent. Comparative tests made at three activated sludge treatment works of The Sanitary District of Chicago showed practically no change in the "settleability" of aeration tank effluent—even after a free fall over a weir and passage through both a venturi meter and a considerable length of conduit and aerated channel.

R. A. MULHOLLAND,[43] ASSOC. M. AM. SOC. C. E.—Although most consulting engineers, from time to time, are faced with the problems of designing sedimentation tanks, it seems that in most cases these consultants do not delve completely into the theories involving sedimentation.

As a result of this method of design there is the continual problem of inadequate settling. This is particularly true of sewage treatment plants. In most industrial processes using sedimentation, such as those involving chemical reaction, the designers seem to have a much better understanding of sedimentation. This can be seen by the results obtained in such plants. Concerning the design of grit chambers, emphasis should be placed on the sixth and seventh paragraphs of Section 2. With the exception of the very largest class of sewage treatment plants, one of the weakest links in the entire process is that of the grit chamber. This is particularly true of sewage treatment plants serving small towns and villages. Here the designers have been faced with controlling financial outlay to eliminate every cost possible. In many instances an excuse for a grit chamber has been installed which could not possibly function to collect any grit whatsoever, and has only been an added expense to the construction of the plant itself.

Mr. Camp states that geometric models for plant-scale tanks cannot be adapted to produce those effects, but are quite useful in the measurement of hydraulic short-circuiting; also, that settling analysis may be corrected for short-circuiting to predict performance in plant-scale settling tanks. It has been the writer's experience with model tanks that their flow characteristics can be correlated to full-scale flow characteristics and zones of sedimentation can be reproduced. It remains a matter of judgment and experience upon the part of the designer to adapt model results to full-scale operation. In regard to Mr. Camp's statement concerning the building of an adjoining tank without connecting conduits, the writer has knowledge of at least a dozen plants built along this pattern in recent years. Virtually all of the recently adapted Hay's process plants have been so arranged in current years. Such construction results in a decided economy, since dividing walls are merely web members of a rigid structure of sufficient strength to withstand the hydraulic load.

---

[43] Consultant, Austin Eng. Co., Austin, Tex.

P. Charles Stein,[44] Assoc. M. Am. Soc. C. E.—It is obvious that a heavy particle suspended in a liquid will tend to settle. The difficulty encountered in applying this casual concept of settling to the design and operation of sedimentation units furnishes enough proof of the need for understanding the principles of settling and related phenomena. A technical basis for the design of settling processes must depend upon specific knowledge of the properties of the suspensions to be treated and of the physical phenomena associated with flow through tanks.

This paper should make more engineers aware of the mechanics of settling tanks. Its scope extends beyond that mission, however, in that the concepts involved in the more important parts of the problem are developed and definite design principles are formulated.

It is to be hoped that the paper will help dispel the erroneous notion that detention time is the important factor in the removal of suspended matter. For a given settling velocity both depth and detention time govern degree of removal since, with a deeper tank, a particle will require a longer time to reach the bottom. Thus, with a given settling velocity, the ratio of depth to detention time determines the number of particles reaching the bottom of an ideal tank. Simple algebra will show that this ratio is equal to the rate of flow divided by the surface area of the tank, which is the definition of overflow rate given by the author following Eq. 6. When one considers a particle settling at a given rate in a tank, it is simple to grasp the fact that depth divided by settling time is the proper criterion for removal and that neither depth nor time alone has real significance.

The tests mentioned by the author are not simple routine ones because standardized methods have not been formulated. Thus far, data on physical properties of suspensions encountered in water and sewage treatment are extremely meager, as the author states. This scarcity of information means not only that there are no acceptable normal values at present to serve as comparators but also that little has been done in the way of developing standard techniques. This lack of development does not nullify the value of the method of design described by the author. Instead, realization of the shortcoming should spur sanitary engineers toward a more scientific study of the treatment methods that they use.

---

[44] Cons. Engr. (Kuchler & Stein), Sharon Hill, Pa.

For new units it is necessary, before design, to determine the nature of the suspension that will be obtained when the unit is in operation. If the new unit is an addition to an existing plant, design information may be secured by suitable interpretation of tests conducted on suspensions in existing units. If the unit is to be a part of an entirely new plant, then recourse should be had to sanitary engineering laboratory design methods or to a pilot plant. In the laboratory method a proposed process is examined critically to determine the variables entering into each stage of the process. Then, the process is completed step by step on batch samples, the important variables in each step such as chemical characteristics, mixing time, degree of turbulence, velocity gradient, etc., being controlled with a view toward determining the optimum values of the several variables. In the course of this procedure, the settling velocity analysis can be made at the proper time in the treatment routine. It is assumed that the steps prior to sedimentation will have been finished in a container of adequate design and dimensions so that there will be no necessity for transferring the sample to another apparatus for the settling analysis.

The paper exposes the neglect with which investigators have treated the mechanism of flocculation and its relationship to the settling problem. Eq. 26, which was introduced by M. von Smoluchowski,[45] and Eqs. 25 are based on rather crude assumptions, since their purpose in this paper is to show relative rather than absolute effects. In their development, the actual hydrodynamics of fluid flow about the particles has been ignored. Microscopic studies by the writer indicate that the process of flocculation by settling is much more complex than the simple mechanism pictured by the assumptions leading to Eqs. 25. Similar comments apply to Eq. 26 but analysis of the results of Darrell A. Root[31] along with torsion dynamometer measurements by the writer to determine work input on the Root apparatus indicate that the proportionalities between rate of flocculation and concentration and between rate of flocculation and velocity gradient are valid.

Despite the very approximate nature of Eq. 26, it discloses important relationships concerning the effect of flocculation during settling. Although actual problems involve polydisperse suspensions, which have been extensively studied by the writer, for simplicity, the considerations will be limited to particles of uniform size. The conclusions with such a restriction are qualitatively valid.

For spherical particles, it is evident that the number of particles per unit volume of the suspension will equal the volumetric concentration divided by the cube of the diameter times a constant. Introduction of this relationship into Eq. 26 discloses that the number of contacts per unit volume per unit of time is proportional to the square of the concentration, and that the percentage of particles involved in contacts is proportional to the volumetric concentration and is independent of the size of the particles. For a velocity gradient of 10 sec^{-1} and a volumetric concentration of 2 parts in 10,000 (roughly equivalent to 200 ppm suspended solids in sewage), the initial flocculation rate given by

---

[45] "Versuch einer mathematischen Theorie der Koagulations-kinetic kolloider Losungen," by M. von Smoluchowski, *Zeitschrift für physikalische Chemie*, Vol. 92 (1917), p. 155.

Eq. 26 is equivalent to contacts involving 12% of the particles per minute. For lower or higher concentrations, the rate of flocculation will be proportional.

From the foregoing, it should be clear that the effect of flocculation on removal should be particularly pronounced where the volumetric concentration of suspended matter is high. With the volumetric concentrations present in water and sewage treatment processes, the effect of flocculation on settling can be substantial. It is only with low concentrations of the order of 10 ppm or 20 ppm that the flocculation effect would be negligible unless both velocity gradient and detention time are large.

The application of the meager available information concerning flocculation in settling tanks certainly indicates that the shallow tanks dictated by the general settling theory are also more favorable from the standpoint of flocculation during settling. It will remain for pilot plant testing to demonstrate the advantages of the method of design presented by the author. Testing should be done also in units of existing plants. The results might well indicate that a necessary increase in settling capacity can be attained by inserting horizontal diaphragms in existing tanks at considerably less cost than would be required for building additional tanks.

The writer would like to point out what he believes to be an error in Example 2, since it might lead to faulty design of final settling tanks for activated sludge. In this example, it is assumed that the concentration of the sludge in the sludge blanket is a function of the time of compacting only and is independent of the depth of the blanket. This means that, for a given degree of compaction, the rate of subsidence of the sludge blanket is proportional to the thickness of the blanket. That this cannot be a valid conclusion is indicated by a consideration of settling and compaction in a very deep tank. The assumption that rate of compaction, in terms of the ratio of the volume occupied by the sludge blanket, is independent of depth will lead to the conclusion that in a very deep tank the sludge blanket must sink at a velocity greater than the hindered settling velocity. This, obviously, is not possible. If, in Example 2, for a tank 10 ft deep, the position of the top of the blanket for a sludge concentration of 6,000 ppm were calculated, it would be found that the rate of subsidence from point A of Fig. 4 to the depth corresponding to 6,000 ppm would be about 0.14 cm per sec, whereas the hindered settling velocity is only 0.11 cm per sec.

There is a similarity between the problem of compaction of sludge and of the consolidation of clays as found in soil mechanics problems. In both cases, the rate of consolidation in a lamina is proportional to the normal gradient of the hydrostatic excess pressure. In a sludge blanket at a given degree of consolidation, it may be argued that the hydrostatic excess pressure at any point is roughly proportional to the depth of sludge over that point. Thus, the pressure gradient causing consolidation will be roughly independent of the depth in the early stages of the compaction process. This means that the rate of drainage of interstitial fluid will be independent of depth and that two blankets, one shallow and the other deep, would compact with approximately the same absolute velocity of subsidence. In the final stages of consolidation the compaction in deep tanks will be greater than in shallow tanks because of the increased weight of sludge over the bottom layers.

In general, the results reported by Willem Rudolfs, M. Am. Soc. C. E., and I. O. Lacy,[16] cited by the author, are at variance with the author's conclusions respecting the effect of depth on sludge compaction. To secure data on this specific problem, Messrs. Rudolfs and Lacy made tests of settling and consolidation in glass tubes with initial depths of 117 in., 93 in., and 45 in. The results taken from curves[16] presented by Messrs. Rudolfs and Lacy have been calculated to give a nondimensional plot, devised by the writer. In this plot, presented in Fig. 19(a), a value of v = 2.5 in. per min was used in computing the abscissa. If the settling velocity were the same for the three samples and the absolute rates of subsidence were equal, the curves for the three depths would coincide. (In Fig. 19 the settling time modulus $\frac{vt}{H}$ is plotted against the ratios and D/H as ordinates, definition being as follows: v = settling velocity; t = time; H = tank depth; and D = depth of sludge.

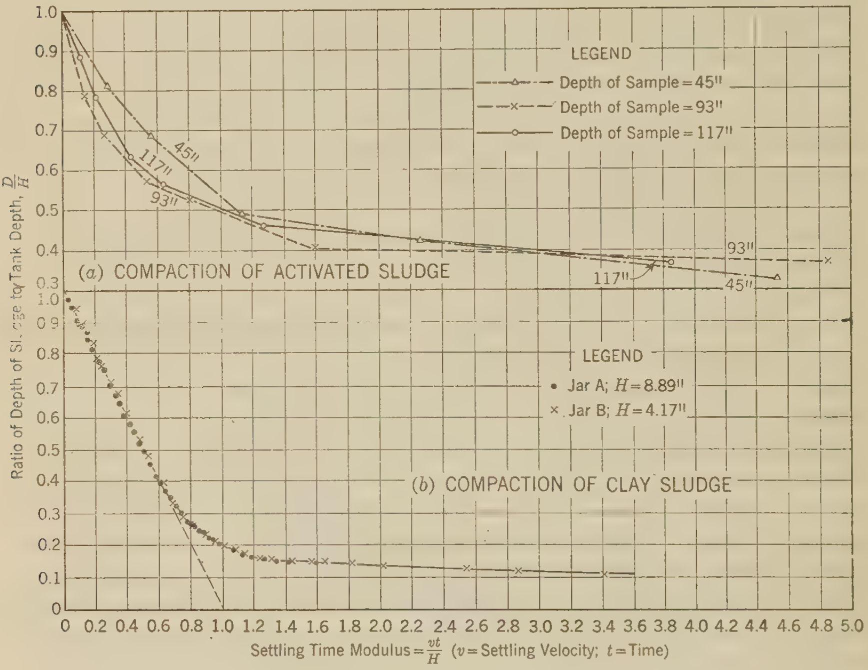

FIG. 19.—EFFECT OF DEPTH ON RATE OF COMPACTION

Actually, the plotted points show a substantial scattering. However, it will be observed that the placement of the curves does not represent a consistent order, the results from the deepest tube being between those of the intermediate and lowest depth. After 19 hr of settling the results were consistent, the sludge depths being, respectively, 12%, 14%, and 16% of the liquid depths for the 117-in., 93-in., and 45-in. samples. The writer believes that the tests shown in Fig. 19(*a*) constitute a rough check of his contention that the absolute rate of consolidation in the early stages is independent of sludge depths. The failure to achieve perfect coincidence of the curves is due to experimental error. From the breaks in the curves for the individual samples, the writer would conclude that there were arching effects present due to the use of settling tubes which did not have a sufficient diameter. The writer has found, in consolidation tests made with calcium carbonate and with clay suspensions, that the settling tube must be large with respect to the depth of the sludge if arching effects are to be negligible.

To secure data of greater precision, the writer performed consolidation tests with two jars containing a floc made by coagulating a suspension of red clay with ferric chloride, ammonia, and sodium chloride. Both jars were 5.2 in. in internal diameter. Jar A had an initial depth of 8.89 in. and the depth in jar B was 4.17 in. After coagulation, the floc was poured back and forth in the two jars to insure equality in condition. It was found that the hindered settling velocities in the two jars, as well as the time rate of subsidence at equal degrees of compaction, were identical within the limits of experimental error as shown on the nondimensional plot presented in Fig. 19(*b*). The hindered settling velocity of the floc used was found to be 0.125 in. per min and the total duration of the test was 9 hr. Although only the first quarter of the test is shown in Fig. 19(*b*), the results of the two samples gave identical curves even for the end of the test. It is to be expected that there would be some disparity between the two samples eventually because of the larger final intergranular pressure in the sludge blanket for the deeper sample.

This material is presented because it serves to throw a small amount of light on the problem of sludge compaction, which is a part of final settling tank design. The data presented were obtained with a clay floc and not with floc from activated sludge plants. Unless the floc from activated sludge plants is radically different from other types of materials, the general conclusions of the test should be valid. Comparison of Fig. 19(*a*) with Fig. 19(*b*) shows that the general types of curves obtained with activated sludge and with a clay floc are the same.

It would appear, then, that better compaction in a given detention time would be possible with shallow final settling tanks than with deep tanks; or, for equal degrees of compaction, less time is required with thin sludge blankets than with thick ones. Thus, shallow final settling tanks would require less detention time to obtain a specified concentration of sludge. With activated sludge, this is an important biological consideration because long absence from a medium rich in oxygen will reduce the viability of the active organisms.

LYNN PERRY,[46] M. AM. SOC. C. E.—Concepts of the fundamental principles of flow and fluids have changed radically during the past generation. Capable investigators with laboratory equipment, frequently inadequate, have correlated widely scattered bits of information, checked over the fundamentals, and secured an immense amount of supporting laboratory data. This work is by no means complete.

The more mature men of the engineering profession who were brought up on "Merriman" and "Hughes and Safford," with their detail about Kutter and other early investigators, find it extremely difficult to imagine that the film of a moving fluid in contact with the wall of a conduit is stationary. They have been engaged in design and construction during the most active and progressive generation in the history of the human race; and they will hold to the empirical methods of design which have been tried and found fairly satisfactory for their purpose. It is the younger generation who, with proper training, will base their fluid analyses on rational fundamentals.

Dimensional analysis gives the proper form for an equation but, unfortunately, it does not yield a numerical result. Numerical results, sufficiently accurate for design, are required by the designer, and are required promptly. Usually, theoretical analysis must be supplemented by considerable laboratory work before it can be put into form for the designer to use. Unfortunately, most of the data that have been made and published in support of empirical formulas are not exactly what is required.

Designing engineers are constantly facing conditions where a deposition of solids is necessary, where no deposition is permitted, or where a partial deposition is desired to separate heavier suspended solids from the lighter. Some years ago, the writer came into the possession of information which led to the curve presented in Fig. 20, the equation of which is

$$V = 424\,(G_r - 1)\,D^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

In Eq. 38, V is the velocity of water in which sand of various particle sizes will settle; G_r is the specific gravity; and D is the diameter of a particle. This curve has been used and found to be trustworthy. The line is for sand—not spheres, cubes, or any other geometrical figures—plain sand ($G_r = 2.35$). It has been checked from time to time, and the small circles indicate the results of laboratory observations at Lafayette College, Easton, Pa. For heavier or lighter suspended solids other such curves are available. For velocities and sizes below the curve, deposition will occur; for velocities above the line, the solids will be carried along with the current of water. In many industrial processes the velocity of the water carrying the solids in suspension can be controlled. The necessary controls for maintaining a constant velocity of water or sewage passing through a municipal treatment plant would be a subject for another paper. Engineers are competent to design a satisfactory water or sewage treatment plant for a predetermined rate, and for a specific quantity and type of suspended and dissolved solids which require a given type, quantity, and quality of chemical. Few designers ever become the operators of the plants they have designed and built. Although they have an academic knowledge of operation, they seldom face the trying problems that confront the operator. This trend in engineering development has produced a rift between the designers and the operators. An unequal settlement of a few hundredths of a foot is the source of much more operating anxiety than a failure to secure a slightly higher efficiency in sedimentation. The designer is always seeking perfection even though he knows that goal is unlikely. He deals almost entirely with the forces of nature. The operator, on the other hand, is constantly confronted with the frailties of human nature.

---

[46] Designing Engr., Dept. of Water and Sewers, City of Miami, Miami, Fla.

Theoretically, engineers should be able to develop the desired effect in the laboratory or in the pilot plant, and attain the same effect in the prototype. When this cannot be done, it indicates that there is something about the model law that is not quite familiar, and another set of empirical constants must be developed to give fairly accurate numerical results. Either engineers should be able to compute these constants or their dimensional analysis needs a review.

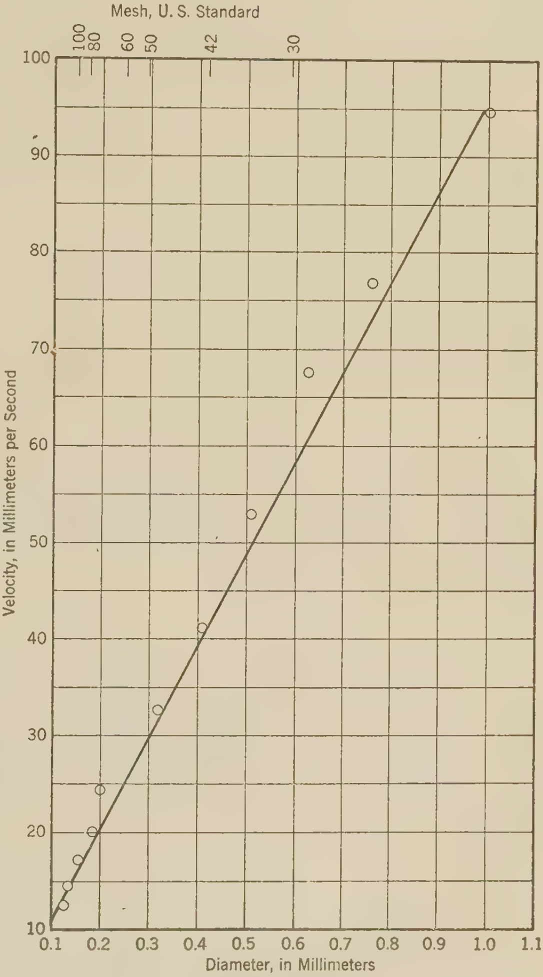

Fig. 20.—Velocity of Water in Which Sand of Various Sizes Will Settle

The conventional circular radial-flow sedimentation tank has several serious faults. Not the least of these is the tendency toward unequal flow in the different quadrants. In some cases it is serious; and in relatively few cases has the problem been solved to the satisfaction of the operator. Wind velocities and wave action may be involved, but it is difficult to imagine any considerable uniform and constant effect from prevailing low wind velocities.

The results of an exhaustive series of observations made on full size units at the Southwest Sewage Treatment Plant, Chicago, Ill., have been reported by Norval E. Anderson,[47] M. Am. Soc. C. E. A careful examination of the results reported would seem to indicate that deep tanks are unnecessary, and that there is plenty of room for improvement in the geometrical figure. It may be that, in order to conserve ground space and economize in construction, many tanks have been built deeper than necessary. Perhaps undue weight has been given to the theoretical period of detention while some of the more essential features have been overlooked.

The writer cannot refrain from entering a protest against the practice of drawing the sludge from the effluent end of a tank. Provision should be made to draw sludge, once settled out of the water, just as far away from the overflow weir as possible. This will provide for resedimentation, if necessary—a feature that is desirable.

The subject of trays is not quite new. Such provisions have not met with marked enthusiasm in the past. Further development in the details of design may bring more favor. In this connection, it might be timely to mention, once more, that handling a hundred million gallons of water or sewage per day presents more problems than merely building a number of smaller units. A multitude of factors, which may be overlooked as of negligible importance or easily met in a small plant, grow to major difficulties in large installations.

The author deserves a great deal of commendation for the logical and attractive manner in which the paper has been arranged; and for gathering, in one place, the pertinent elements on this subject. It serves to focus attention to the present status and recent developments in this extremely active and progressive field. It deserves amplification to several times its present length, and time for discussion.

E. Sherman Chase,[48] M. Am. Soc. C. E.—Thirty odd years' experience has demonstrated to the writer the difficulties involved in reducing to formulas the various phenomena encountered in sanitary engineering practice; particularly those relating to that nonconstant, unpredictable, exasperating material known as "sewage." However, these difficulties have not discouraged inquiring minds like that of the author, from trying, and commendation is due Mr. Camp for the effort.

The function of settling tanks is to remove suspended matter from the liquid passing through them. The character of this matter varies with the type and condition of the liquid. In the case of raw sewage the solids in suspension are of such a heterogeneous and variable nature that no formula could possibly be devised of general applicability. Furthermore, the effluents from various types of secondary sewage treatment differ from each other as regards the nature of the solids carried in suspension. Even the effluents from the same type of secondary treatment will contain suspended solids which vary from place to place and time to time as regards shape, size, specific gravity, and settling characteristics.

The relatively greater importance of overflow area as compared with detention period, as demonstrated by the author, has long been appreciated, and overflow rates have been used in the design of settling tanks for many years. In nature, the clarification of sewage-polluted waters in streams of little depth is a common example of the effectiveness of shallow flowage.

---

[47] *Sewage Works Journal*, Vol. XVII, No. 1, January, 1945, p. 50.

[48] Partner, Metcalf and Eddy, Boston Mass.

The tray clarifier, somewhat similar to that advocated by the author, was developed some time ago, but its practicability has yet to be demonstrated. In a recent communication from the company that has promoted this type of tank, the writer was advised that the company had decided to abandon this piece of equipment. Apparently in practice it failed to fulfil its theoretical advantages.

An interesting type of settling tank for flocculated water has been described by Ian M. E. Aitken.[49] This tank contains a series of annular baffles so spaced as to give alternate downward and upward flows with the upward flows at velocities considerably less than those of the downward, and with the upward velocities decreasing toward the effluent weir at the perimeter.

Intriguing as the pursuit of elusive formulas may be to those so fortunate as to be possessed of a precise mathematical turn of mind, the design of practicable settling tanks will continue to be based upon judgment, experience, and common sense seasoned with a moderate amount of theoretical computations used as aids to judgment.

Rolf Eliassen,[50] Assoc. M. Am. Soc. C. E.—The expressed purpose of the paper is to develop the theory of sedimentation to such an extent that all the basic factors affecting the sedimentation of water and sewage solids may be so evaluated that it is possible to use mathematical functions to predict the economic design of settling tanks. Mr. Camp has developed mathematical functions for some of the variables affecting sedimentation. The questions that the designing engineer must ask are whether all the important factors have been considered, whether these factors have been evaluated properly, and whether the conclusions drawn are valid for conditions encountered in practice.

In the "Synopsis," the author makes a statement that "The settling characteristics of the suspensions to be clarified are rarely considered in the design of settling tanks." On the basis of his experimental work, Mr. Camp defines these settling characteristics in terms of overflow rates of from 200 gal per min to 2,000 gal per min per sq ft—which are equivalent to settling velocities of from 1.1 ft per hr to 11.1 ft per hr.

An analysis of the design of settling tanks selected at random from sewage treatment plants throughout the United States is shown in Table 3. These plants have been designed on the basis of overflow rates well within the limits prescribed by Mr. Camp. Some of them are close to the value of 667 gal per min per sq ft mentioned in Section 10 as a desirable overflow rate for the primary sedimentation of sewage. Thus, one would tend to believe that sanitary engineers, state boards of health, and equipment manufacturers have taken into account the settling characteristics of the suspensions involved.

The major difference between the practices of designing engineers and the conclusions of Mr. Camp is not in the matter of settling velocities and overflow rates, but in detention times. Modern settling tanks in water treatment and sewage treatment plants are designed on the basis of settling periods of from 1 hour to 4 hours and involve the use of tanks with depths from 5 ft to 15 ft. The author comes to no definite conclusions as to settling times, since these are involved in mathematical functions which may be solved for each condition of flow and character of suspension. However, he does cite examples wherein detention periods of from 0.1 hour to 2.4 hours are calculated for tanks with depths ranging from 0.5 ft to 11.6 ft. Mr. Camp places particular emphasis on the need for tanks with short detention periods, shallow depths, and relatively high velocities of the liquids flowing through the tanks.

[49] "A Fresh Approach to the Problem of Precipitation Tank Design," by Ian M. E. Aitken, *Water and Water Engineering*, Midsummer, 1945, p. 320.

[50] Prof. of San. Eng., New York Univ., New York, N. Y.

TABLE 3.—OVERFLOW RATES FOR SETTLING TANKS AT SEWAGE TREATMENT PLANTS

City	Type of treatment	Design flow (mgd)	Area of tanks (Sq ft)	Gallons per day per Square foot
Huntington Beach, Calif.	Trickling Filter	0.60	804	746
Sayreville, N. J.	Chemical precipitation	0.75	1,232	609
Birmingham, Ala. (Shades Valley)	Chemical precipitation	2.0	3,180	1,590
Dayton, Wash.	Trickling filter	3.6	1,964	545
Olean, N. Y.	Primary	5.0	3,927	786
Neenah-Menasha, Wis.	Primary	10.	8,836	1,132
New York, N. Y. (Coney Island)	Chemical precipitation	35	25,448	1,372
Atlanta, Ga. (Clayton)	Primary	42	39,408	1,065
Denver, Colo.	Chemical precipitation	54	61,576	880
Cleveland, Ohio (Easterly)	Activated sludge	123	157,632	780
Washington, D. C.	Primary	130	105,900	1,230
Buffalo, N. Y.	Primary	150	80,424	1,868
Chicago, Ill. (Southwest)	Activated sludge	400	395,000	1,010

Much attention is given to the derivation of equations involving the effect of velocity gradients on the flocculation of particles suspended in water and sewage. From these equations, the author proceeds to a consideration of the most economical settling tank design. Examples are presented leading to numerical values for tank dimensions. Some of the intermediate steps in the process should be recognized by the designing engineer so that he is cognizant of the limitations of this method of analysis.

In the first place, only the velocity gradients caused by drag on the floor and walls of a tank are considered by the author—the factors of inlet turbulence and density currents being neglected. Both of the latter may have an appreciable influence in tanks where the ratio of $\frac{L}{H}$ is comparatively low, in the range of from 2 to 10. These low ratios are found in most circular tanks and many of the shorter rectangular tanks in common use throughout the United States. Thus, any numerical or quantitative results derived from these mathematical equations must be examined critically to determine whether the basic assumptions made by the author are valid for the tank under consideration.

Within the limitations of long shallow tanks in which the drag on the tank floor and walls will have a dominating influence on velocity gradients, the author develops a sound theory leading to quantitative results in several examples. However, the suspensions given in the examples are hypothetical ones as far as velocity gradients and mixing coefficients are concerned. The author has specified the type of laboratory equipment that should be developed to obtain the necessary analyses of suspensions; but, as of early 1946, the equipment is not available. The logical approach to a correct analysis of the problem is by the construction and testing of pilot plants. Engineers frequently have difficulty in securing funds from their clients for pilot-plant work. For this reason, it is not easy to evaluate many of the factors influencing sedimentation. Therefore, designing engineers proceed on an empirical basis.

In Section 9 Mr. Camp departs from considerations of the theoretical aspects of sedimentation and discusses short-circuiting and stability in tanks. The writer believes that Mr. Camp places too much emphasis on short-circuiting as the criterion of settling tank performance. In the third paragraph of Section 9, the author states, "Short-circuiting studies are usually made on model tanks operating in accordance with Froude's law." This law is applied in an attempt to secure dynamic similarity between model and prototype when gravity forces predominate and leads to the equation known as Froude's number, $\left(\frac{V^2}{l\,g}\right)_p = \left(\frac{V^2}{l\,g}\right)_m$, in which the subscripts p and m refer to the prototype and the model, respectively. Gravity forces may predominate in the study of some settling tank inlets in the case where high velocities exist and head becomes a factor. However, Mr. Camp has chosen to neglect the effect of inlet turbulence and to consider only the case in which the forces of drag on the floor and walls of the tank predominate. These are viscous forces which also predominate in the settling of particles in water and sewage, as mentioned by Mr. Camp in Section 1. Consequently, if dynamic similarity is to exist with the predominance of viscous forces, the relationship between prototype and model should be governed by Reynolds' number, $\left(\frac{V\,l\,\rho}{\mu}\right)_p = \left(\frac{V\,l\,\rho}{\mu}\right)_m$. Mr. Camp presents no data based on model studies operated in accordance with Reynolds' law. Thus, the results as depicted in Fig. 15 are open to question.

Furthermore, the selection of an arbitrary hydraulic efficiency as the criterion of settling tank efficiency is not consistent with the theory previously developed in the earlier sections of the paper. In Section 4 Mr. Camp concludes that, in an ideal basin:

> "For any given discharge, the removal is a function of the surface area and is independent of the depth of the basin; or, the removal is a function of the overflow rate and, for a given discharge, is independent of the detention period * * *."

In Section 9 he states that:

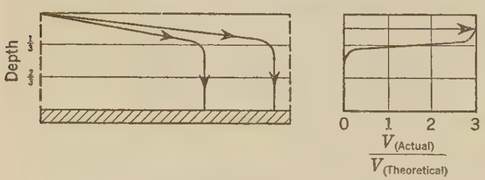
> "A rough estimate of the effect of short-circuiting on removal may be had if it is assumed that the suspension is subjected to various settling times, distributed as indicated by the dispersion curve."

All the liquid passing through the tank is subjected to the same overflow rate, but various fractions of the liquid are given different detention times. If overflow rate is the criterion, as claimed in Section 4, then no appreciable effect should be noted on the efficient removal of settleable solids in the tank. If detention time is the criterion, as suggested in Section 9, short-circuiting should have a marked effect. The former possible criterion is based on sound theory and the latter is based on an opinion, shared by many other engineers, but not borne out by experimental evidence.

Tests by the writer have shown that many circular settling tanks experience greater short-circuiting than do rectangular tanks; but the average effect on settling efficiency seems to be inappreciable. This statement is borne out by results in existing water treatment and sewage treatment plants. With similar overflow rates and theoretical detention periods, no great difference in settling efficiency is noted between the performance of rectangular and circular tanks at many plants throughout the United States. On the whole, average values of removals are quite consistently alike, as may be indicated by perusal of the wealth of operating data in the literature on the subject.[51] Selection of circular or rectangular settling tanks seems to be based on preferences of designing engineers and economy of plant design.

Consider a settling tank, either circular or rectangular, with a dispersion curve similar to curve B in Fig. 15. This has a "probable flowing through time," $\frac{t_A}{T}$, of 0.831. The author claims that the other curves shown in Fig.15, each having higher values of $\frac{t_A}{T}$, and thus greater hydraulic efficiencies, "are characteristic of progressively better types of settling tanks."

For the sake of argument assume that the flow is concentrated in the upper third of the tank with the entire lower two thirds dead space. The average velocity will be three times the theoretical and the "flowing through time," $\frac{t_A}{T}$, will approximate 0.33. Since the lower part of the tank is assumed to be quiescent water, the paths of particles will be as shown in Fig. 21. On a hydraulic basis the tank would only be considered 33% efficient. However, a glance at Fig. 21, together with consideration of the significance of settling velocities and overflow rates, shows that particles will be removed as well as if the entire tank were utilized. This tank is merely the shallow high velocity tank recommended by Mr. Camp in Section 4 as the economical tank for settling.



(a) PATHS OF PARTICLES

(b) VELOCITY DISTRIBUTION

Fig. 21

The main argument against this type of flow pattern might be that the time theoretically available for flocculation is not utilized to the fullest extent. However, this might not even be correct if the statement by Mr. Camp following Eq. 31 holds true. He considers the effect of velocity gradients on flocculation and states,

---

[51] "Sewage Treatment Works," by C. E. Keefer, McGraw-Hill Book Co., Inc., New York, N. Y., 1940, p. 125.

> "From Eq. 31, it may be seen that the rate of flocculation due to velocity gradients is proportional to $V^{1.5}$ and inversely proportional to $\sqrt{R}$. Hence this type of coagulation is greatest for shallow tanks with relatively high velocities."

It must be admitted that short-circuiting can have an adverse effect on settling efficiency if strong currents travel along the bottom of the tank at such a rate that the tractive force will dislodge particles already settled, or will carry the particles along as part of the bed load. The effect of velocities on bed loads is discussed in Section 5. Inlet baffles should be so designed that this type of short-circuiting is avoided. As long as bottom velocities are low enough, short-circuiting in the upper regions of the tank should have no appreciable effect since overflow rate is the governing factor.

This discussion of the effect of short-circuiting is not meant to imply that no attempt should be made by designing engineers to secure good flow distributions in settling tanks. It is merely a plea for a rational approach to the determination of settling tank efficiencies. These should be determined by actual tank performance, as measured by solids removals, and not by an arbitrary assumption that settling efficiency is almost a direct function of hydraulic efficiency. By theoretical analysis in another section of his paper, Mr. Camp proves, and emphasizes time and again, that overflow rate is the controlling function in removal of solids. This is sound practice and should be the main criterion of settling tank design.

The conclusions in Section 10 do not constitute a summary of the salient factors developed from theoretical considerations in the main body of the paper. In his closing discussion Mr. Camp should summarize the most important conclusions regarding the clarification theory, the effects of tractive force and bed-load movement, and the effects of turbulence and flocculation on sedimentation. Such a summary would make the paper much more valuable to the designing engineer.

As presented, the conclusions are opinions of the author on the design of mechanisms and general arrangements for settling tanks. Several factors not mentioned under theoretical considerations and principles are introduced when the author abandons theory and writes about practice.

To utilize shallow tanks with high velocities, Mr. Camp suggests the design of a tray settling tank as shown in Fig. 17. Such tanks have been used for many years in the chemical and metallurgical industries for the sedimentation of particles somewhat different from those encountered in water treatment and sewage treatment plants. This type of tank has been made available to the sanitary engineering profession by a number of equipment manufacturers but has been accepted for relatively few installations.

In 1940 the writer saw one such unit installed in a sewage treatment plant at Springfield, Mo. Considerable difficulty had been experienced when the sludge that had settled on the trays began to digest. Entrapped gas caused some of the sludge to rise as scum and accumulate on the underside of the tray above where it must have collected in considerable quantity and solidified to a degree. Further digestion of this scum released gas which could not escape readily. Pressure must have built up within the mass of scum and sludge to the extent that the concrete slab forming the tray was broken and lifted, with the virtual destruction of the tray. There is no assurance that the same condition might not develop in the design proposed by Mr. Camp. The mechanism would be required to scrape the sludge that rises as well as that which settles. Much experimental work must be conducted before a practical design can be developed. The design of final settling tanks for the activated sludge process does not necessarily result from the material developed in the paper.

In summarizing, it should be emphasized that Mr. Camp has accomplished one part of his announced objective—namely, "to collect in one compendium the known principles of sedimentation essential to the development of design theory." However, he has only partly accomplished his other goal, which he announced was "to present the theory of design developed to a stage which will permit its use in practice." Some of the numerical examples are based on hypothetical analyses, the laboratory equipment for whose determination is yet to be developed. Other factors influencing sedimentation are too complex for mathematical analyses or cannot be evaluated on the basis of the present state of knowledge of the art.

Mr. Camp's paper should be valuable to the designing engineer because it provides for a better understanding of the principles affecting sedimentation. It should also encourage pilot-plant studies of settling tank design, applying those principles developed in the paper. The accumulation of much data on the operation of shallow tanks using high velocities at appropriate overflow rates, together with the interpretation of these data by engineers and mathematicians, is necessary before many of the factors influencing sedimentation can be evaluated and formulated to such an extent that they are directly applicable to the problems of the designing engineer.

THOMAS R. CAMP,[52] M. AM. SOC. C. E.—To those who have found time during these busy days to study and discuss the paper the writer wishes to express his appreciation. The paper was intended to be a comprehensive treatise on a subject which has long been neglected, but because of space limitations some important aspects of the subject had to be omitted and explanatory notes had to be kept to a minimum.

The writer and the profession are indebted to Mr. Stein for his careful scientific analysis of the contents of the paper—particularly for indicating the error in Example 2 which was based on the writer's erroneous statement regarding the compacting of activated sludge. Based on a much too hasty analysis of the experiments by Messrs. Rudolfs and Lacy, the writer concluded that the rate of compacting in terms of the ratio of the volumes occupied by the sludge blanket is a function of time only and is independent of the depth of the blanket. Mr. Stein has shown that this is not the case. He has demonstrated conclusively that the rate of compaction is also a function of the depth of the blanket. His experiments and analysis indicate that the absolute rate of subsidence of the top of the sludge blanket is substantially independent of the depth of the blanket. Thus, the shallower the depth of the blanket, the greater will be the rate of compacting in terms of the ratio of the volumes occupied by the blanket. This finding is very important because it demonstrates the desirability of shallow tanks for sludge compaction. The writer has shown that shallow tanks are both desirable and economical for free settling. Mr. Stein indicates that this is also the case for sludge concentration.

---

[52] Cons. Engr., Boston, Mass.

Mr. Perry suggests that the paper might have been amplified to several times its present length and Professor Eliassen states that the paper lacks a concise summary. Mr. Anderson objects because the conclusions appear abrupt. The original manuscript on which this paper was based was nearly three times the printed length. It contained an extensive development of the theory of design of inlets and outlets as well as other important details—all of which were omitted to hold the length of the paper within permissible limits. In this manner, a full treatment of the subject of turbulence created by inlets (which Professor Eliassen believes to have been neglected) was omitted for lack of space.

Mr. Chase states that:

> "* * * the design of practicable settling tanks will continue to be based upon judgment, experience, and common sense seasoned with a moderate amount of theoretical computations used as aids to judgment."

This attitude has undoubtedly been that of most of the designers of settling tanks for water and sewage treatment purposes and should be sufficient to explain to Mr. Anderson why multiple-tray settling tanks have had such limited acceptance. The moderate amount of theoretical computations which Mr. Chase suggests for seasoning the judgment has unfortunately been so moderate that it has been almost completely absent. Design has consisted almost wholly of conformity to previous practice in size and shape with little regard for the principles involved or for the nature and settling characteristics of the particles to be settled.

A tray-type settling tank was constructed at Springfield, Mo., as mentioned by Professor Eliassen. A careful analysis of the removals effected in this plant before and after the trays were introduced will reveal that the improvement which should be expected by such an increase in the settling area was actually obtained.[53] Professor Eliassen's criticism of the Springfield tray settling tanks deals with details of mechanical design rather than with the principles involved. Obviously, if the sewage contains entrained gas and scum, they will rise to the roof of a tray; and a competent designer will consider skimming in this type of tank just as it is customarily provided for in conventionally designed tanks.

Mr. Anderson suggests that the writer might have shown in what way his proposed design for multiple-tray settling tanks may be more acceptable than those which have been patented and promoted for many years. The reason why the proposed design should be more acceptable than previously constructed tray-type tanks was carefully stated in the paper. Any tank that will produce the same removal as other tanks at less cost should be more acceptable. All previously constructed multiple-tray tanks that have come to the writer's attention have tray depths of about 2 ft and are designed with such low velocities that the flow is unstable. The Springfield tanks, moreover, are of the radial-flow type with the high inlet velocities and unstable flow conditions which characterize all radial-flow tanks. The design proposed suggests only rectangular tanks and high velocity shallow trays. The writer does not propose, however, that any such tank should be designed without experimental knowledge of the settling and flocculating characteristics of the suspension to be settled.

---

[53] "Report of Research Committee," *Sewage Works Journal*, March, 1942, p. 323.

Mr. Anderson states that the conclusions on the trends in design of final settling tanks for the activated sludge process may be questioned on the basis of an extensive study of plant-size experiments and operating data. In support of this statement Mr. Anderson submits the results of his own experiments.[42] On the basis of these experiments, Mr. Anderson argues that activated sludge should be withdrawn from the inlet end of the final settling tank. In a discussion of Mr. Anderson's paper,[54] R. H. Gould, M. Am. Soc. C. E., draws precisely the opposite conclusions and from the same experimental data—that is, Mr. Gould believes that activated sludge should be withdrawn from the outlet end of final settling tanks to counteract, partly, the effect of density currents. The writer believes that Mr. Gould's arguments are sound.

Mr. Anderson presents the results of experiments on a circular tank at Chicago, Ill., in which the sludge blanket was allowed to build up to great depths, as evidence that density currents are not avoided by the use of shallow high velocity final settling tanks. In this experiment the mixed liquor was introduced in a vertical flow pipe at the center of the tank and was discharged into the tank above the sludge blanket. The mixed liquor, being heavier than the supernatant liquor in the tank, must fall to the bottom of the supernatant liquor and thus produce the density current which was observed. A shallow high velocity tank is not in itself sufficient to avoid density currents. The inlet to the tank must be placed low enough, as indicated by Fig. 18(*c*), so that the mixed liquor enters below the top of the sludge blanket. It must also be introduced at a low inlet velocity.

An examination of all the final settling tanks referred to by Mr. Anderson reveals that the mixed liquor is introduced near the surface of the tank, and in many cases it may fall through a depth of as much as 10 ft. A rough estimate of the velocity of this fall may be made by assuming that the velocity head which induces the velocity of the density current is equal to the height of the fall multiplied by the net specific gravity of the mixed liquor. The specific gravity of the mixed liquor is approximately 1.0005; and, since the specific gravity of the supernatant is substantially equal to about 1.0000, the net specific gravity is the difference, or 0.0005. For a fall of 10 ft the corresponding velocity of a density current is 34 ft per min. The actual velocity, of course, is somewhat less because of the resistance to fall imposed by the supernatant liquor.

Mr. Anderson asks why this so-called short-circuiting of fresh sludge should be avoided when one of the most desirable features of a final settling tank is the withdrawal of fresh return sludge. The withdrawal of fresh return sludge is a desirable feature, of course, but it is only one of many desirable features that the designer should endeavor to secure. The tank should be so designed that all the sludge remains fresh and contains some dissolved oxygen. It should also be so designed that sludge is withdrawn only after it has received a maximum amount of compaction so as to reduce the volume of sludge that must be pumped. The sludge blanket after compacting is not a "flocculent suspension" as inferred by Mr. Anderson since the particles are resting on one another.

---

[54] *Sewage Works Journal*, January, 1945, p. 63.

Mr. Anderson states that:

> "* * * it appears that 'destruction of floc by excessive velocity gradients' * * * is not an important factor with aeration tank effluent."

It is well known that certain types of floc such as those in water treatment plants, particularly color floc, are easily destroyed by moderately high velocity gradients. The writer suspects that activated sludge flocs are much tougher and less easily destroyed, and it is reassuring to learn that the Sanitary District of Chicago has made tests which show practically no change in the settleability of aeration tank effluent even after a free fall over a weir and passage through both a venturi meter and a considerable length of conduit and aerated channel. The results of these tests at Chicago, however, should not be taken as an indication that all activated sludge flocs are tough. One cause of bulking of sludge in final settling tanks may be the destruction of floc at the inlet of such tanks. Since it is a comparatively simple matter to avoid any danger of destruction by designing the inlets as suggested in Fig. 18 (*c*), there appears to be no valid argument against such design.

Mr. Mulholland calls attention to the fact that the design of grit chambers is one of the weakest links in the entire process of sewage treatment plant design. This is true not only of sewage treatment plants serving small towns and villages but also of the largest plants because the principles involved have not been well understood by the designer.

Geometric scale models for studying sedimentation are not practicable because the laws of hydraulic similitude require that all dimensions should be scaled down proportionately, and obviously this is not practicable for the particles to be settled. Geometric scale models are useful in studying hydraulic short-circuiting because the flow patterns that are obtained in plant-scale tanks can be reproduced in the model. When a prototype suspension is introduced into a model settling tank, the results obtained are not an indication of the performance of the prototype settling tank as inferred by Mr. Mulholland. This statement should not be interpreted, however, as an argument against the use of pilot plants for sedimentation experiments. A well-designed and well-operated pilot plant should yield all the information the investigator needs regarding the settling and the flocculation of the suspension to be dealt with in a prototype plant. A pilot settling tank, however, is not a model tank in the true sense.

Mr. Chase states that:

> "In the case of raw sewage the solids in suspension are of such a heterogeneous and variable nature that no formula could possibly be devised of general applicability."

The theory developed in the paper applies not only to sewage solids but to all liquid suspensions. In fact, much of the basic theory applies to many other types of disperse systems such as solids in gas, liquid in gas, liquid in liquid, and gas in liquid. It is obviously impossible to develop any man-made theory which is complete and correct in all respects. It is the duty of engineers, nevertheless, to endeavor to place their analyses and designs on as rational a basis as can be obtained. If sanitary engineers do not follow this philosophy generally, in due time the business of designing treatment plants will be taken over by more competent experts. Many of the real advances in treatment plant design have been brought about through the efforts of equipment manufacturers and even now there is a tendency to look to manufacturers, rather than to consulting engineers, for expert service.

Professor Eliassen's principal criticism seems to be that the writer did not go far enough in his development. This is obviously true of any presentation of new theory or new experimental facts. One should not be condemned for starting the rationalization of settling tank design on the grounds that he has not presented a completed and fully tested theory. The responsibility for progress belongs to the profession as a whole.

Professor Eliassen attempts to show that practicing engineers have taken into account the settling characteristics of the suspension involved because they have employed overflow rates which are within the ranges used by the writer in some of his examples. On the contrary, the ranges in overflow rates mentioned by the writer were taken from current practice and not from any experimental measurements of the settling characteristics of suspension. These overflow rates were not recommended by the writer as desirable, but were simply used in examples for the purpose of illustrating the theory and methods of application.

Professor Eliassen suggests that some of the intermediate steps in the process of analysis of tank dimensions in terms of velocity gradients should be recognized by the designing engineer so that he is cognizant of the limitations of this method of analysis. Surely the obligations of the designing engineer extend further than this. As one limitation Professor Eliassen suggests that the velocity gradients produced by inlet turbulence and density currents have been neglected. Both density currents and inlet turbulence may be reduced to negligible proportions. In fact, the implications of the paper are that economical design makes this mandatory. Professor Eliassen's arguments are based on a knowledge of settling tanks currently in use rather than on a consideration of how tanks should be designed.

He states that:

> "Within the limitations of long shallow tanks in which the drag on the tank floor and walls will have a dominating influence on velocity gradients, the author develops a sound theory leading to quantitative results in several examples."

The natural corollary to this statement is that this type of tank should be used provided that experimental tests on the suspensions to be settled indicate that the optimum velocity gradients are within the required range. There is plenty of evidence in the literature that the flow conditions are unstable in short low velocity, deep tanks and that removal of suspended solids per unit volume of tank is not what it should be. This is particularly true of radial-flow circular tanks.

Professor Eliassen, questioning the use of Froude's law in model studies of short-circuiting, states that: "Mr. Camp presents no data based on model studies operated in accordance with Reynolds' law." To be strictly correct, geometric model studies should conform both to the Reynolds and Froude model laws. This is physically impossible, however, and the experimenter must use the law that yields flow patterns in the model which are most nearly similar to the flow patterns in the prototype. Both experience and tests indicate that Froude's law gives acceptable results.

Model tests were made by the Department of Water Supply of the City of Detroit (Mich.) on short-circuiting in the settling tanks in the water works park filtration plant as a preliminary to the design of guide vanes to reduce short-circuiting. These basins are of the "round-the-end" baffled type, and the change in direction of flow resulted in considerable short-circuiting and reduced settling efficiency. The model was operating in accordance with Froude's law, and the results obtained in the model were found to agree with those obtained in the prototype.

An experimental study was made at Massachusetts Institute of Technology at Cambridge, Mass., in 1939 under the writer's direction by William Christensen and Sylvester Morabito,[55] Jun. Am. Soc. C. E., to determine the applicability of Froude's model law in connection with model studies of the flow patterns in cubically-shaped mixing chambers operating with and without mechanical agitation by paddles. Two tanks, one four times the size of the other, were used in these experiments. The experiments revealed that, within the limits of experimental accuracy, Froude's law may be employed in model studies of the flow pattern in cubically-shaped mixing chambers and that, when paddles are employed, Froude's law also applies to the peripheral velocity of the paddles. No similarity in flow patterns was observed when Reynolds' law was used.

Professor Eliassen states that the writer has placed too much emphasis on short-circuiting as a criterion of settling tank performance. He feels that, since removal is determined by overflow rates, short-circuiting should have no marked effect. As commonly defined, overflow rate is the discharge per unit of surface area of the tank. For the purpose of this discussion, the definition given by Mr. Stein is preferable—that is, overflow rate is equal to the ratio of depth to detention time. Since all the particles of water do not have the same detention time, they do not have the same overflow rate. In other words, short-circuiting affects the overflow rate in precisely the same manner as it does the detention time.

The literature is full of experimental evidence that short-circuiting impairs the removal in settling tanks. Nearly all the papers describing improvements made to inlets and the baffling of tanks reveal that the effect of such improvements was to increase the removal of suspended solids. These improvements have no effect on the ratio of discharge to surface area. The improvements in removal must therefore have been caused by reduced short-circuiting.

---

[55] "Model Studies of Short-Circuiting in Mixing Chambers," by William Christensen and Sylvester Morabito, thesis presented to Massachusetts Institute of Technology at Cambridge, Mass., in 1939, in partial fulfilment of the requirements for the degree of Bachelor of Science.

Professor Eliassen states that tests made by himself indicate that settling efficiency is as great in circular tanks as in rectangular tanks despite the fact that short-circuiting is known to be worse in circular tanks. This is contrary to the experience of others. Operating experience on the long rectangular tanks at Detroit, Minneapolis, Minn., and Elizabeth, N. J., show much better suspended solids removal than does operating experience on the radial-flow circular tanks at Buffalo, N. Y.

In conclusion, the writer wishes to repeat for emphasis the statement made in the "Synopsis," relative to sedimentation, as follows:

> "Despite the importance of the process, current understanding of the principles involved has progressed so slightly that there is as yet no such thing in practice as the economic design of tanks from a functional viewpoint."

The responsibility for the development of the art of water treatment and sewage treatment rests squarely with the sanitary engineering profession since the public considers the sanitary engineer as the legitimate expert in this field. If he is to maintain this position he must participate in research and development. More participation in the field of sedimentation research is badly needed.

MATHEMATICAL EXAMINATION OF THE HIGHWAY TRANSITION SPIRAL

BY JOHN ORAN EICHLER,[1] ASSOC. M. AM. SOC. C. E., AND
HOWARD W. EVES,[2] ESQ.

WITH DISCUSSION BY MESSRS. JOSEPH BARNETT, RALPH W. STEWART, DONALD THOMPSON, T. F. HICKERSON, ALLEN H. BROWNFIELD, RENÉ S. PULIDO Y MORALES, C. C. WILEY, MAX C. KOEHLER, AND WILLIAM T. PRYOR.

SYNOPSIS

The growing importance of superhighways demands that increased attention be given to the inherent problems of construction and design. One of the most important of these problems is that of horizontal curvature and the attendant superelevation. A rational solution of this problem is the adaptation of a transition spiral, whose curvature varies inversely as the arc length. From considerations of speed, safety, and comfort it is found that two cases arise—that in which a central piece of circular arc is required, and that in which the curve is transitional throughout. The second case is desirable on grounds of relative simplicity of calculations, formulas, and field work. The question then naturally arises: "When, under certain given limiting conditions, can a curve be transitional throughout?" An answer to this question (and to other office and field problems related to the spiral) necessitates an examination of the mathematics of the transition spiral. Most existing mathematical treatments seem to suffer shortcomings due to lack of proof, or to failure to consider comfort and safety, or to loss of generality, or to confusion between exact and approximate relations, or to failure to be concise. Therefore, it is felt that an exposition of the curve and its properties obviating these faults and conducted primarily as a basis for examining questions, such as the foregoing, is eminently desirable. Such an attempt is offered in this paper.

1. INTRODUCTION

It seems safe to predict that the road engineers of the postwar period will have to give ever-increasing attention to the problems connected with the

---

NOTE.—Published in May, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Prof., Civ. Eng., College of Applied Science, Syracuse Univ., Syracuse, N. Y.

[2] Asst. Prof., Mathematics, College of Puget Sound, Tacoma, Wash.

development of superhighways. The aim will be to construct a roadway capable of carrying high-speed traffic, designed for maximum safety and comfort to drivers. Of the many problems involved, that of horizontal curvature, accompanied with proper superelevation, is one of the most important, and it is essentially with this feature of the future road that this paper is concerned. In particular, the writers would like to offer a simple and definite answer to the question: "When can a curve be transitional throughout?" Considerable theoretical research, table construction, and discussion have already taken place, as a complete bibliography of the subject would testify; but, because of the scattered nature of these references, the complete theory of easement curves is not readily available to the average road engineer. It would seem desirable, therefore, to have a clear, concise, and easily accessible account of the mathematical theory of the ideal easement curve, since it is only through a sound grasp of the mathematical properties of this curve that the dependent practical field work of laying out easement curves can be conducted intelligently. A representative bibliography is included as an Appendix to the paper.

2. The Transition Spiral

The forces acting on a vehicle and its passengers are altered when the vehicle passes from a straight to a curved path. The value of the centrifugal force P acting on a body of weight W, traveling at a speed V, and rounding a curve of radius r, is

$$P = \frac{W\,V^2}{g\,r} \qquad \text{(1)}$$

in which g is the acceleration due to gravity. If the path of the vehicle changes immediately from a straight line to a circle of radius r, the force P will be applied instantaneously, and the vehicle and passengers will be subjected to a proportionate shock. However, if the radius of curvature of the path is gradually reduced from infinity to its minimum value, the centrifugal force P will be increased gradually and little shock will be experienced by the vehicle and its passengers. Any curve that provides this transition is called an "easement curve." J. Glover (9)[3] and W. H. Shortt (27) have argued that the rational way to achieve this transition is to make the rate of gain of the "centrifugal ratio," P/W, constant throughout the curve. This is equivalent to the demand that the driver sharpen his curve by turning his steering wheel at a constant rate. Since, for a fixed speed V, P/W is proportional to $1/r$, it follows that the mathematical requirement for the perfect easement curve is that the radius of curvature, r, at any point should be inversely proportional to the distance, s, of that point from the beginning of the curve. Such an easement curve may be termed a "transition spiral." For a fixed speed, superelevation slope is proportional to curvature and hence, for the transition spiral, to s. It follows, therefore, that this curve is also ideal for the application of superelevation.

---

[3] Numerals in parentheses, thus: (9), refer to corresponding items in the Bibliography (see Appendix).

Many other forms of easement curves have been suggested and used, such as empirical or bastard transitions (possessing little to recommend them), the quadratic parabola (advocated by E. L. Leeming (16)), the cubic parabola (used extensively for short transitions in railroad work), the lemniscate (developed and used by F. G. Royal-Dawson (22) in England), the multi-compound spirals (such as the one evolved by W. H. Searles (25)), and the ten-chord spiral (13) adopted by the American Railway Engineering Association (which is essentially a transition spiral laid out in ten equal chord lengths). All these curves are modifications or approximations of the theoretically ideal transition spiral. It is not proposed here to enter into the arguments favoring any one easement curve over the others, but to develop the mathematics of the transition spiral and then, in the interests of economy in calculation and field work, to examine briefly some approximate formulas derived from the exact ones.

3. INTRINSIC EQUATION OF SPIRAL

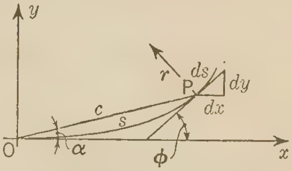

FIG. 1

In Fig. 1, let O be the beginning of the spiral on the initial tangent or x-axis. Then, if s is the arc length of the spiral from O to any point P on the curve, r is the radius of curvature at point P and ϕ is the angle that the tangent at point P makes with the x-axis, by the definition of a transition spiral:

$$\frac{1}{r} = k\,s \qquad (2)$$

in which k is a constant of proportionality; but, since curvature is the arc rate of change of ϕ: $\frac{1}{r} = \frac{d\phi}{ds} = k\,s$; whence, at the end of the spiral,

$$s = K\sqrt{\phi} \qquad (3)$$

in which

$$K = \sqrt{\frac{2}{k}} = \sqrt{2\,R\,S} \qquad (4)$$

R and S being the final radius of curvature and length of the spiral, respectively.

4. PARAMETRIC CARTESIAN REPRESENTATION

Letting ds, dx, and dy be differential changes in s, x, and y, respectively:

$$dx = ds\cos\phi = 0.5\,K\,\phi^{-1/2}\cos\phi\,d\phi \qquad (5a)$$

and

$$dy = ds\sin\phi = 0.5\,K\,\phi^{-1/2}\sin\phi\,d\phi \qquad (5b)$$

whence

$$x = 0.5\,K\int_0^{\phi}\phi^{-1/2}\cos\phi\,d\phi$$

$$= K\,\phi^{1/2}\left[1 - \frac{\phi^2}{5(2!)} + \frac{\phi^4}{9(4!)} - \frac{\phi^6}{13(6!)} + \cdots\right] \qquad (6a)$$

and

$$y = 0.5\,K \int_0^{\phi} \phi^{-1/2} \sin\phi \, d\phi$$

$$= K\,\phi^{1/2}\left[\frac{\phi}{3} - \frac{\phi^3}{7(3!)} + \frac{\phi^5}{11(5!)} - \frac{\phi^7}{15(7!)} + \cdots\right] \qquad (6b)$$

5. Polar Deflection Angle α

Let α be the polar deflection angle of point P with respect to O as origin and the tangent to the curve at O as x-axis. Then, by Eqs. 6,

$$\tan\alpha = \frac{y}{x} = \frac{\dfrac{\phi}{3} - \dfrac{\phi^3}{7(3!)} + \dfrac{\phi^5}{11(5!)} - \dfrac{\phi^7}{15(7!)} + \cdots}{1 - \dfrac{\phi^2}{5(2!)} + \dfrac{\phi^4}{9(4!)} - \dfrac{\phi^6}{13(6!)} + \cdots}$$

$$= \frac{\phi}{3} + \frac{\phi^3}{105} + \frac{\phi^5}{5{,}997} - \frac{\phi^7}{198{,}728} - \cdots \qquad (7)$$

Solving for α and setting

$$C = \frac{\phi}{3} - \alpha \qquad (8)$$

one may now compute the following values, expressing C, in minutes, corresponding to given values of ϕ, in degrees:

ϕ, in degrees	C, in minute
15	0.2
20	0.4
25	0.8
30	1.4
35	2.2
40	3.4
45	4.8
50	6.6

Such a table is given by J. Barnett, M. Am. Soc. C. E. (2), and is valuable for quickly obtaining the corrections C which must be subtracted from one third of any given ϕ in order to obtain the corresponding α. Use of this table will be made in section 9, where is developed the program for finding the control data of a required spiral.

6. Chord Length c

Denoting the chord length corresponding to arc s by c:

$$c = (x^2 + y^2)^{1/2} \qquad (9)$$

Substituting from Eqs. 6:

$$c = K\,\phi^{1/2}\left[1 + \frac{\phi^4}{25(2!)^2} + \frac{\phi^8}{81(4!)^2} - \frac{2\,\phi^2}{5(2!)} + \frac{2\,\phi^4}{9(4!)} - \frac{2\,\phi^6}{13(6!)} + \frac{2\,\phi^8}{17(8!)} - \frac{2\,\phi^6}{45(2!)(4!)} + \frac{2\,\phi^8}{65(2!)(6!)} + \cdots + \frac{\phi^2}{9} + \frac{\phi^6}{49(3!)^2} - \frac{\phi^4}{21(3!)} + \frac{2\,\phi^6}{33(5!)} - \frac{2\,\phi^8}{45(7!)} - \frac{2\,\phi^8}{77(3!)(5!)} + \cdots\right]^{1/2} \ldots\ldots\ldots(10a)$$

or

$$c = K\,\phi^{1/2}\left[1 + \phi^2\left(\frac{1}{9} - \frac{2}{5(2!)}\right) + \phi^4\left(\frac{1}{25(2!)^2} + \frac{2}{9(4!)} - \frac{2}{21(3!)}\right) + \phi^6\left(-\frac{2}{13(6!)} - \frac{2}{45(2!)(4!)} + \frac{1}{49(3!)^2} + \frac{2}{33(5!)}\right) + \cdots\right]^{1/2} \ldots(10b)$$

Eq. 10*b* is in the form

$$c = s\,[1 + (A\,\phi^2 + B\,\phi^4 + C\,\phi^6 + \cdots)]^{1/2} \ldots\ldots\ldots\ldots(11a)$$

or, expanding Eq. 11*a* by the binomial theorem,

$$c = s\left[1 + \frac{(\quad)}{2} - \frac{(\quad)^2}{8} + \frac{(\quad)^3}{16} - \cdots\right] \ldots\ldots\ldots\ldots(11b)$$

This then gives

$$c = s\left[1 + \phi^2\left(\frac{A}{2}\right) + \phi^4\left(\frac{B}{2} - \frac{A^2}{8}\right) + \phi^6\left(\frac{C}{2} - \frac{A\,B}{4} + \frac{A^3}{16}\right) + \cdots\right] \ldots(12a)$$

or

$$c = s\,[1 - 0.0444444\,\phi^2 + 0.0007054\,\phi^4 - 0.0000025\,\phi^6 + \cdots] \ldots(12b)$$

in which ϕ, of course, is given in radians. If ϕ is to be given in degrees:

$$c = s\,[1 - 1.354\,(10^{-5})\,\phi^2 + 6.6\,(10^{-11})\,\phi^4 - \cdots] \ldots\ldots\ldots(13)$$

Setting

$$p = \frac{c}{s} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(14)$$

one may use Eq. 12*b* or Eq. 13 for constructing a useful table (or a graph, as has been done by H. J. Collins and C. A. Hart, Assoc. Members, Am. Soc. C. E. (5)) giving the values of p corresponding to values of ϕ.

7. SAFETY AND COMFORT REQUIREMENTS FOR DRIVING THE SPIRAL

(*A*) The centrifugal ratio $\frac{P}{W} = \frac{V^2}{g\,r}$ must have an upper limit ρ, for the following reason: Let μ be the angle of superelevation and ν the angle of friction for the tires on the road. Then, from mechanics,

$$\frac{V^2}{g\,r} = \tan(\mu + \nu) = \frac{\tan\mu + \tan\nu}{1 - \tan\mu\,\tan\nu} = \frac{e + f}{1 - e\,f} \ldots\ldots\ldots(15)$$

in which $e = \tan \mu$ and $f = \tan \nu$. For practical reasons the superelevation slope e must be limited, and f (which is the coefficient of friction for transverse sliding of tires on the roadway) seems to depend on the speed. According to present American practice e seldom exceeds about 0.10, and, from a number of driving tests (19), it seems that f may be assumed at about 0.14 for a speed of 70 miles per hr to perhaps 0.08 for 100 miles per hr. According to Messrs. Collins and Hart (5):

> "The maximum centrifugal ratio for railways is normally taken as 1/8, but owing to the lower centre of gravity of motor vehicles, it may be safely increased to 1/4 for road work. This value is quite arbitrary and the 'factor of safety' will depend on a great number of considerations such as degree of superelevation, adhesion between road and tyres, bumpiness of road, etc."

(*B*) The rate of change of radial acceleration must have an upper limit γ. Let t be the time required to travel the entire length S of the spiral. Then

$$\gamma = \frac{V^2/R}{t} = \frac{V^2/R}{S/V} = \frac{V^3}{R\,S}\left(\frac{\text{ft}}{\text{sec}^3}\right).$$

This average rate varies for different drivers and many tests are needed to determine the maximum average rate. From considerations of comfort, Mr. Shortt (27) has fixed γ at $1\ \frac{\text{ft}}{\text{sec}^3}$, but more recent experiments by R. A. Moyer, Assoc. M. Am. Soc. C. E. (19), indicate that $\gamma = 2\ \frac{\text{ft}}{\text{sec}^3}$ is both safe and comfortable.

Paragraphs (*A*) and (*B*) yield the formulas,

$$R = \frac{V^2}{g\,\rho} \qquad \text{(16}a\text{)}$$

$$S = \frac{V^3}{R\,\gamma} = \frac{V\,g\,\rho}{\gamma} \qquad \text{(16}b\text{)}$$

and

$$\Phi = \frac{S^2}{K^2} = \frac{S}{2\,R} = \frac{V^3}{2\,R^2\,\gamma} = \frac{g^2\,\rho^2}{2\,\gamma\,V} \qquad \text{(16}c\text{)}$$

in which Φ is the deflection angle, R the radius of curvature, and S the arc length of the spiral for the point where the maximum centrifugal ratio is reached.

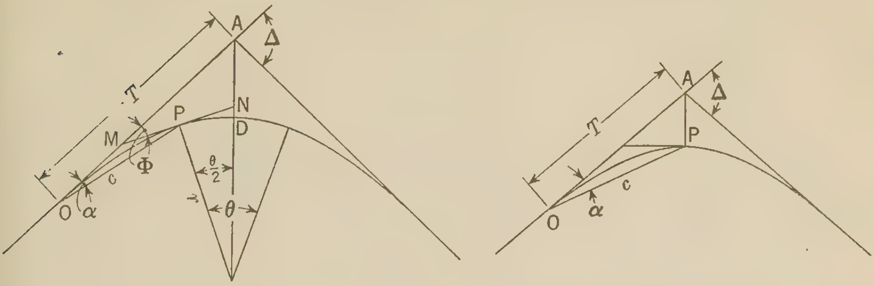
8. COMPUTATION OF TANGENT DISTANCE *T* AND EXTERNAL DISTANCE *E*

Let Δ be the intersection angle of the highway curve. For a given velocity V and selected values of ρ and γ, Eq. 16*c* indicates that Φ cannot exceed $\frac{g^2\,\rho^2}{2\,\gamma\,V}$. Hence, in designing a curve for a given speed V and selected values of ρ and γ, two cases need to be considered—that for which $\Phi < 0.5\,\Delta$ and that for which $\Phi \geqq 0.5\,\Delta$. In the first case the curve must contain a central circular arc; and, in the second case, the curve will be transitional throughout.

Thus, as an example, for a velocity of 100 miles per hr, $g = 32 \frac{\text{ft}}{\text{sec}^2}$, $\rho = 0.25$, and $\gamma = 2 \frac{\text{ft}}{\text{sec}^3}$, Eq. 16c yields $\Phi = 0.1091$ radian, or about 6.25°. Hence, if $\Delta \leqq 12.5°$ the curve, under these conditions, will be transitional throughout; otherwise a central circular arc will be needed.

Case 1. *$\Phi < 0.5\,\Delta$ (Central Circular Arc Required).*—In Fig. 2(*a*), angle MAN $= 90° - 0.5\,\Delta$ and angle MNA $= 90° + 0.5\,\Delta - \Phi$. Also,

$$T = \overline{\text{OM}} + \overline{\text{MA}} = \frac{c \sin (\Phi - \alpha)}{\sin \Phi} + \frac{\overline{\text{MN}} \sin (90° + 0.5\,\Delta - \Phi)}{\sin (90° - 0.5\,\Delta)} \quad \text{. . (17}a\text{)}$$



(*a*) CASE 1, $\Phi < 0.5\,\Delta$ (*b*) CASE 2, $\Phi \geqq 0.5\,\Delta$

FIG. 2

Again,

$$\overline{\text{MN}} = \overline{\text{MP}} + \overline{\text{PN}} = \frac{c \sin \alpha}{\sin \Phi} + R \tan 0.5\,\theta \quad \text{. . . . . (17}b\text{)}$$

Therefore,

$$T = \frac{c \sin (\Phi - \alpha)}{\sin \Phi} + \frac{\left(\dfrac{c \sin \alpha}{\sin \Phi} + R \tan 0.5\,\theta\right) \sin (90° + 0.5\,\Delta - \Phi)}{\sin (90° - 0.5\,\Delta)} \quad \text{. . (18)}$$

Furthermore,

$$\overline{\text{AN}} = \overline{\text{MN}} \frac{\sin \Phi}{\sin (90° - 0.5\,\Delta)} = \frac{c \sin \alpha + R \tan 0.5\,\theta \sin \Phi}{\sin (90° - 0.5\,\Delta)} \quad \text{. . . . (19}a\text{)}$$

and

$$\overline{\text{ND}} = R \sec 0.5\,\theta - R \quad \text{. . . . . (19}b\text{)}$$

Combining Eqs. 19,

$$E = \overline{\text{AN}} + \overline{\text{ND}} = \frac{c \sin \alpha + R \tan 0.5\,\theta \sin \Phi}{\sin (90° - 0.5\,\Delta)} + R \sec 0.5\,\theta - R \quad \text{. . (20)}$$

Case 2. *$\Phi \geqq 0.5\,\Delta$ (Transitional Throughout).*—In Fig. 2(*b*), angle OPA $= 90° + 0.5\,\Delta - \alpha$. Therefore,

$$T = \frac{c \sin (90° + 0.5\,\Delta - \alpha)}{\sin (90° - 0.5\,\Delta)} \quad \text{. . . . . (21}a\text{)}$$

and

$$E = \frac{c \sin \alpha}{\sin (90° - 0.5\,\Delta)} \quad \text{. (21}b\text{)}$$

9. Curve Control Data for Spiral

It is desirable to know the curve data for a transition spiral for which V, ρ, γ, and Δ are given. After computing Φ by Eq. 16*c*, such data may be found, for the two cases, in six steps, as follows:

Step	Case 1	Case 2
1	Compute R by Eq. 16*a*	Compute K by Eqs. 4, 16*a*, and 16*b*
2	Compute S by Eq. 3, 4, or 16*b*	Compute S by Eq. 3
3	Find α by referring to Section 5	Compute R by Eq. 4 or 16*b*
4	Find c by referring to Section 6	In Section 5, find α corresponding to $\phi = 0.5\Delta$
5	Compute $\theta = \Delta - 2\,\Phi$	Find c by referring to Section 6
6	Compute T by Eq. 18	Compute T by Eq. 21*a*

It must not be thought that there is only the one transition spiral suitable for a given velocity V and intersection angle Δ. On the contrary, because of the freedom of choice in selecting the limits ρ and γ, there are any number of permissible spirals. For example, in case 1, it is not necessary for the vehicle actually to achieve the maximum centrifugal ratio. By reducing ρ, the radius and the central angle of the central circular section are increased, and the lengths of the bounding spirals are reduced. In both cases γ can be reduced, thus increasing the total length S. As a matter of fact, in the three formulas, Eqs. 16, there are six variables, Φ, ρ, γ, V, R, and S. This means that any three of them may be chosen arbitrarily (within practical limits) and the other three thereby determined. In forming tables of curve data it may be considered convenient to fix, say, V, S, and R. For a given V and an accompanying variety of suitable values of S and R the designer would thus be able to give data for a number of allowable spirals for each degree of Δ. This has been done, for example, by Mr. Barnett (2*a*).

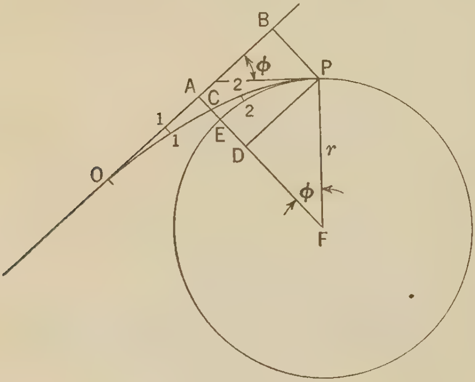


Fig. 3

10. Two Useful Relations

Let O (Fig. 3) be the origin and P any point of the spiral, and let F be the center of the osculating circle for P. Let the perpendicular FA from F to the tangent line OA cut the circle at point E and the spiral at point C. Denote length AE by σ and length OA by τ. Let D be the base of the perpendicular from P on FA and B the base of the perpendicular from P on OA (see Fig. 3). Then, $\sigma = \overline{\mathrm{BP}} - \overline{\mathrm{ED}} = y - r\,(1 - \cos\phi) = K\,\phi^{1/2}\left(\dfrac{\phi}{3} - \dfrac{\phi^3}{42} + \cdots\right)$

$$-r\left(\frac{\phi^2}{2}-\frac{\phi^4}{24}+\cdots\right) = s\left(\frac{s^2}{3\,K^2}-\frac{s^6}{42\,K^6}+\cdots\right)-\left(\frac{K^2}{2\,s}\right)\left(\frac{s^4}{2\,K^4}-\frac{s^8}{24\,K^8}+\cdots\right),$$

since $\phi = \frac{s^2}{K^2}$ and $K^2 = 2\,r\,s$. Finally

$$\sigma = s\left(\frac{s^2}{12\,K^2}-\frac{s^6}{336\,K^6}+\cdots\right)\ldots\ldots\ldots\ldots\ldots(22a)$$

Similarly, $\tau = \overline{\text{OB}} - \overline{\text{DP}} = x - r\sin\phi = K\,\phi^{1/2}\left(1-\frac{\phi^2}{10}+\ldots\right)$

$$-r\left(\phi-\frac{\phi^2}{6}+\cdots\right) = s\left(1-\frac{s^4}{10\,K^4}+\cdots\right)-\frac{K^2}{2\,s}\left(\frac{s^2}{K^2}-\frac{s^4}{6\,K^4}+\cdots\right).$$

Finally,

$$\tau = s\left(\frac{1}{2}-\frac{s^4}{60\,K^4}+\cdots\right)\ldots\ldots\ldots\ldots\ldots\ldots(22b)$$

11. APPROXIMATE RELATIONS GOOD FOR SPIRALS OF SMALL DEFLECTION

There are a number of approximate relations that apply for small values of ϕ, and, within their ranges of negligible error, are extremely useful for both computation and field work. In this section, a few of these relations are developed. Nine such approximations are presented, as follows:

1. For $\phi < 6°$, offsets from the initial tangent vary approximately as the cubes of the distances along the tangent;
2. Angle α is approximately equal to one third of ϕ; that is, $\alpha \approx \frac{\phi}{3}$;
3. Angle α varies approximately as the square of s;
4. For $\phi < 10°$, the tangent distance τ is approximately equal to $0.5\,x$; that is, $\tau \approx 0.5\,x \approx 0.5\,s$;
5. For $\phi < 10°$, the tangential offset AC, Fig. 3, is equal approximately to $0.5\,\sigma$;
6. When an upper limit ρ is developed, $\sigma \approx \frac{g^3\,\rho^3}{24\,\gamma^2}$, which is a constant;
7. The tangent distance T is equal approximately to $0.5\,S + (R + \sigma)\tan 0.5\,\Delta$;
8. The external radial distance E, from the point of intersection of two tangents to the curve, is approximately equal to $(R + \sigma)\sec 0.5\,\Delta - R$; and
9. Offset distances (1-1, Fig. 3) from the tangent to the spiral are approximately equal to the distance (2-2, Fig. 3) from the spiral to the tangent osculating circles, at equal distances from the opposite ends of a spiral.

Approximation 1.—For $\phi < 6°$, offsets from the initial tangent vary approximately as the cubes of the distances along the tangent. By Eqs. 6, $y \approx \frac{1}{3}\,K\,\phi^{3/2}$ and $x \approx K\,\phi^{1/2}$. Eliminating ϕ:

$$y \approx \frac{x^3}{3\,K^2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(23)$$

Thus, for small deflection angles, the transition spiral is approximated by a cubic parabola. The cubic parabola can be used successfully as an easement curve (6) for deflections up to about 8.5°, because all cubic parabolas reach their maximum curvature at $\phi = \text{arc tan } \frac{\sqrt{5}}{15} \approx 8.5°$.

Approximation 2.—Eq. 8, Section 5, indicates that when $\phi = 15°$ the error in assuming $\alpha \approx \frac{\phi}{3}$ is about 10″ (see list of C-values in Section 5).

Approximation 3.—Angle α varies approximately as the square of s because $\phi = \frac{s^2}{K^2}$; and therefore $\alpha \approx \frac{s^2}{3 K^2}$.

The formula for the lemniscate (see Fig. 4) is

$$c^2 = m^2 \sin 2\, \alpha \quad \text{.......................(24)}$$

in which m is the value of c at the midpoint of the lobe. For this curve the angle α equals exactly $\frac{\phi}{3}$. A special study of the lemniscate was made by Mr. Royal-Dawson (22). It can be shown that for the lemniscate $c\, r$, and not $s\, r$, is a constant. The objections to the lemniscate seem to be that s bears no simple relationship to any of the angles involved and hence the curve does not lend itself readily to calculations concerning s and r. Moreover, it is not a simple matter to lay out a lemniscate from a point on itself.

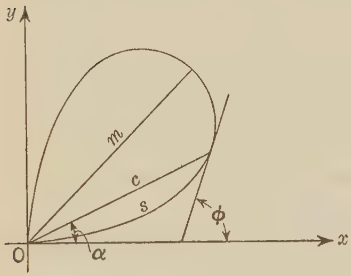

FIG. 4

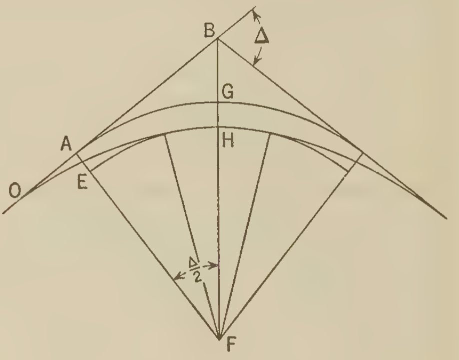

FIG. 5

Approximation 4.—For $\phi < 10°$, the tangent distance $\tau \approx 0.5\, x \approx 0.5\, s$ as can be concluded from Eq. 22*b*.

Approximation 5.—For $\phi < 10°$, the distance AC $\approx 0.5\, \sigma$ because (see Section 10):

$$y = s \left(\frac{s^2}{3 K^2} - \frac{s^6}{42 K^6} + \cdots \right) \quad \text{................(25)}$$

Therefore,

$$\overline{\text{AC}} = \frac{s}{2} \left(\frac{s^2}{12 K^2} - \frac{s^6}{2{,}688 K^6} + \cdots \right) \approx \frac{\sigma}{2} \quad \text{............(26)}$$

Thus, by approximations 4 and 5, it is clear that s and σ bisect each other approximately when ϕ is small.

Approximation 6.—When ρ is developed, $\sigma \approx \frac{g^3\,\rho^3}{24\,\gamma^2}$ (which is a constant) because (see Eq. 26) $\frac{\sigma}{2} \approx \overline{\mathrm{AC}} \approx \frac{\overline{\mathrm{BP}}}{8} = \frac{y}{8}$. Therefore,

$$\sigma \approx \frac{y}{4} \approx \frac{s^3}{12\,K^2} = \frac{s^2}{24\,r} = \frac{g^3\,\rho^3}{24\,\gamma^2} \qquad (27)$$

Approximation 7.—From Fig. 5,

$$T = \overline{\mathrm{OA}} + \overline{\mathrm{AB}} = \tau + (R + \sigma)\tan 0.5\,\Delta \approx 0.5\,S + (R + \sigma)\tan 0.5\,\Delta \qquad (28)$$

Approximation 8.—In Fig. 5, $\overline{\mathrm{BH}} = E$, $\overline{\mathrm{HF}} = R$, and $\overline{\mathrm{AE}} = \sigma$. Then, by geometry:

$$E = (R + \sigma)\sec 0.5\,\Delta - R \qquad (29)$$

Approximation 9.—In Fig. 3, let 1-1 be an offset from the tangent (perpendicular to the tangent) and let 2-2 be an offset from the osculating circle (normal to the osculating circle), and further assume that spiral arc O1 equals spiral arc P2. Then 1-1 ≈ 2-2, because, from Section 3, $\frac{d\phi}{ds} = k\,s$, whence $\frac{d^2\phi}{ds^2} = k$. Thus, the arc rate of change of the curvature for the spiral is constant; and the spiral departs from any osculating circle at the same arc rate as from the initial tangent. Hence, if ϕ is small, 1-1 ≈ 2-2. This property is convenient when using the method of deflection angles and the entire spiral cannot be set out from the origin, necessitating moving up along the spiral (21).

12. STAKING THE TRANSITION SPIRAL

There are three field methods establishing intermediate points on the spiral—the method of deflection angles, the method of tangential offsets, and the method of middle ordinates. Of these the first is the one most generally used in highway work and this section will be devoted to a brief examination of the method. For the remaining two procedures the reader is referred to the work of the late G. W. Pickels and C. C. Wiley, Members, Am. Soc. C. E. (21).

The problem is to lay out the spiral by polar deflection angles and constant chord lengths. The constant chord length will be referred to as the "unit chord." This unit chord must approximate closely the corresponding arc length, and should therefore not exceed 0.1 R. Denoting the unit chord by $\bar{s}$ and its deflection angle by $\bar{\phi}$, since ϕ varies as s^2,

$$\bar{s} = S\sqrt{\frac{\bar{\phi}}{\Phi}} \qquad (30)$$

To determine $\bar{s}$, set ϕ in Eq. 30 equal to 3′, 12′, 27′, or 48′, selecting that value which makes $\bar{s}$ of most suitable length. Having thus chosen $\bar{s}$ and $\bar{\alpha} = \bar{\phi}/3$, proceed to set out the spiral by polar deflection angles. In Table 1, the polar deflection angles have been computed by the fact that ϕ varies as

s^2 and that (see Eq. 8) $\alpha = \phi/3 - C$, and then recorded to the nearest 0° 0′ 20″, this being the limit of graduation of instruments in normal use (5).

It may be considered desirable to divide the spiral into a number of equal chords and then to set out the points from the formula,

$$\bar{\alpha} \approx \alpha \left(\frac{s}{S} \right)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

which is sufficiently accurate for values of ϕ to about 18°. Extensive tables, corrected for the approximation, have been prepared for this method (2), yielding the so-called ten-chord and twenty-chord spirals, ten or twenty usually being the adopted number of equal chords.

Both of these methods are open to the objection that the points fixed do not coincide with the even chain lengths along the curve; but in the absence of complete tables for the spiral the saving of time and computation is considered worth while.

TABLE 1.—POLAR DEFLECTION ANGLES FOR STAKING A SPIRAL BY CONSTANT CHORD LENGTHS

Values of α:[a]				Polar deflection
0° 1′	0° 4′	0° 9′	0° 16′

[a] Number of unit chord lengths from the beginning of the curve, for the values of α shown.

13. DEGREE OF CURVATURE

Without entering into the arguments for or against (23) the use of the idea of "degree of curvature," it remains a fact that it is the present American practice to treat curves in terms of this concept; hence a word or two will be offered in this section relating the equations of the previous sections to those involving the degree of curvature. Many definitions of degree of curvature exist, but that which seems most acceptable at present is the following (21):

Definition 1.—The degree of curvature, d, of a circular curve is the central angle of an arc of 100.007 ft.

Definition 2.—Extending Definition 1, the degree of curvature, d, of a transition spiral at any point is the degree of curvature of its osculating circle at that point. The final degree of curvature of the spiral is D.

Definition 3.—Let κ represent the rate of change of the degree of curvature of the transition spiral per 100 ft of arc length. The spiral can then be classified as a $\kappa°$-spiral (21). Relations connecting r and d, K and κ may be found as follows: The circumference of a circle equals $2\,\pi\,r = \dfrac{100.007 \times 360}{d}$; whence,

$$r = \frac{100.007 \times 360}{2\,\pi\,d} = \frac{5{,}730}{d} \quad\ldots\ldots\ldots\ldots\ldots\ldots(32)$$

From Eq. 4, $2\,r\,s = K^2$; and $\dfrac{2\,(5{,}730)\,s}{d} = K^2$. Making $s = 100$ ft and $d = \kappa$:

$$\kappa = \frac{200 \times 5{,}730}{K^2} = 100 \times 5{,}730\,k \quad\ldots\ldots\ldots\ldots\ldots(33)$$

By use of Eqs. 32 and 33, r (or R) and K can be substituted in any of the formulas of this paper by d (or D) and κ. Messrs. Pickels and Wiley (21) have presented a treatment along these lines.

14. Conclusion

One of the many problems encountered in highway engineering is that of curve construction and the consequent superelevation. The staking of the superelevation on unspiraled curves was a hit-or-miss affair, placing most of the burden on the motorist. In addition to speed, considerations of safety and comfort must also be treated attentively in curve design. The answer to the problem is a continuous spiral whenever that is possible. In determining when a curve may be transitional throughout it became necessary for the writers to examine the mathematical theory of the transition spiral. The first step was to examine the existing readily obtained literature, where it was found that the mathematical theory of the spiral was often obscured for one or more of the following reasons:

1. Although numerous formulas were offered, often no proof, or very little proof, was given;
2. Comfort and safety requirements were not sufficiently considered;
3. Generality was lost because field men were soon weaving into formulas specially adopted or favored values for certain parameters (for example, numerical values of ρ and γ might be adopted early in the treatment with the result that the significance of these parameters is lost forever in the sequel);
4. In an effort to be practical the essential mathematics was obscured by the mathematically extraneous idea of "degree of curvature";
5. Confusion and inconsistency were created by neglecting to make clear which mathematical properties of the curve are exact and which are approximate, or by neglecting to inform the reader to what extent a formula is approximate;
6. Often the mathematics was developed with the principal object of explaining or developing a particular set of tables, or the treatment was otherwise (purposefully, perhaps) one-sided; and

7. In a few cases (British), the treatment was too massive or exhaustive.

Perhaps this paper obviates some of these faults and will better serve the growing number of persons who need a clear and concise introduction to the fundamental principles of the curve.

Historically, the transition spiral was first investigated by the Swiss mathematician, Leonard Euler, and seems to be a mathematically rich curve. R. C. Archibald has presented an excellent historical sketch concerning the curve and its earlier applications to the study of elastic springs and to the theory of optics (35). An amazingly rich bibliography of the mathematical development of the properties of this curve is given. There is no duplication between this bibliography and the remaining items in the Appendix. In all likelihood the Euler curve possesses some still unknown properties (exact or approximate) which perhaps could be valuable to the engineer. Who knows, for example, how well the engineer might improve on the present osculating circle method of laying out the spiral when he faces the need for moving up along the curve (15)? The mathematical pole of the spiral can be found easily; can it be used? What new problems will the spiral present? Will there be any need for a rational method of applying vertical transition at the ends of the spiral? How can the engineer best devise such a method? Can he improve upon existing methods of describing right of ways for these curves (8)?

DISCUSSION

Joseph Barnett,[4] M. Am. Soc. C. E.—In several respects this paper is valuable, and not the least of these is its importance in calling the attention of highway engineers to a neglected phase of geometric highway design. Despite the surprisingly large bibliography, for which engineers are indebted to the authors, the use of transition approaches to curves on highways has not been generally accepted even though greater safety, smoother riding, and a more graceful alinement are attained without extra cost. Only about half the state highway departments now use transitions in highway alinements.

Among the reasons for this are reluctance to change existing practices and to revise standards; a belief that a vehicle using the highway is not confined to a track and is able to effect the change from a straight to a circular motion smoothly; a belief that widening at a sharp curve together with the gradual attainment of this widening accomplishes a satisfactory transition; and a belief that transitions involve tedious calculations both in the office and field, resulting in increased costs of engineering. There has also been considerable confusion as to what factors should determine the minimum length of a transition.

Some of these reasons were valid when road speeds were slower than at present but they do not apply now. At moderate speeds the average driver can traverse a satisfactory short transition path within the limits of a vehicle lane, but with increased speeds longer transitions are required. These can be traversed only by hazardous crowding or occupation of adjoining lanes. The increase in the speeds at which vehicles are operated, the desire for increased speed with safety, and the mounting accident toll make it imperative that highways be constructed in such manner that a driver traveling at the safe speed for which the highway is designed will not only find it possible to confine his vehicle to the occupied lane but will be encouraged to do so.

A discussion of the highway transition spiral might be divided into two general sections—theoretical and practical. Too much already has been written regarding theory. Several forms of curve have been advocated. The form used by the authors is that in which the radius varies inversely as the distance from the beginning of the transition curve. It is the same form of transition used by the late Arthur N. Talbot, Past-President and Hon. M. Am. Soc. C. E. (29), except that Professor Talbot developed a set of tables around the symbol a which represents the rate of change of degree of curve per 100 ft of length, and which equals the degree of curve at a point 100 ft from the "TS," the common point of tangent and spiral. T. F. Hickerson, M. Am. Soc. C. E. (13), used the same form of transition as the authors and gave the mathematical derivation for the coordinates x and y, but extended the mathematical derivation no further, since almost all values required for tables can be computed from x and y. W. H. Searles (25) developed a transition effected by a series of compound circular curves. In England, F. G. Royal-Dawson (23) advocated the use of the lemniscate, a form of curve which permits a certain type of field simplification. Several other forms are available. As regards riding qualities, safe speeds, or rates of change of superelevation, no one form of transition has any particular advantage over other forms.

---

[4] Chf., Urban Road Div., U. S. Public Roads Administration, Federal Works Agency, Washington, D. C.

There have been differences of opinion regarding the length of transition which should be used in highway design. Suggested lengths have been developed by theory but unfortunately there have been differences regarding the basis on which theoretical lengths should be developed. In developing lengths of transition for railways, W. H. Shortt used an average rate at which the vehicle on the transition approaches the final constant centripetal acceleration on the circular curve (27), but the rate to be used on highways is largely a matter of opinion. In a similar approach the time to turn the steering wheel to attain a certain degree of curvilinear motion at a certain speed has been advocated as a basis for length determination. Rate of runoff (that is, the change of superelevation in a unit of length) has many advocates, but there are differences of opinion regarding both the rate of runoff and the rate of superelevation. In all these determinations the speed of the vehicle is assumed and that is the basic difference of approach, particularly between designers in England and in the United States.

In England most designers assume that the geometric features of each curve, the radius, superelevation, and length of transition, determine the speed of the vehicle, an idea which has many advocates in the United States. Under this assumption a driver will change his speed at each curve. Although scientifically controlled observations are needed for a proper determination, most engineers have observed that once the average driver escapes the influences of urban conditions that tend to force a wide range of speeds, he is inclined to settle down to a uniform speed which, in his mind, is as great as the traffic and the physical characteristics of the highway permit. The speed is seldom the maximum speed of the vehicle since almost all passenger vehicles and some buses and trucks can attain speeds greater than that considered safe on existing highways and greater than that for which the public and highway engineers deem it economically feasible to construct most highways at the present time. For purposes of design it is assumed that traffic is not dense enough to slow down a vehicle and that the steady speed adopted by the driver depends largely upon the physical characteristics of the highway.

The personal factor cannot be ignored. Some drivers choose higher speeds than others. Some passengers feel comfortable at higher speeds than others. Those physical characteristics of the highway that tend to make a fast driver slow down also tend to make a slow driver reduce speed; but an approximately uniform speed, rather than a variable speed changed at each curve, is generally the aim of all drivers.

The difference in thinking regarding speed to be used in design has led to still another difference—one which relates to the use of a curve transitional throughout. The idea that each curve is traversed at its maximum permissible speed leads to use of curves transitional throughout for the smaller values of the intersection angle, Δ, and has been advocated chiefly in England. Highway designers in the United States incline to the use of two transitions and a central circular curve each taking up about a third of the central angle.

These differences can be reconciled only by the application of the results of tests of speeds on highways generally, tests of speed in relation to curvature and superelevation, and tests of driving comfort around curves. Results of tests on speed and comfort have been reported by D. W. Loutzenheiser (36), O. K. Normann (37)(38), and A. Taragin (39). The tests by John J. Leeming and A. N. Black (40) constitute one of the few attempts to measure comfort and driving practice around curves and, although they leave much to be desired to make them completely scientific and conclusive, they point the way toward conclusions which the writer feels are significant and which he has assumed for many years as the result of sheer logic. In their conclusions, Messrs. Leeming and Black state:

> "* * * it is tentatively suggested that curves should be designed to have about two-thirds of their length transitional, which would mean that the transition angle would be about one-quarter of the deviation angle. Curves designed according to this rule would then conform to what appears to be the average practice of drivers. As far as the information goes at present, it does not appear that any better compromise is available. As, however, the length of transition is not very important, it will be amply good enough for all practical purposes to make the transition angle as near as convenient to one-quarter of the deviation angle. In general, transitions should be short rather than long, and the main object should be simplicity and ease of layout and construction."

It is evident that precision in the form or length of transition curve is not necessary. The differences of opinion regarding the factors that determine length and type (particularly the factor of speed and its relation to curvature and superelevation) prove this. Then the problem of encouraging the adoption of transition curves for highway alinements is not one of persuading highway engineers to use a particular type of curve or particular relationship that results in a particular length, but in persuading engineers to use some kind of a transition curve. The mathematics presented by the authors should be simple to any one who has completed the average college course in calculus, or even advanced algebra; but it will "scare the shirt off" many surveyors on highway work. In addition the calculations must be made frequently in the field and supervisors are discouraged from adopting any procedure that requires a survey party to await the results of tedious calculations.

The control on most highway alinement problems, once the deviation angle Δ is measured, is either the tangent distance, T, or the external distance, E, from the point of intersection to the center of the curve, or both. If the common practice is followed of first designing and locating a circular curve and later adjusting the curve for inclusion of transition approaches, it results in odd values of the degree of curve and length of transition, and tedious calculations are necessary. If the uselessness of precision in length of transition is recognized, however, tables can be prepared which give the tangent distance T_s for curves with transitions, and the external distance E_s for curves with transitions, directly, and it becomes as easy with such tables to design and locate curves with transitions as to design and locate simple curves, provided the curves are designed initially as curves with transitions. Such tables, referred to by the authors (2), were prepared by the writer in 1938.

Several years of experience with these tables have revealed wherein they have proved their worth and where there are shortcomings. Where they have been tried on actual work and the designer or locator has jumped the hurdle of the explanatory mathematics which was kept to the minimum, no difficulty was encountered. In fact, the writer now advises that initiates omit the text and proceed to actual trial using the numerical examples to learn the simple operations. The choice of lengths of transition is limited to multiples of 50 ft and the degrees of curvature to even degrees, in some cases half degrees, so that except for straight-line interpolation no calculations are necessary that cannot be made, for all practical purposes, mentally; and, for every combination of the length of spiral L_s and the degree of curve D_c additional tables give all salient features of the transition curve including deflection angles to points on the transition divided into ten equal lengths.

Incidentally, although mathematicians do not take kindly to the concept of the degree of curvature used by the writer, it is a mighty handy tool to the man who must make calculations quickly. The length of arc subtending a central angle to be known as the degree of curve should be an even 100 ft and not 100.007 ft which the authors apparently chose in order to make the value representing the relationship between radius and degree of curve come out even. The necessity for having this value even is obscure. However, the use of radius instead of degree of curve does not minimize the usefulness of the type of tables proposed by the writer. In their Spanish translation in 1941, M. San Miguel, E. F. Tagle, and A. J. L. Bolognesi used the radius of curve in recomputing the writer's tables (2) to the metric system.

The principal shortcomings revealed by use of the tables in "Transition Curves for Highways" (2) are two in number: (*a*) For the larger values of Δ small values of D_c will seldom be used and corresponding values of T_s and E_s are unnecessary. It would be better to devote the limited space to giving a greater choice of the larger values of D_c; that is, values corresponding to degrees and half degrees instead of degrees only; and (*b*) for the very large values of Δ used in mountainous areas, and sometimes in turnouts, values for L_s = 100 ft and possibly values for sharper curvatures should be added.

RALPH W. STEWART,[5] M. AM. SOC. C. E.—As a mathematical examination of the transition spiral this paper is very thorough and complete. The bibliography, although unusually well prepared, omits what is probably the first presentation for practical use in America of the mathematics of the true transition spiral whose curvature uniformly increases from point to point. This was a paper (41) by the late Elliot Holbrook, M. Am. Soc. C. E., which appeared in 1880. The same mathematical procedure was used by A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E. (42), in a paper published in 1891, later to be included in Professor Talbot's book, "The Railway Transition Spiral" (29). In 1899, F. K. Vial used the law of constant increase in curvature of the transition spiral to devise a universal table of coefficients for deflections for laying out the curve. By the use of this table of coefficients (43) (29*a*), an instrument could be set at any chord point of any spiral which was divided into uniform chord lengths and the deflections to all other chord points could be computed by multiplying the spiral constant by the series of coefficients.

---

[5] **Bridge Engr., City of Los Angeles, Los Angeles, Calif.**

There were, in former years, many engineers who boycotted such mathematical procedures as the expansion of a function into an infinite series of terms by Maclaurin's theorem or otherwise, and who were annoyed by formulas such as Eqs. 10 and 11. This led to the use of the curve composed of a series of finite circular arcs whose properties could be computed by trigonometry.

The author states that he does not propose to enter into arguments favoring any one type of easement. The writer, however, wishes to call attention to the disadvantages (discovered through actual field experience) of the curve composed of a series of finite circular arcs; and also to show how to lay out a true spiral curve which, for all practical purposes, will coincide with a multi-arc curve.

The chief disadvantage of the multi-arc curve is that, with the transit set at the beginning of the first arc, which is called the beginning of the curve, accurate deflections are known only to the points where the arcs are compounded. If it is necessary to set points for the bents of a trestle bridge, a common procedure is first to set stakes at the compound points of the arcs and then move the transit from compound point to compound point to set the intermediate points at the bent locations. This and similar situations are not rare. It is sometimes necessary to set points that do not coincide with the compound points in order to investigate side clearances and to locate track crossings or other intersecting lines. The accumulation of all such incidents is quite appreciable. At one time the writer had to lay out the points of a multi-compound-arc spiral on the floor beams of a high steel bridge which was under construction. Not knowing at that time how to run the equivalent true spiral it was necessary for the bridge construction crew to lay temporary plank platforms at the compound points of the curve.

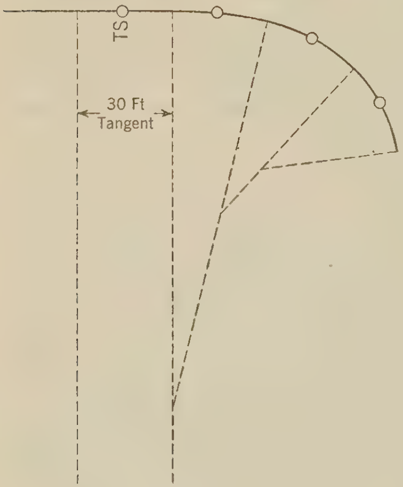

Fig. 6.

The true spiral, which (for all practical purposes) will coincide with a multi-arc substitute curve, can be determined easily. It is only necessary to lay out one arc length of tangent behind the beginning of the first arc. The center point of this tangent and the center points of the consecutive arcs will then define a true spiral of ample accuracy for practical use which will have the same rate of increase in curvature per unit arc length as the multi-compound substitute curve.

This is best illustrated by a numerical example. Let Fig. 6 represent a compound curve composed of arcs each 30 ft long. Let the first arc be a 0° 30 curve, the second a 1° curve, etc. Note that this provides for an increase in the rate of curvature of 0° 30′ in 30 ft or 1′ per ft. The radial lines in the figure indicate the ends of the arcs. The small circles indicate the centers of the arcs, and also the center point, marked TS (change from tangent to spiral), of the arc length of tangent which precedes the curve. If the accumulated curvature from TS to the center of each arc is computed, it will be found to vary as the square of the distance along the center line which is the intrinsic equation of the true spiral. It will also be found that a true spiral having a rate of curvature increase of 1′ per ft and beginning at the TS point will pass through the center points of the arcs, subject to negligible errors depending on whether chord lengths or arc lengths are measured and other causes of minute differences.

Since ample tables are available for laying out spirals, it is not necessary to cope with equations that involve an infinite series of terms.

The following analogy is useful in general engineering practice: A transition spiral represents uniform increase in rate of curvature. Uniformly accelerated motion represents uniform increase in velocity. This makes the total curvature in a spiral for any distance x along the curve equal to $0.5\ a\ x^2$, in which a is the rate of increase in curvature. This is analogous to the formula $0.5\ g\ t^2$ which represents the distance that a body falls (starting from rest) in any elapsed time t under the rate of acceleration g. Also, the elastic curve of a cantilever beam of uniform section caused by a concentrated load at its free end is a transition spiral as long as the deflection is small, because the bending moment, and consequently the elastic curvature, increase uniformly with the distance from the load.

Donald Thompson,[6] Esq.—The review of the mathematical theory of the highway transition spiral, as presented in this paper, should prove interesting and instructive to engineers designing high-speed highways. Recent publications on transition curves, notably the work of Joseph Barnett, M. Am. Soc. C. E., cited by the authors (2), have avoided an exposition of the mathematical theory on which the true transition curve is based. Thomas F. Hickerson, M. Am. Soc. C. E. (13), gives the derivation of most of the spiral formulas but omits the mathematical theory for the formula for the deflection angle.

Earlier publications on the true transition curve, however, gave the derivation of all the fundamental equations developed by Professors Eichler and Eves. In 1893 the late C. L. Crandall, M. Am. Soc. C. E. (44), developed all the formulas for the true transition curve. Professor Crandall credits the late Elliot Holbrook, M. Am. Soc. C. E., with first describing the true transition curve in which curvature increases directly with the distance (41), and developing the formulas and practice for small angles.

It is true, of course, that knowledge of the mathematical theory is not essential either for designing or for staking transition curves. With either Mr. Barnett's or Professor Hickerson's book, the use of transition curves will involve scarcely any more work than the use of circular curves. The authors' method of calculating the elements of a particular spiral by substituting in the fundamental formulas, although interesting from a mathematical standpoint, is not practicable. The spiral elements can be taken directly from tables in either of the afore-mentioned books (2) (13) in a fraction of the time consumed in substituting appropriate values in the formulas of this paper.

---

[6] Civ. Eng. Associate, Bureau of Eng., City of Los Angeles, Los Angeles, Calif.

The derivation of the formula for the deflection angle α in Section 5 is not complete. Eq. 7 was given as $\tan \alpha = \frac{\phi}{3} + \frac{\phi^3}{105} + \frac{\phi^5}{5{,}597}$, in which ϕ is in radians. To derive a formula for α (not $\tan \alpha$) the deflection angle must be expanded in terms of its tangent. Thus,

$$\alpha = \tan \alpha - \frac{1}{3} \tan^3 \alpha + \frac{1}{5} \tan^5 \alpha \ldots\ldots\ldots\ldots\ldots (34a)$$

Substituting Eq. 7 in Eq. 34*a*, dropping higher powers than the third, and converting to degrees, the correct formula for the deflection angle is

$$\alpha^\circ = \frac{\phi^\circ}{3} - 0.000000859\ (\phi^\circ)^3 \ldots\ldots\ldots\ldots\ldots\ldots (34b)$$

The formula for the correction C that must be subtracted from one third of any given value of ϕ in order to obtain the corresponding value of α is, therefore,

$$C = 0.000000859\ (\phi^\circ)^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (35a)$$

In calculating the deflection angles for a particular spiral it is necessary to express the deflection angle α in terms of the length s along the curve to the point for which the deflection is desired, the total length S of the spiral, and the total spiral angle Φ. In terms of these variables

$$\alpha = \frac{\Phi^\circ}{3} \left(\frac{s}{S} \right)^2 - 0.000000859\ (\Phi^\circ)^3 \left(\frac{s}{S} \right)^6 \ldots\ldots\ldots\ldots (35b)$$

The formula for the centrifugal ratio, Eq. 15, is given as $\frac{V^2}{g\,R} = \frac{e + f}{1 - e\,f}$ in which e is the superelevation in feet per foot, f is the coefficient of friction, R is the radius in feet, g is acceleration of gravity, and V is the velocity in feet, per second. This is the exact formula for superelevation with friction considered. It would be useful in designing a racing track where large values of e might be necessary, but it is never used in highway design. Since the maximum values of e and f permitted in the design of highways are quite small, $1 - e\,f$ will be very nearly equal to 1 and the formula for the centrifugal ratio can be simplified to

$$\frac{V^2}{g\,R} = e + f \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36a)$$

Converting V to miles per hour, Eq. 36*a* becomes

$$\frac{0.067\ V^2}{R} = e + f \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36b)$$

which is the approximate formula for the centrifugal ratio and the one always used in highway design. Since the approximate formula will give slightly lower velocities than the exact, it is on the side of safety.

A value of $f = 0.14$ for the unbalanced centrifugal ratio (which is mentioned by the authors in Section 7 as being the accepted standard) seems too great for comfort at high speeds. Ralph A. Moyer, Assoc. M. Am. Soc. C. E. (45), has recommended that the unbalanced centrifugal ratio f should not exceed 0.10 at 60 miles per hr. Charles M. Noble, M. Am. Soc. C. E. (46), after exhaustive high-speed tests on the Pennsylvania Turnpike, recommended that, for velocities of 70 miles per hr, f should not exceed 0.10. In designing parkways for the Bureau of Engineering of the City of Los Angeles, Calif., the writer uses a value for f which varies with the velocity. The variation is considered to be linear and, expressed as a formula, is

$$f = 0.16 - 0.001\,V \qquad (37)$$

in which V is in miles per hour. At 60 miles per hr, f would be 0.10. Using a maximum value of 0.10 for e, the maximum value of the centrifugal ratio would be 0.20. For the maximum superelevation of 0.10 the minimum radius will be $R = \frac{0.067 \times 60^2}{0.20} = 1{,}200$ ft. For curves larger than the minimum the superelevation should vary inversely as the radius so that the general formula for superelevation for a design speed of 60 miles per hr is

$$e = \frac{120}{R} \qquad (38)$$

in which e is in feet per foot, and R is in feet. For the length of the transition spiral and the superelevation transition the writer is using a value of 1.5775 ft per sec^3 for γ instead of the commonly accepted 2 ft per sec^3 which results in a value for the length of the transition of

$$S = \frac{2\,V^3}{R} \qquad (39a)$$

in which V is in miles per hour and S and R are in feet. For a design speed of 60 miles per hour, Eq. 39a can be expressed as

$$S = \frac{432{,}000}{R} \qquad (39b)$$

This length of transition will limit the difference in grade throughout the superelevation transition between the center line of a 36-ft roadway and the outside edge of a 36-ft roadway to 0.5% or 1 in 200 provided the superelevation is attained by rotating about the center line of the roadway.

It is the present practice in the City of Los Angeles to first project a circular alinement making proper allowances for external distances and lengths of tangents between reversing curves and then to insert the transition curves. With this method it becomes a very simple matter to determine whether a curve will be transitional throughout or have a remaining circular arc. If any circular arc on the projected alinement has a length equal to 432,000/R, the transition curves when inserted will take up all the circular arc and the resulting curve will be transitional throughout. If a circular curve on the original alinement has a length greater than 432,000/R, then there will be some circular arc left after the transitions have been inserted. For the sake of appearance, the minimum length of any circular curve has been set at 500 ft. Since the maximum length of transition would be 432,000/1,200 = 360 ft, occurring on the minimum radius of 1,200 ft, all curves will have a portion of a circular arc remaining and will not be transitional throughout.

In their conclusion the authors state that they hope their paper will serve as a clear and concise introduction to the fundamental principles of the true transition curve. The paper has accomplished its purpose and should stimulate interest in, and promote, the wide acceptance of the true transition curve by highway engineers.

T. F. HICKERSON,[7] M. AM. SOC. C. E.—In their mathematical examination of the highway transition spiral the authors have cited some, but not by any means all, of the contributions that have been made in adapting this curve to the layout of highways. For example, the writer has prepared a table containing the deflections from a tangent to any point on a spiral (13*a*). This table meets the objection mentioned by the authors, in their description of two methods of staking the spiral (Section 12), that "the points fixed do not coincide with the even chain lengths along the curve * * * ." In connection with the curve that is transitional throughout, the writer prepared a table (13*b*) giving "Tangents and Externals to the Unit Double-Spiral Curve of Length 100 Ft."

Knowing the intersection angle Δ and the actual length of this curve which is transitional throughout, the tangents and externals can be written at once. Thus, if $\Delta = 40°$ and the length of each spiral is 600 ft (total length of curve 1,200 ft), then $T_s = 102.987 \times 6 = 617.92$ ft and $E_s = 12.275 \times 6 = 73.65$ ft. These tabular values of T_s and E_s for the unit curve were computed by the writer from the formulas:

$$T_s = T + k + p \tan 0.5\,\Delta \qquad (40a)$$

and

$$E_s = E + p \sec 0.5\,\Delta \qquad (40b)$$

in which T and E are the tangents and external distances for the osculating circular curve;

$$k = x_c - R_c \sin \phi_c \qquad (41a)$$

and

$$p = y_c - R_c \operatorname{vers} \phi_c \qquad (41b)$$

In Eqs. 41 the subscripts c refer to point P (Fig. 1) at the end of the spiral where it coincides with the circle.

Eqs. 40 are more simple than Eqs. 21 presented by the authors inasmuch as the data required for their solution are already known to a high degree of accuracy (13*c*). The tabular values of T_s and E_s have been checked by the writer by means of the following independent pairs of formulas:

---

[7] Prof. of Applied Math., Univ. of North Carolina, Chapel Hill, N. C.

$$T_s = x_c + y_c \tan \phi \dots\dots (42a)$$

$$T_s = c\,(\cos \alpha + \sin \alpha \tan \phi) \dots\dots (42b)$$

$$E_s = y_c \sec \phi \dots\dots (43a)$$

$$E_s = c \sin \alpha \sec \phi \dots\dots (43b)$$

The values of x and y for any point of the spiral are:

$$x = s\left(1 - \frac{\phi^2}{10} + \frac{\phi^4}{216} - \frac{\phi^6}{9{,}360} + \cdots\right) \dots\dots (44a)$$

and

$$y = s\left(\frac{\phi}{3} - \frac{\phi^3}{42} + \frac{\phi^5}{1{,}320} - \frac{\phi^7}{75{,}600}\right) \dots\dots (44b)$$

in which ϕ is measured in radians.

Expressing ϕ in degrees, Eqs. 44 become:

$$x = s\,[1 - 0.304617\,(10)^{-4}\,\phi^2 + 0.429592\,(10)^{-9}\,\phi^4 - 0.301987\,(10)^{-14}\,\phi^6 + \cdots] \dots\dots (45a)$$

and

$$y = s\,[0.581776\,(10)^{-2}\,\phi - 0.126585\,(10)^{-6}\,\phi^3 + 0.122691\,(10)^{-11}\,\phi^5 - 0.65256\,(10)^{-17}\,\phi^7 + \cdots] \dots\dots (45b)$$

Calculating machines and eight-place tables of logarithms and trigonometric functions are needed to compute the tabular values correct to the sixth significant figure. Such accuracy would establish the parts of a spiral to the nearest hundredth of a foot even when the length of the spiral is 1,000 ft. Now that these tables have been compiled and checked independently by different parties it is to be hoped that engineers will use them in good faith just as they do tables of logarithms.

The authors brought up a good point in stating that there are any number of permissible spirals suitable for a given velocity V and intersection angle Δ. In Eq. 16b, if $\gamma = 2 \frac{\text{ft}}{\text{sec}^3}$ (a safe limiting value) and if $V \frac{\text{ft}}{\text{sec}}$ is expressed as $v \frac{\text{miles}}{\text{hr}}$:

$$S = \frac{1.58\,v^3}{R} \dots\dots (46)$$

Eq. 46 is often misinterpreted. It gives the minimum permissible length of transition curve that may be used without exceeding the maximum allowable rate of change of acceleration while driving a car from a straight path to the full curvilinear path.

Assume that $v = 60$ miles per hr; then if $R = 2{,}000$ ft, $S = 170.6$ ft; and if $R = 4{,}000$ ft, $S = 85.3$ ft. These values of S are strictly according to the arbitrary formula, but if a much longer transition is feasible the change from a straight to a curved path would be all the easier and the general appearance of the curve all the more improved.

ALLEN H. BROWNFIELD,[8] ASSOC. M. AM. SOC. C. E.—This paper and its extensive bibliography should prove quite useful in highway design for establishing departmental standards involving transition curves. In addition to the authorities cited previously the following should be included: R. C. Archibald (47), the late D. E. Hughes, M. Am. Soc. C. E. (48) (49), the late William Cain, M. Am. Soc. C. E. (50), the late C. L. Crandall, M. Am. Soc. C. E. (44), the late S. W. Robinson, M. Am. Soc. C. E. (51), who cites the work of the late Elliot Holbrook, M. Am. Soc. C. E. (41), Southern Pacific Railroad Company (52), J. C. Nagle (53), who cites the work of Mr. Crandall (44), the late W. B. Lee, M. Am. Soc. C. E. (54), John H. Fletcher (55), the late N. B. Kellogg, M. Am. Soc. C. E. (56), A. L. Higgins (57), H. Criswell (58), and William T. Pryor, Assoc. M. Am. Soc. C. E. (59). Each of these articles deals directly with Euler's spiral (sometimes referred to as the American spiral) and will help to trace its development in the United States.

A complete treatment of the Euler spiral will involve three steps: (*a*) A discussion of the background, as has been done so ably by the authors; (*b*) analyses by tables or graphs showing the authors' recommendations regarding length of curve and superelevation (also a more extensive list of useful formulas correlating all parts of the spiral to be used by highway planners); and (*c*) solutions of numerical examples for field and office use in staking this curve.

There seems to be considerable hesitancy on the part of some highway departments to adopt the Euler spiral. Maybe this is due to the apparent complexity of the formulas and difficulty in finding the proper tables. Several of the references have quite extensive tables and one of these is a seven-place table of natural functions at 3-min intervals.

From the following it should be clear that the spiral, with tables, is nearly as simple as a circular curve, and more simple than a compounded curve. Evidently the circle would be difficult without extensive tables of natural and logarithmic functions.

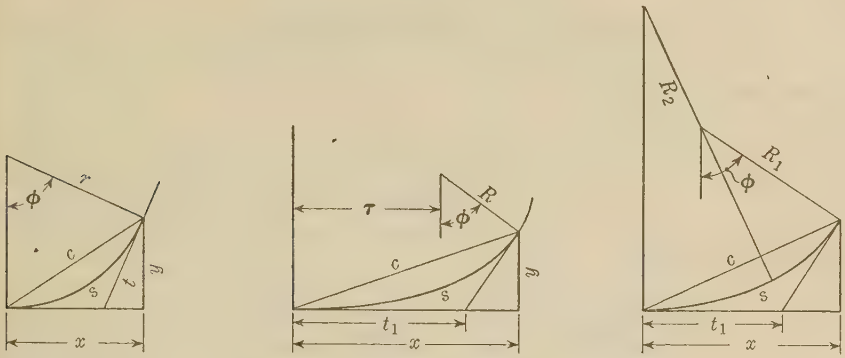
Since most of the spiral tables are developed in terms of s and ϕ, it is convenient to compare them with a circle using the x-axis along a tangent, as follows:

Dimension	Circle (Fig. 7(*a*))	Euler's spiral (Fig. 7(*b*))
s	$r\,\phi$	$2\,R\,\phi$
y	$s\,\frac{\text{vers}\,\phi}{\phi}$	$s\,\text{vers}_s\,\phi$
x	$s\,\frac{\sin\phi}{\phi}$	$s\,\sin_s\phi$
c	$\frac{2\,s}{\phi}\sin\frac{\phi}{2}$	$s\,f(\phi)$
t (and t_1)	$\frac{s}{\phi}\tan\frac{\phi}{2}$	$s\,\tan_s\phi$
α	$\frac{\phi}{2}$	$\frac{\phi}{3}$ − correction

---

[8] Senior Structural Engr., Div. of Architecture, State of California, Sacramento, Calif.

The terms $\sin_s$, vers_s, and $\tan_s$ are introduced to show the parallelism and are defined as "sine spiral," "versine spiral," and "tangent spiral," respectively. They are similar to the circular functions of $\frac{\sin \phi}{\phi}$, etc.



(a) CIRCLE (b) EULER'S SPIRAL (c) COMPOUND CIRCLE

FIG. 7

From an examination of Figs. 7(*b*) and 7(*c*) it is evident that the tables for Euler's spiral are faster to use than those for a compound circle.

In the following discussion the writer has not included the derivations as they may detract from, rather than enhance, the use of spirals.

Apparently the authors followed the same procedure as F. G. Royal-Dawson (23) in deriving Eq. 7. If the division is made as indicated in the foregoing a formula is evolved which is nearly identical to Eq. 7:

$$\tan \alpha = \frac{y}{x} = \frac{\phi}{3} + \frac{\phi^3}{105} + \frac{26\,\phi^5}{155{,}925} - \frac{17\,\phi^7}{3{,}378{,}375} - \cdots\cdots\cdots\cdots \quad (47)$$

or

$$\alpha = \frac{\phi}{3} - c = \frac{\phi}{3} - \frac{8\,\phi^3}{2{,}835} - \frac{32\,\phi^5}{467{,}775} - \frac{128\,\phi^7}{83{,}284{,}288} - \cdots\cdots\cdots \quad (48)$$

The last term of Eq. 48 is nearly correct; thus:

$$\phi = 3\,\alpha + \frac{8}{35}\,\alpha^3 + \frac{1{,}376}{13{,}475}\,\alpha^5 + \frac{207{,}488}{3{,}678{,}675}\,\alpha^7 + \cdots\cdots\cdots\cdots \quad (49)$$

and

$$c = s\left(1 - \frac{2\,\phi^2}{45} + \frac{2\,\phi^4}{2{,}835} - \frac{316\,\phi^6}{127{,}702{,}575} + \cdots\right)\cdots\cdots\cdots \quad (50)$$

Solution of Eqs. 7 to 13 will seldom be needed in practice since all values necessary for their solution have been tabulated by several authors.

The writer has found the following equations useful on several occasions (one or two terms will usually suffice). Let σ equal the offset AE in Fig. 3; then:

$$n = \frac{6\,\sigma}{r}\text{; and } \phi = \sqrt{n + \frac{n^2}{28} + \frac{29\,n^3}{16{,}170} + \frac{1{,}391\,n^4}{13{,}582{,}800} + \cdots}\cdots\cdots \quad (51)$$

The area under the curve between s, x, and y equals

$$A = s^2 \left(\frac{\phi}{12} - \frac{\phi^3}{42} + \frac{23\,\phi^5}{10{,}395} - \frac{2\,\phi^7}{17{,}325} + \cdots \right) \ldots\ldots\ldots\ldots (52)$$

In Fig. 2(b),

$$T = s\left(1 + \frac{7\,\phi^2}{30} + \frac{139\,\phi^4}{1{,}512} + \frac{8{,}927\,\phi^6}{240{,}240} + \cdots\right) \ldots\ldots\ldots\ldots (53)$$

As compared with Eq. 22b,

$$\tau = s\left(\tfrac{1}{2} - \frac{\phi^2}{60} + \frac{\phi^4}{2{,}160} - \cdots\right) \ldots\ldots\ldots\ldots (54a)$$

or

$$\tau \approx \frac{2\,s + x}{6} \ldots\ldots\ldots\ldots (54b)$$

Similarly (see Eq. 22a),

$$\sigma = \frac{s}{2}\left(\frac{\phi}{3(2!)} - \frac{\phi^3}{7(4!)} + \frac{\phi^5}{11(6!)} - \frac{\phi^7}{15(8!)} + \cdots\right) \ldots\ldots\ldots\ldots (55)$$

Many simple and useful relations can be derived from the following, some of which have been published by Mr. Hughes (48) (49):

$$s^2_2\,\phi_1 = s^2_1\,\phi_2 \ldots\ldots\ldots\ldots (56a)$$

$$R^2_1\,\phi_1 = R^2_2\,\phi_2 \ldots\ldots\ldots\ldots (56b)$$

$$R_1\,s_1 = R_2\,s_2 = \text{constant} \ldots\ldots\ldots\ldots (56c)$$

Typical formulas for s are:

$$s = x\left(1 + \frac{\phi^2}{10} + \frac{29\,\phi^4}{5{,}400} + \frac{127\,\phi^6}{702{,}000} + \cdots\right) \ldots\ldots\ldots\ldots (57a)$$

$$s \approx x_1 + \frac{x^5_1}{40\,R^2_1\,s^2_1} \pm \ldots\ldots\ldots\ldots (57b)$$

and

$$s = c\left(1 + \frac{2}{45}\,\phi^2 + \frac{2\,\phi^4}{1{,}575}\cdots\right) \ldots (57c)$$

Eq. 57b is derived from the cubic parabola. Referring to Fig. 8,

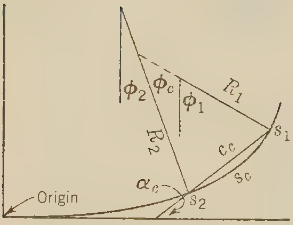


FIG. 8

$$s_c = s_1 - s_2 = 2\,R_c\,\phi_c \ldots\ldots\ldots\ldots (58)$$

in which s_c is any part of the spiral arc, R_c is its mean radius, and ϕ_c is the subtended angle. Also:

$$R_c = \frac{R_1\,R_2}{R_1 + R_2} \ldots\ldots\ldots\ldots (59a)$$

$$\phi_c = \phi_1 - \phi_2 \ldots\ldots\ldots\ldots (59b)$$

and

$$s_m = \frac{s_1 + s_2}{2} = 4\,R_c\,\phi_m \ldots\ldots\ldots\ldots (60)$$

Some useful approximations can be derived from Eqs. 58 to 60:

$$c_c \approx 4\,R_c \sin\frac{\phi_c}{2}; \qquad (61a)$$

$$\alpha_c \approx \frac{\phi_1 + \sqrt{\phi_1\,\phi_2} + \phi_2}{3} = \frac{\phi_1 + 4\,\phi_m + \phi_2}{6}; \qquad (61b)$$

and

$$c_c = s_c - \text{correction} \qquad (61c)$$

The correction in Eq. 61*c* is nearly proportional to $(\phi_c)^2$, which fact makes it possible to traverse a spiral along its chords.

By Eq. 50 the first chord correction (see Table 2) is:

$$\text{Correction} = -\,s \times \frac{2\,(\phi^\circ)^2}{45} \times \frac{\pi^2}{180^2} \qquad (62)$$

That is,

$$-\,s \times \frac{2\,(\phi^\circ)^2}{45} \times \frac{\pi^2}{180^2} = -\,50 \times 0.5^2 \times 0.0000135386 = -\,0.00016923 \text{ ft.}$$

Assume the following conditions as an example: $s_1 = 300$ ft, $\phi_1 = 18°$, $R_1 = 477.465$, $x_1 = 297.053$ ft, $y_1 = 31.195$ ft, $\tau = 149.508$ ft (by Eq. 54*b*, $\tau = 149.509$ ft), $\sin_s \phi = 0.9901754$, and $\text{vers}_s\,\phi = 0.1039838$. Referring to Table 2, x_1 is computed as 297.050 ft, which checks the foregoing value of 297.053. Similarly, 31.195 checks the foregoing value of y. The values of $\phi°$ in Col. 2, Table 2, are proportional to $(\text{point})^2$ in Col. 7; thus, for point 5, $\phi° = \frac{25}{36} \times 18° = 12.5°$, etc. In Cols. 8 and 9, a is the difference between adjacent values of $(\text{point})^2$, the values of a^2 being factors used in determining the chord correction in Col. 10. Eq. 61*b* is used for computing the values of $\alpha°_c$ in Col. 4. The length of any given chord is equal to s_s minus the correction for that chord computed by Eq. 62 and Col. 9.

TABLE 2.—COMPUTATIONS FOR TRAVERSING ALONG SPIRAL CHORDS

Point	Station (1)	$\phi°$ (2)	Chord (ft) (3)	$\alpha_c°$ (4)	$\cos\alpha_c$ (5)	$\sin\alpha_c$ (6)	$(\text{Point})^2$ (7)	a (8)	a^2 (9)	Correction (ft) (10)

Many trick problems can be solved directly. For example, given s and σ, let $z = \frac{12\,\sigma}{s}$. Then

$$\phi = z + \frac{z^3}{28} + \frac{397\,z^5}{129{,}360} + \frac{55{,}437\,z^7}{162{,}993{,}600} + \cdots\ldots\ldots\ldots\ldots \text{(63}a\text{)}$$

Another case arises when a given curve center and a given spiral s are fixed. Let R equal the radius of the existing circle; it is required to compute the new radius R_n. If $q = \frac{s}{2\,R}$—

$$\phi = q + \frac{q^3}{6} + \frac{25\,q^5}{504} + \frac{20{,}167\,q^7}{1{,}164{,}240} + \cdots\ldots\ldots\ldots\ldots \text{(63}b\text{)}$$

from which, knowing ϕ and s, $R_n = \frac{s}{2\,\phi}$ can be computed readily.

As indicated by the authors, the spiral and its involute wind about a point (35) (47) (49) that lies on a 45° line from the origin and is distant from it a length $\sqrt{\frac{\pi\,R\,s}{2}}$. This is the value of c as ϕ approaches ∞. The maximum chord and maximum ϕ-values have been calculated. The involute of Euler's spiral is not the hyperbolic spiral; nor is the evolute of a hyperbolic spiral a simple transition curve.

The idea of a curve that is transitional throughout has occurred to many engineers and, as indicated in the paper, it presents a grade transition problem where the curves meet. Compound spirals similar to compound circles are feasible and the writer has seen this arrangement on a set of plans only once.

The authors are to be commended for their extensive research as indicated by the bibliography. Their list of "approximate relations" will be found useful and may be verified by plotting corrections to s on either log-log paper or alinement graphs.

It should be obvious from the foregoing that Euler's spiral is an exact curve and that tables can be used for most of the work. Some writers use the degree-of-curve system. This should be a personnel choice because either system works if one can establish a definition for it. Since s, R, and ϕ (or Δ) are quantities used by all surveyors, there seems to be little need for any particular one of a dozen degree systems.

Right of ways can be described as parallel to a center-line spiral and this center-line curve can be retraced from any two parts such as s and R or R and ϕ. Areas can be computed by Eq. 52, and they can be checked approximately by the traverse.

The use of tables has been emphasized because the writer has seen many men shrink from the extensive formulas and derivations. The body of data presented herein is only a small portion of the material available and it should be needed only on rare occasions. Eqs. 51 to 63 should prove useful particularly to any designer trying to aline a transition around a bridge pier. The subject of computing a spiral between two circles has not been given much attention in this discussion. Most cases are quite simple if Eqs. 56 are combined with Eqs. 58, 59, and 60. These are exact equations and will not require extensive tables.

RENÉ S. PULIDO Y MORALES,[9] ESQ.—The use of any of the easement curves to provide a safe and comfortable transition around a curve is only a rough method of obtaining the maximum possible high speed with safety and comfort. It is necessary to study more intently the path and characteristics of the center of gravity of the vehicle, endeavoring to keep it approximately at the same height, and on a predetermined trajectory. Another cause of discomfort is the acceleration of the center of gravity of the vehicle in a transverse direction. This effect cannot be eliminated, but it can be reduced.

The spiral that is transitional throughout is composed of two symmetrical spirals of a length:

$$S = R_m \Delta \ldots\ldots\ldots\ldots (64)$$

in which Δ, the total deflection of the curve, is in radians, and R_m is the radius at the point of maximum curvature. Therefore, the total length is equal to:

$$S_t = 2\, R_m \Delta \ldots\ldots\ldots\ldots (65)$$

Also,

$$S = 1.6 \frac{V^3}{R_m} \ldots\ldots\ldots\ldots (66)$$

Combining Eqs. 64 and 66, and solving for R_m:

$$R_m = \sqrt{\frac{1.6\, V^3}{\Delta}} \ldots\ldots\ldots\ldots (67)$$

Eq. 67 is a valuable guide for determining the minimum radius of a spiral that is transitional throughout.

A mathematical expression whose derivation is readily available in standard texts is

$$\gamma = -\frac{V^3}{R^2}\frac{dR}{dS} \ldots\ldots\ldots\ldots (68)$$

Eq. 68 demonstrates that the spiral is the most advantageous of all types of transition curves. It yields the spiral of minimum length and is particularly useful when space is restricted.

Integrating Eq. 68:

$$S = \frac{V^3}{R\,\gamma} + C \ldots\ldots\ldots\ldots (69)$$

Noting that $\frac{V^3}{\gamma} = K$ is a constant:

$$S = \frac{K}{R} + C \ldots\ldots\ldots\ldots (70)$$

which is the typical spiral equation. The formula for the determination of the transition length—$S = \frac{V^3}{R\,\gamma}$ (Eq. 16*b*)—is not precisely applicable to other transitions than the spiral. It is derived by the following reasoning: In the path of a vehicle traveling on a transition curve at constant speed, the centripetal acceleration is zero at the beginning where the radius is equal to ∞, and $\frac{v^2}{R}$ at the end where the radius is the minimum for that case. If t is the time of travel, the rate of acceleration along the curve is expressed by:

---

[9] Civ. Engr., Havana, Cuba.

$$\frac{v^2}{R} \times \frac{1}{t} = \gamma . : \ldots\ldots\ldots\ldots\ldots\ldots (71)$$

Substituting $t = \frac{S}{v}$ in Eq. 71, $S = \frac{v^3}{R\,\gamma}$; but this is only an expression for the mean value and cannot be accepted as an elegant conclusion, although it is admitted that mean acceleration is equal to maximum acceleration.

The mathematical requirement for the perfect easement curve—that the radius of curvature r at any point should be inversely proportional to the distance s to that point—is not precise, since these two quantities vary approximately (but not precisely), in inverse ratio, as stated in the paper.

In the writer's opinion, all the easement curves—the cubic parabola, the lemniscate, the Talbot, Searles, Crandall, and Ericson curves—are satisfactory and give substantially the same results in the field. The lemniscate advocated by F. G. Royal-Dawson (24) in England is the most rational at the single point where the radius of spiral curvature is greatest; but it is not rational for any other point along the spiral. This easement curve requires more length than the spiral.

The paper is a good contribution to the literature on easement curves.

C. C. Wiley,[10] M. Am. Soc. C. E.—Every one who uses the spiral must, at some time, learn how. Consequently, in addition to being mathematically sound and practical in application, the treatment should be such that it can be comprehended easily. The first requirement is that the basic geometry shall be presented simply and clearly, and that it be kept constantly in the foreground. The second is that formulas, computations, and operations shall be simple, direct, universally applicable without auxiliaries, and conform to accepted engineering practices.

Most writers on spiral transitions have failed in these things—partly, because they seem to have been too anxious to plunge into mathematical derivations, but more particularly, because they have attacked the problem in such a manner, and from such premises, as to result in cumbersome formulas, tedious computations, and awkward field work, which have obscured the geometry and given the spiral an unmerited reputation of complexity.

The purpose of a curve is to provide a safe, convenient, and comfortable change of direction. The critical factor in traveling on curves is the centrifugal force, which must be kept within satisfactory limits. Basically, centrifugal force is a function of the angular velocity which, in turn, is a function of curvature. The conventional formulas for centrifugal force, however, have been written in terms of linear velocity and radius of curvature. This may explain why so many writers have started with the radius of curvature instead of curvature itself.

---

[10] Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

The circle is universally used as the basic curve because its geometry is simple; it is symmetrical with respect to traffic; and conditions of travel on it are constant. Its defect lies in that, mathematically, it requires instant change from rectilinear to curvilinear motion, which is mechanically impossible. Consequently, spirals are introduced at the ends of the circular arc to provide a gradual transition in curvature to control the centrifugal force. Any change of direction made by the spiral is only a by-product.

A circle may be defined properly as "a curve whose angular change of direction per unit of arc is a constant." When expressed in ordinary engineering units this is nothing more nor less than the familiar "degree of curve" whose merits have been recognized by railroad engineers for about a century, but which many highway engineers still ignore. The degree of curve expresses the curvature of the circle directly, whereas the radius is merely an incidental linear dimension useful in certain computations. Since the spiral is designed to provide transition in curvature, it would seem that the "rational" attack would be on the basis of curvature rather than radius.

All writers on this subject seem to agree that the ideal spiral should be a curve whose curvature increases uniformly with the distance from the origin. Therefore, the intrinsic equation of the spiral may be written directly from the definition in the form

$$d = k\,s \qquad \text{(72)}$$

which, in engineering terms, makes d the degree of curve at any point; k the rate of change of the degree of curve in degrees per 100 ft (station); and s the distance from the origin in stations (100 ft). Every term now has a simple geometric conception which is easily comprehended and easily learned. An examination of the writings of the late A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., and those of others using his method shows that it has many intrinsic advantages.

In practice, the curvature of the basic circle is selected with respect to expected speed subject to topographic restrictions. A length of arc is then cut from it to provide the required total change of direction. Rarely, if ever, is the length chosen and the curvature made to conform. In contrast, most writers have chosen the length of spiral and made the curvature to fit; probably because the first spirals were to be superimposed on existing arbitrary lengths of superelevation runoff. This mode of attack, especially when combined with the radius of curvature, inevitably leads to cumbersome formulas, complicated computations, and other troubles, which have obscured, and sometimes almost obliterated, the basic geometry. As stated, the basic geometry must be understood if the spiral is to be used intelligently.

Under the Talbot method, when k is chosen, a spiral of indefinite length is "fixed" from which arcs of proper length may be cut to fit between a tangent and any circle, or between two circles as in the case of the compound curve. Thus, this method becomes fully "rational" and of simple and universal application.

Various writers have shown that the curvature characteristics of a satisfactory spiral are a function of the cube of the speed. The authors express this in Eq. 16*b* which is not readily usable, whereas R. A. Moyer, Assoc. M. Am. Soc. C. E. (19), gives it in the simple arithmetical form

$$L = \frac{1.58\,V^3}{R} \qquad (73)$$

stating that this is the minimum length (L) for safety. In order to provide for both safety and comfort, the writer and the late G. W. Pickels, M. Am. Soc. C. E., have recommended a desirable highway spiral in the form

$$k = \frac{230{,}000}{V^3} \qquad (74)$$

which is practically equivalent to a coefficient of 2.5 in Eq. 73 and gives a spiral one half as long as that considered desirable on the railroads (21).

Since moderate variations of the speed are permissible on any curve, and since the same speeds will apply over moderate variations in curvature, it follows that a comparatively small number of different spirals having simple and convenient values of k will fully cover all ranges of speed and curvature to be found in highway alinement. On the other hand, the use of arbitrary lengths, each covering a range of curvature, results in inconvenient values and requires the computation of an entirely new spiral for each change of curvature. Thus the Talbot method of fixing the spiral curvature and selecting a length to meet the given circle provides simple formulas, a minimum of computations, and a maximum flexibility in application.

The term ϕ, total change of direction at any point on the spiral, appears in many of the authors' formulas, but none of the formulas seem to give an expression for evaluating it. Perhaps this is a result of the idea of making $\phi = \frac{1}{2}\Delta$; but if Eq. 4 is extended a step or two further, the result is:

$$\phi = \tfrac{1}{2}\,k\,s^2 \qquad (75)$$

which is identical in form with the Talbot formula but is in different units. In the Talbot formula ϕ is given directly in degrees, whereas the authors give it in radians, which is undesirable.

Various writers show that α, the spiral deflection angle, is very nearly $\frac{1}{3}\,\phi$ and, in Table 1, the authors give corrections from which they show that in most cases the difference is very small, and may be omitted. Professor Talbot came to the same conclusion. As a matter of fact, in practice α can always be taken as $\frac{1}{3}\,\phi$ because the sole effect of omitting the correction is to move the circular curve bodily a very small distance outward. In a very extreme case, with $\phi = 30°$, this movement was only about 1 in., which is utterly insignificant.

In Eq. 75, α becomes $\frac{1}{6}\,k\,s^2$ in degrees which, when converted to minutes, becomes the ridiculously simple equation

$$\phi = 10\,k\,s^2 \qquad (76)$$

Obviously, with uniform chord lengths, it is necessary to compute only the first value of α by the formula and then find the others by multiplying the first by the square of the digits. If simple values of k are used with stakes at the usual distances of 25 ft, 50 ft, or 100 ft, the spiral deflections may be written almost as fast as those of a circular curve (with possibly a last one equal to $\frac{1}{3}\,\phi$ if the spiral has an odd length). This is so simple, and so in accord with basic geometry, that it is easily learned.

The general solution for the tangent distance of a spiraled curve, in Section 8, is interesting. It is cumbersome because it involves the calculation of the otherwise useless spiral chord c and the solution of one right triangle and two oblique triangles. The geometry of the solution is well shown in the figure, but the authors "spoiled the show" by writing out all the mechanical operations, culminating in the appalling appearance of Eq. 18, which completely obliterates the geometry. The day is past when either engineers or students want, or need, a formula like this which only adds to the forbidding appearance of the spiral treatment.

A few additions to Fig. 3 would have shown directly that

$$T = (R + \sigma)\ tan\ \tfrac{1}{2}\Delta + \tau \ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

which is far simpler as it involves the solution of only one right triangle plus two spiral elements often wanted for other purposes. This solution is shown by the authors in approximation 7, Section 11, in which the only approximation is the very slight one of using $\tau = \frac{1}{2}\,S$.

Obviously, safety and comfort are highly important but it must not be inferred that they have not received, or are not receiving, careful attention. The railroads originally derived lengths of runoff from studies of safety and comfort, and later derived their spirals in a similar manner. Highway engineers, however, had little factual data to aid them until the work of Professor Moyer appeared (19). Unfortunately, present data are scarcely adequate and those that are available must be used with care and judgment.

Eq. 15 may be reduced to the slightly approximate "safe speed" formula often used by highway engineers

$$V^2 = 15\,R\,(e + f) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

in which: e is the actual superelevation cross slope built into the road; and f is usually defined as the safe coefficient of friction against lateral skidding. Actually, it is a coefficient of unbalanced centrifugal force expressed in terms of cross slope. Thus, the quantity $e + f$ becomes the equivalent theoretical superelevation for the maximum speed V. If the maximum value of f against skidding only is used, no allowance is made for comfort; hence the latter must be introduced merely by judgment in choosing f since, at present, factual data are not available.

Shortly after the appearance of Professor Moyer's work (19), the U. S. Public Roads Administration suggested a value of $f = 0.16$. Several highway departments objected and several made test runs. The Illinois Division of Highways, on the basis of both safety and comfort, reached the conclusion that a maximum value of $f = 0.10$, for speeds of approximately 50 miles per hr, was satisfactory. An examination of available data indicates that, for both safety and comfort, f may be taken as about 0.10 at 40 miles per hr and about

0.04 at 100 miles per hr. This agrees well with the railroad rule for excess speed which is equivalent to about $f = 0.05$.

The idea of curves "transitional throughout" is an old one. It seems to result from a misinterpretation of "transitional" and the failure to give due consideration to the elements of comfort and convenience on curves. The primary function of the spiral is to make a transition in curvature to control centrifugal force—not to provide change of direction. To require also that it provide change of direction is to impose a duty for which it is not fitted.

When traveling on a tangent both driver and passengers are subject to constant conditions. In traveling on a circle they are also subjected to constant conditions although these conditions are not the same as on a tangent. The function of the spiral is to provide a transition between these different conditions. With proper spirals the change is made with comfort and convenience as well as safety, and the driver and passengers must adjust themselves to changing conditions only on the spirals. If the curve is "transitional throughout" there is no part of its entire length where travel conditions are constant.

Furthermore, since a spiral is twice as long as the circle with the same final curvature and total central angle, making the curve transitional throughout adds greatly to the length of curve over all of which travel conditions are constantly changing. For example, assume a speed of 60 miles per hr on a 4° curve ($R = 1{,}432.5$) with $\Delta = 64°$. A spiral with $k = 1$ is suitable, giving spirals 400 ft long. The unspiraled circle would have a length of 1,600 ft, with bad conditions at the end; but most of its length would offer constant travel conditions. When spiraled, the total length would be 2,000 ft, of which 1,200 would have uniform travel conditions with 400 ft at each end to make the transitions. If "transitional throughout," the length would be 3,200 ft with no part having constant conditions. If the latter curve is reduced to 2,000 ft its central curvature would be increased to 6° 24′ ($R = 895.3$), which is entirely too sharp for the given speed.

If, for a given speed, curvature, and change of direction, it should happen that $\phi = \frac{1}{2}\Delta$, the curve is short and automatically and properly is transitional throughout. If the computed value of ϕ is greater than $\frac{1}{2}\Delta$ then, because of speed, the same spiral should be used but it should merely be shortened until $\phi = \frac{1}{2}\Delta$. If the computed value of ϕ is somewhat less than $\frac{1}{2}\Delta$, speed would again call for the same spiral and the residual circular arc, no matter how short, should be retained for simplicity. Making $\phi = \frac{1}{2}\Delta$ would not improve the curve and would require completely new calculations and field notes. For greater values of Δ the benefits of uniform travel conditions on the curve would become increasingly evident.

In 1923 the writer had a graduate student who spent much time in trying to develop a curve "transitional throughout." Several such curves were laid out and test runs made over them. Except for short curves they were disliked by both drivers and passengers. If they were made of suitable middle curvature, the lengths became unreasonably long, and if they were shortened to reasonable length, the middle curvature became too sharp for the speeds. In addition, the geometry was complex, the formulas ponderous, the calculations long and tedious, and the field work awkward. In short, the results were so unsatisfactory that they were never published.

The spiral is intrinsically so simple that it is a misfortune that it should have been so mutilated as to be almost unrecognizable, and to acquire a forbidding if not sinister appearance. When properly presented, its applications are so simple that an average field engineer can make complete computations and field notes in very little more time than is required for an unspiraled curve and the field operations are practically identical. In some schools students are required to be able to spiral, completely, either a simple or a compound curve with no auxiliaries whatever (not even the textbook) except the usual tables of the trigonometric functions. Until something simpler than this is devised the writer is perfectly contented with his present methods.

To summarize the writer's honest view of this paper: It contains nothing really new in mathematical treatment. The general mode of attack is the same as that used by a number of other writers, as are many of the forms of mathematical derivations. It adds nothing to expedite or improve the use and applications of the spiral; if anything, it confuses them more than before. The use of ϕ in the formulas is an innovation, but it is objectionable for several reasons. The principal objection is that it is based on a false premise since ϕ, the total change of direction on the spiral, is an incidental result and not a basic function. Some of the incidental items such as "safety and comfort" have merit but might have been given more attention. The "approximations" have all been long recognized whereas the manner in which they are given still leaves a hazy impression that they should not be tolerated.

What the highway spiral needs is some way of eradicating all the old awkward treatments of the spirals as given in most field manuals, and of avoiding the need for tabular data. State highway departments are wasting plenty of persons, pencils, paper, patience, and profanity on a problem which, actually, is little, if any, more complex than circular curves.

MAX C. KOEHLER,[11] ASSOC. M. AM. SOC. C. E.—With the nation returning to a normal economy, reconstruction of existing highways and the construction of new superhighways will be one of the major programs of the postwar period, and a discussion of the spiral easement curve is timely. Prior to World War II this refinement of design was going through its "growing pains"; it is still in that process and will possibly continue so for ten years or more. It has followed, and will follow, the same processes of development as the railroad easement curves in the nineteenth century; wherein every one from roadmaster to college professor advanced his pet idea on how to make the transition from a tangent to a circular curve without throwing the locomotive off the track or the passengers in the aisles. The smooth gliding ride of the modern "streamliners" at from 70 to 100 miles per hr has forced the passengers again to rely on the weather as a topic of conversation. A short history of this period may reveal the pattern that will be followed in highway design.

Writing at the University of Glasgow in Glasgow, Scotland, in 1862, W. J. M. Rankine (60) stated that a Mr. Gravatt, in 1828, was using the sine curve for railroads in England. This curve was transitional throughout, but was objected to by many because there was no simple curve. Rankine recommended the use of a transition curve developed by William Froude in 1841. Froude made "short shift" of curve staking as follows:

---

[11] Engr. P-3, U. S. Engr. Office, Seattle, Wash.

(1) Locate the center of the railroad, using simple curves and tangents.

(2) Determine the length for the "curve of adjustment" by the formula $L = 300\,x$ the greatest change of cant (superelevation) in feet.

(3) Compute the shift b, in terms of the length L and the radius R, as follows:

$$b = \frac{L^2 R}{24} \qquad (79)$$

(4) Set out the curve by use of formula (a cubic parabola):

$$y = 4\,b\,\frac{l^3}{L^3} \qquad (80)$$

in which l is the distance measured on the circular arc and y is the ordinate. For further information, Rankine refers to a technical article (61) published in 1860 and 1861. Rankine also advised raising the outer rail above the center line for one half the cant, and depressing the inner rail an equal amount. Happily, the outer rail is now adjusted for the full cant and "grade" is carried on the inner rail. The highways passed through this same experience, complicated by parabolic crowns and extra widening on the inside. It is now fairly uniform practice to omit the crown as soon as the superelevation begins, carry the grade on the inside edge of the pavement, and "throw" all the superelevation to the outside of the curve. Where the curve is located on a "ruling grade" the grade is "compensated"; that is, it is reduced so that the grade of the high edge does not exceed the "ruling grade."

In the United States the late Elliot Holbrook, M. Am. Soc. C. E. (41), seems to have been the first to publish a comprehensive article on the transition spiral. It contains a rigorous proof that the spiral angle θ, when the ratio of degree of curve to length L is unity, is:

$$\theta = \frac{L^2}{200} \qquad (81)$$

This is the first published account the writer has been able to find of the "American Spiral," in which the degree of curve varies directly as the distance along the curve. The editor remarks at the end of Holbrook's article, that "In Germany, and on some roads in France, the tangent is connected with the curve proper, or circular curve by what is called a 'connecting-curve,' which in Germany is made parabolic." However, the late William Cain, M. Am. Soc. C. E. (50), claims that the late A. M. Wellington, M. Am. Soc. C. E. (62), was the first man to define the true transition spiral. Wellington himself refers to it as a cubic parabola in which the length is proportional to the square root of the offset.

Holbrook prepared a table for a spiral increasing 10 min in degree of curve for every 10 ft of length along the spiral up to 210 ft where $\theta = 3^\circ\,30'$. This same table contains a column for deflection angles from the beginning of the spiral. For lengths as great as 50 ft, d (deflection) seems to be $\frac{\theta}{2}$; but after that $d = \frac{\theta}{3}$ which has since been proved true for any deflection, using a slight correction when θ exceeds 15°. A short but rigorous proof of the intrinsic equation of the spiral has been presented by the late D. E. Hughes, M. Am. Soc. C. E. (63), as follows: Referring to Fig. 9, R varies as $\frac{1}{L}$; that is, $R = \frac{K}{L}$. Also, $R = \frac{dL}{d\theta}$, from which $\frac{dL}{d\theta} = \frac{K}{L}$, or

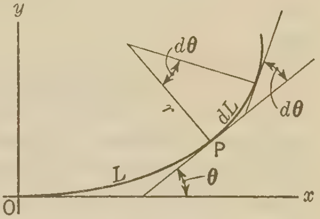

FIG. 9

$$L\,dL = K\,d\theta \ldots\ldots\ldots\ldots (82)$$

Integrating Eq. 82, $\frac{1}{2} L^2 = K\,\theta$; or

$$L = \sqrt{2\,K\,\theta} \ldots\ldots\ldots\ldots (83)$$

In other words, θ varies as L^2 (see Eq. 83) and $L = 2\,R\,\theta$, or twice a circular arc of the same radius and angle. Hughes then expands the sine and cosine series of $d\theta$ to derive:

$$x = \sqrt{2\,K\,\theta}\left(1 - \frac{\theta^2}{5^2} + \frac{\theta^4}{9^4} - \frac{\theta^6}{13^6} + \cdots\right) \ldots\ldots\ldots\ldots (84a)$$

and

$$y = \sqrt{2\,K\,\theta}\left(\frac{\theta}{3^1} - \frac{\theta^3}{7^3} + \frac{\theta^5}{11^5} - \frac{\theta^7}{15^7} + \cdots\right) \ldots\ldots\ldots\ldots (84b)$$

suggesting that a table be prepared for values of x and y. It is to be noted that Hughes does not use the degree of curve. Messrs. Eichler and Eves prefer this same reasoning. They call K a constant of proportionality which is equal to $\sqrt{2\,R\,L}$.

In 1901 the late Arthur N. Talbot, Past-President and Hon. M. Am. Soc. C. E. (29), gave the definition of this spiral as: "The Transition Spiral is a curve whose degree-of-curve increases directly as the distance along the curve from the point of spiral," which is expressed mathematically as

$$D = a\,L \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (85)$$

in which D = degree of curve $= \frac{5{,}730}{R}$; a is the constant ratio $\frac{D}{L}$; and L is the length of the spiral in 100-ft stations. Eq. 85 is the same expression as $\frac{1}{R} = K\,S$ "dressed in different clothing."

In computing and staking curves it is always necessary to know how much central angle has been consumed by any given length of curve. In the simple curve it is the degree of curve times the length of arc in stations, since, by definition, 100 ft of arc subtends 1° of central angle. All other arcs are directly proportional, and therefore their degree is an expression of the number of times their radius will divide into the unit radius of 5,730 ft. For convenience, these values are usually in simple whole numbers. In the spiral curve, since one starts from a tangent and progresses at a uniform rate of change of curvature a until the desired degree of curve is reached, the amount of central angle consumed is exactly half that of the simple curve of the same length. This is the application of the law of averages.

Since $R = \frac{dL}{d\theta} = \frac{5{,}730}{D}$,

$$d\theta = \frac{D\,dL}{5{,}730} \qquad \text{(86a)}$$

From Eq. 85, $D = a\,L$; but L is in stations, and

$$d\theta = \frac{a\,L\,dL}{57.30} \qquad \text{(86b)}$$

Also,

$$\theta = \int \frac{a\,L\,dL}{57.30} = \frac{a\,L^2}{114.6}\ \text{(radians)} = \frac{a\,L^2}{2}\ \text{(degrees)} \qquad \text{(87)}$$

The 100-ft arc was chosen to subtend 1° of central angle because the radius of such a circle is 5,730 ft (nearly) and is not, by coincidence, the number of degrees in one radian. Eq. 87 is exact, even though two incommensurable numbers appear in the solution. They are the same and divide equally into each other.

Talbot seems to have been the first to recognize that "A spiral diverges from its osculating circle, at any point, at the same rate that the spiral deflects from the initial tangent" and as a result devised the best method of computing the backward and forward deflections to any point on a spiral from any other point in the spiral. This is such a valuable tool, to the locating engineer, when moving up along the line in heavy timber or brush, that it is worth repeating:

> "The deflection angle between the local tangent, at any point on the spiral, to any other point on the spiral is the sum or difference of the deflection angle of the osculating circle for a length equal to the distance between the two points and the deflection angle for the spiral from the P.S. for a length equal to the distance between the two points."

Referring to Fig. 10, PP′ = PC = AB; $\phi = \frac{\theta_1}{3}$; and $\delta = \frac{i}{2}$. According to the rule, the forward deflection is $(\delta + \phi)$ and the backward deflection is $(\delta - \phi)$. A more comprehensive treatment of this rule has been published by T. F. Hickerson, M. Am. Soc. C. E. (13).

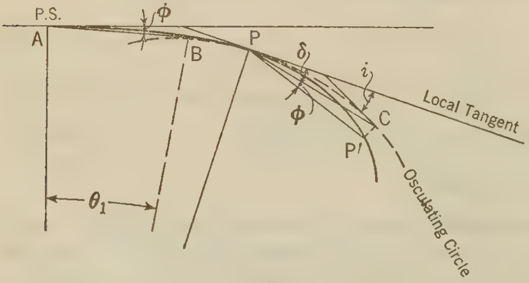

FIG. 10

Orville Kofoid, Assoc. M. Am. Soc. C. E., computed the deflection angle from any point back on the spiral to any point forward without reference to the local tangent by the following formula (15):

$$(L_1 + L_2 + L_3)\,(L_3 - L_1)\,\frac{\theta}{3\,(L)^2} \qquad \text{(88)}$$

in which L_1 is the distance from point of spiral PS to backsight; L_2 is the distance from PS to transit point; L_3 is the distance from PS to foresight; L is the total length of spiral; and θ is the total spiral angle. Although it is useful, Eq. 88 is not well suited for field work because of the multiplication and division involved; and the use of logarithms by field men is becoming a lost art since the introduction of the computing machine.

Most field men prefer the "ten-chord spiral" because of available tables in which all ten deflections from the PS may be read directly. "Moving up along the spiral" is accomplished simply by multiplying the first deflection by a suitable coefficient which is also selected from a table. Since the coefficients are mostly two-digit numbers, and the first deflection $\left(\frac{\theta}{300} \text{ in all cases}\right)$ is also a small number, the multiplication is not involved (25). The writer once edited a table (not published) for staking a "ten-chord spiral" backward—that is, from the sharp end toward the tangent. The table was prepared by several of the field engineers in the Portland (Ore.) office of the U. S. Public Roads Administration so that staking could proceed along the spiral in the direction of the stationing at all times. The objection to the "ten-chord spiral" is the tendency of the field men to omit staking the "breaks" unless they happen to fall at a chord point.

It seems fairly certain that the type of spiral to be used on highway work is finally accepted as a curve whose degree of curvature or radius varies as the distance along the curve, and that sine curves, series of compound curves, lemniscates, logarithmic and Archimedes spirals, etc., have been tested and found wanting in one respect or another. The tempest in the teapot now raging is whether to abandon the degree of curve in favor of the even-radius curves, such as 1,000 ft, 2,000 ft, etc. One argument in favor of the latter is that the radius of the curve could be posted on the highway and would be understood readily by the layman, whereas the degree of curve means nothing to him. Time alone will decide that issue.

In applying the spiral to highway design, the present tendency is to combine it with superelevation, since both begin at the PS and both progress uniformly until the central circular curve is reached where both curvature and superelevation become some predetermined constant. The degree of curve is determined by the designing engineer to fit the topography of the ground; the superelevation is determined by the "design speed" of the highway and varies with the degree of curve. These conditions are usually set by the county, state, or bureau doing the design. L. I. Hewes, M. Am. Soc. C. E., has prepared a useful table (11*a*) which also recommends the length of spiral to be used for each combination of "design speed" and degree of curve.

It is evident from the foregoing data that the question of whether a curve is transitional throughout will be self-determined by the various restrictions of design.

At the conclusion of the paper by Messrs. Eichler and Eves, the authors raise several questions for further study and discussion. While studying the locus of the center of radius of the spiral, the writer seemingly stumbled on a conclusion that the spiral is restricted to 90° of central angle. It would be interesting to discover if this theory can be either proved or disproved.

The question was raised as to how to improve upon existing methods of describing right of ways, a subject that the writer has treated in some detail elsewhere (64).

Attention is invited to the fact that, in Eq. 7, the correction C is subtracted from $\frac{\phi}{3}$ when ϕ exceeds 15°.

William T. Pryor,[12] Assoc. M. Am. Soc. C. E.—Messrs. Eichler and Eves have presented their paper for the purpose of clarifying certain features regarding the spiral curve. They recognized that it is the aim of highway engineers to construct a highway capable of carrying high-speed traffic with maximum safety and driving comfort. They wrote in Section 1:

> "Of the many problems involved, that of horizontal curvature, accompanied with proper superelevation, is one of the most important, and it is essentially with this feature of the future road that this paper is concerned."

The large Bibliography given by the authors, although not complete, will show that they selected the "clothoid"—the transition spiral—the curve which has a uniform change in length of radius in exact inverse ratio to its length. There are other forms of curvature transition or easement; but, upon careful analysis and by actual use, none have proved to be as easy to handle and as adaptable to highway alinement design and to field staking.

A moving vehicle cannot, safely and comfortably, change immediately from straight-line motion to constant angular motion. Circular curves possess a constant angular change per unit length of arc (the degree of circular curve, D). The transition spiral does not have a constant angular change per unit length, but it does have a uniform rate of angular increase (29) per unit length (the spiral degree of curvature increase, k). A logical way of using these angular changes to design the spiral curve in conformity with the speed of the vehicle and the superelevation and dependable friction factor on the highway are of vital importance.

At the end of the spiral curve the rate of angular change attained produces a computable centrifugal force for any given vehicle speed; and for the same speed the rate of angular change and centrifugal force are halved at a point midway between the beginning and end of the spiral curve. This persists proportionally throughout its entire length. On the circular curve the centrifugal force and angular change are constant for any given vehicle speed.

An easy procedure for applying the basic formulas in the geometric design of highway alinement is demonstrated by the diagrams in this discussion. Fundamentally, this discussion has been prepared to show, in a graphical manner, the general application that can be made of the authors' developments to serve as a guide in choosing spiral curves for transition in highway alinement.

Tables are available (2)(59) which will be found very useful for the solution of most of the functions of spiral curves and circular curves for use in design layout and field staking, thus avoiding the labor of solving long-series equations. The use of tables that have been calculated and found sound in actual practice should be emphasized. Field and office men alike hesitate to begin the use of long formulas, and recoil quickly from such formulas if some other method will yield the same results.

---

[12] Highway Engr., Dept. of Design, Public Roads Administration, Federal Works Agency, Washington, D. C.

The superelevation, the friction factor (expressed as a cross slope to be in the same units as superelevation), degree of circular curve, and the spiral degree of curvature increase are all intrinsically related. These, as well as the geometry of the spiral curve, must be clearly understood if intelligent use is to be made of all principles. Then full application can be made of the flexible features of the basic formulas.

If the velocity, Eq. 1, is measured in v miles per hour instead of in V feet per second:

$$\frac{P}{W} = \frac{0.0669\, v^2}{r} \qquad (89)$$

The ratio P/W is illustrated in Fig. 11(*a*). The centrifugal force P must be opposed equally or the moving vehicle will slide outward off the curve. Opposition may be accomplished by inclining the curving path so that its cross slope is everywhere normal (at right angles) to the component force of weight W and the centrifugal force P, Fig. 11(*b*). Angle CAB may be thought of as being the sum of two angles, s and t, Fig. 11(*c*). The tangent of the sum of these two angles is e (superelevation) plus f (friction factor). Considering the length of line AB as unity, by similar triangles $\frac{(e+f)}{1} = \frac{P}{W}$, and from Eq. 89 if D, in degrees per one hundred foot arc, is used instead of $1/r$:

FIG. 11

$$(e + f) = 0.0000117\, D\, v^2 \qquad (90)$$

Use of Eqs. 89 and 90 made it easy to prepare Fig. 12 to show the relationship of degree and radius of circular curve for vehicle speeds, superelevation, and friction factors. The sum of e plus f, Fig. 11(*c*), is shown as the abscissa in Fig. 12.

In the use of Fig. 12, line SSSS represents the superelevation rate suggested for circular curves in climatic regions where snow and icy conditions may be expected on the road. It was computed by Eq. 90, setting f equal to zero and v equal to 30 miles per hr. Line SSS′S′ represents the superelevation rate suggested for circular curves in climatic regions where no snow or ice is expected on the roadway. Line SSS′S′ has an upper limit of 0.12 ft per ft for a 12° circular curve, and all sharper circular curves. Use of this upper limit to the superelevation rate is considered the maximum for safety and comfort where road surface conditions are likely to be good throughout the entire year, with no snow or ice on the road at any time. Line ffff represents 0.08 ft per ft of friction added to the line SSSS, and line fff′f′ the same amount to line SSS′S′. Likewise, line FFFF represents 0.16 ft per ft of friction added to line SSSS, and line FFF′F′ the same amount to line SSS′S′.

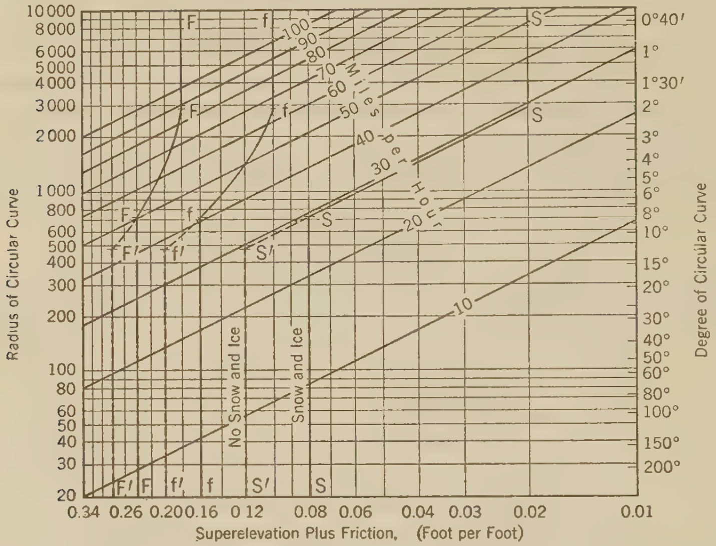

FIG. 12.—DEGREE AND RADIUS OF CIRCULAR CURVE FOR VEHICLE SPEEDS, SUPERELEVATION, AND FRICTION FACTORS

A circular curve may be selected easily and quickly for any combination of conditions within the practical limits of e, f, $(e + f)$, and maximum vehicle speeds of from 10 to 100 miles per hr. This represents a graphical method of showing the results obtainable by the full use of Eq. 1 of the paper. For spiral curve design the superelevation-plus-friction factor, the degree of circular curve, vehicle speed, and rate of change of radial acceleration (or the spiral degree of curvature increase) are combined.

Eq. 16b can be reduced to more easily used terms. Change from $1/R$ to D in degrees per 100 ft-station of arc and from V in feet per second to v in miles per hour; and:

$$S = \frac{0.0005506\,D\,v^3}{\gamma} = \frac{D\,v^3}{1{,}816\,\gamma}\ldots\ldots\ldots\ldots\ldots\ldots(91a)$$

and

$$\phi = \frac{0.000002753\,D^2\,v^3}{\gamma} = \frac{D^2\,v^3}{363{,}200\,\gamma} = 20{,}202\,\frac{(e+f)^2}{\gamma\,v}\ldots\ldots(91b)$$

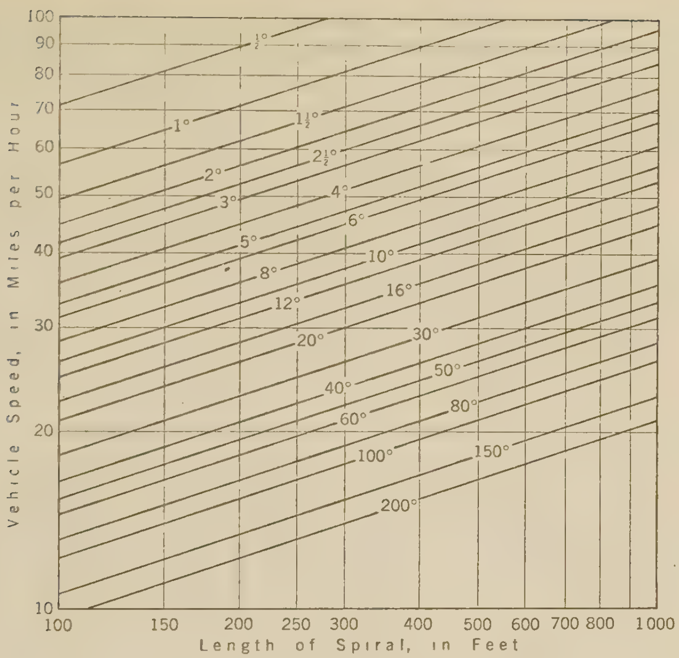

Fig. 13.—Length of Spiral Curve, According to Vehicle Speed and Degree of Circular Curve

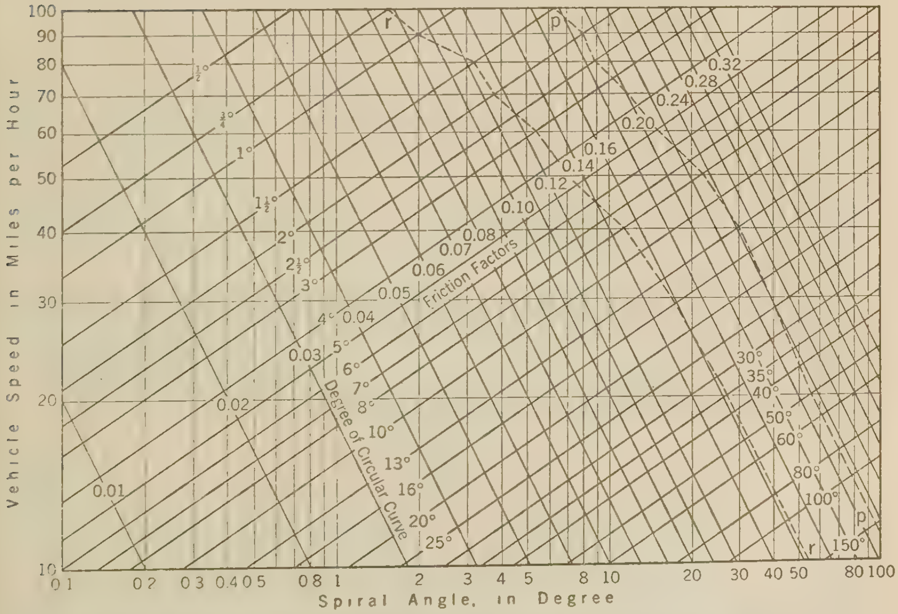

Fig. 14.—Spiral Angles Corresponding to Various Vehicle Speeds, Degree of Curve, Superelevation, and Friction Factors

Fig. 13 was constructed simply by substituting appropriate values for the respective variables in Eq. 91a and plotting the S-answers. The rate of change of radial acceleration (γ) in feet per second^3 was set at one, as explained subsequently herein. Fig. 14 was constructed by use of Eq. 91b with $\gamma = 1$. In design, if a value of $\gamma = 2$ is used, spiral angles will be exactly one half of those shown. Line pp in Fig. 14 indicates the limit of the sharpest permissible circular curves; and the line rr indicates the limit of recommended curves. The diagonal lines marked "Friction Factors" are $(e + f)$-factors. They apply to either superelevation or friction alone, or to the sum of the two, whichever the engineer may wish to consider, as e, f, and $(e + f)$.

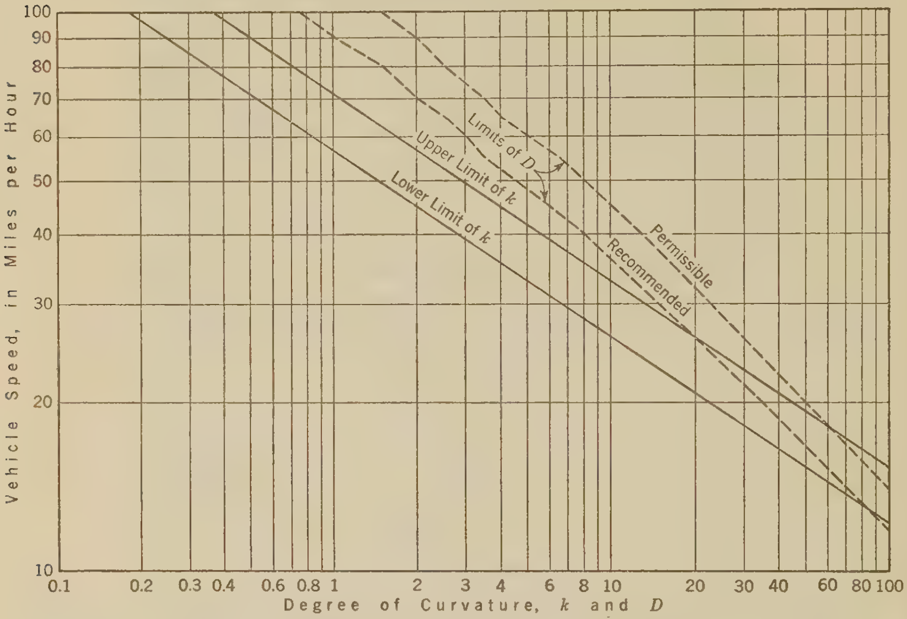

FIG. 15.—DEGREE OF SPIRAL AND CIRCULAR CURVES FOR DIFFERENT VEHICLE SPEEDS

Fig. 15 shows the relationship between the upper limits of degree of circular curve D and the spiral degree of curvature increase k for vehicle speeds of from 10 to 100 miles per hr. The limits of D were chosen from critical points in Fig. 12, and the limits of k were calculated by simple manipulation of Eq. 91a. Since $k = D/S$, if S is measured in 100-ft stations:

$$k = \frac{181{,}600}{\gamma\, v^3} \qquad (92)$$

For the upper limit of k a value of $\gamma = 2$ was chosen, and for the lower limit, $\gamma = 1$.

In order to ascertain, rationally, the value for γ to be used in Eqs. 91a to 92 so that they will satisfy the requirements for safety, and provide comfort and ease in gaining the radial acceleration for the driver while the vehicle is moving around the spiral curve, four items of fact should be kept in mind, as follows:

(1) Vehicles will be driven over the highway at speeds of from 10 to 20 miles per hr faster than the speed rating of the highway, especially for passing;

(2) As a factor of safety, designers should plan for this faster moving vehicle when and wherever it is possible, and then the slower moving vehicles will be provided for;

(3) Steering wheels must be turned much more when the vehicle is being driven considerably faster than the speed for which the curve is superelevated, in order to generate sufficient friction to counteract the unbalanced centrifugal force; and

(4) Although R. A. Moyer, Assoc. M. Am. Soc. C. E. (19), indicates that γ should be equal to 2, W. H. Shortt (27) uses a value of $\gamma = 1$.

By casual examination of the V^2/r-values in Table 3 it is evident that, for $\gamma = 2$ ft per sec^3, the time to attain these rates of radial acceleration would be from 1 sec to 5 sec. Actually the circular curves and vehicle speeds giving V^2/r-values greater than 9 ft per sec^2 require $(e+f)$-values that are too high, relatively, for safety and comfort and ease in traveling around the curves. Therefore, if γ is fixed at 2 ft per sec^3, all acceleration rates would be attained in less than 5 sec. This is not much time, but perhaps the efficient and alert vehicle driver will not experience any difficulty and will experience not too much discomfort in the process. In the light of the foregoing analysis, most engineers will undoubtedly agree that $\gamma = 2$ should be the largest value used in design.

TABLE 3.—SUPERELEVATION PLUS FRICTION $(e+f)$ FOR GIVEN RATES OF RADIAL ACCELERATION

V^2/r (ft per sec^2)	$(e+f)$ (ft per ft)
2.0	0.06
3.0	0.09
4.0	0.12
5.0	0.16
6.0	0.19
7.0	0.22
8.0	0.25
9.0	0.28
10.0	0.31

It is believed, however, that a smaller value of γ (say, $\gamma = 1$) would be preferable. In Table 4 the vehicle speed in miles per hour (Col. 1), the degree of circular curve (Col. 2), and recommended length of spiral curve (Col. 3) were taken from Figs. 12 and 13, respectively, and other columns were computed for: The vehicle speed rating of the highway (Cols. 4 and 5); the rated speed plus 10 miles per hr (Cols. 6, 7, and 8); and the rated speed plus 20 miles per hr (Cols. 9, 10, and 11).

It is quite obvious that the vehicle driver who attempts to exceed the safe speed of the highway, either at constant speed or by increasing his speed,to pass another vehicle quickly creates $(e+f)$-conditions that are not safe and comfortable, but hazardous. This is especially so for vehicles moving at speeds exceeding the vehicle speed rating of a slow-speed highway. Fixing a value of $\gamma = 1$, however, keeps the value of γ in Col. 8 (Table 4) between limits of 1.3 at 110 miles per hr and 3.4 at 30 miles per hr, and, in Col. 11, between the limits of 1.7 at 120 miles per hr and 4.7 at 50 miles per hr. These resulting values for γ are then near or within the maximum value of $\gamma = 2$ established previously, except in those cases where the highway speed ratings of 10 miles per hr and 20 miles per hr (Col. 1, Table 4) are exceeded by 10 miles per hr (Cols. 6, 7, and 8) and those of from 10 to 40 miles per hr (Col. 1), are exceeded by 20 miles per hr (Cols. 9, 10, and 11). In view of this analysis, the graphs, Figs. 13, 14, and 15, were prepared by making $\gamma = 1$ ft per sec^3, which should be the desirable upper limit.

TABLE 4.—COMPARATIVE EFFECT OF EXCEEDING SAFE DESIGN SPEEDS ON A HIGHWAY

[a] The sharpest permissible curve. [b] Recommended length of spiral curve. [c] For the speeds given in Col. 1, $\gamma = 1$ in each case. [d] Results for 10 miles per hr in excess of speeds shown in Col. 1. [e] Results for 20 miles per hr in excess of speeds shown in Col. 1.

Fig. 14 is a graph designed to give the total spiral angle, in degrees, for vehicle speeds of from 10 to 100 miles per hr, the degree of circular curve, and superelevation-plus-friction factor, as well as the sharpest circular curve permissible and recommended. Because of these features, it is a composite graph which may be used in lieu of Figs. 12 and 13. For example, if the vehicle speed rating of the highway is to be 60 miles per hr and a spiraled 3° 00′ circular curve will fit the topography, the spiral angle should be 5.4°, and only 0.126 ft per ft of superelevation plus friction would be required to balance the centrifugal force. Moreover, for example, let us assume that the central angle ($\triangle$) between two tangents is 20° 00′, and that it is desired that the curve joining these straights be transitional throughout, and the vehicle speed rating of the highway is to be 60 miles per hr. (It is not a recommended practice to design curves transitional throughout, but it is useful as a means of demonstrating the easy application of a flexible procedure.) Proceed from the line marking the spiral angle of 10° $\left(\frac{20^\circ}{2}\right)$ on the graph and follow the line upward until it intersects the vehicle speed line of 60 miles per hr. These two lines intersect at almost the same point as the 4° circular curve and 0.17 ft per ft superelevation-plus-friction factor line. Use of a superelevation rate of 0.04 ft per ft would mean 0.13 ft per ft of friction would be required. Almost at a glance, practical results are obtainable in spiral curve design for a transition to any circular curve usable for the intended vehicle speed rating of the highway. It is a simple graphical means of combining Eqs. 89, 90, and 16*b* for ready use.

Messrs. Eichler and Eves expressed an interest in the possibility of improving on the present osculating circle method of laying out the spiral whenever the transit must be set up at any point, *t*, on the curve. This is a simple problem to solve.

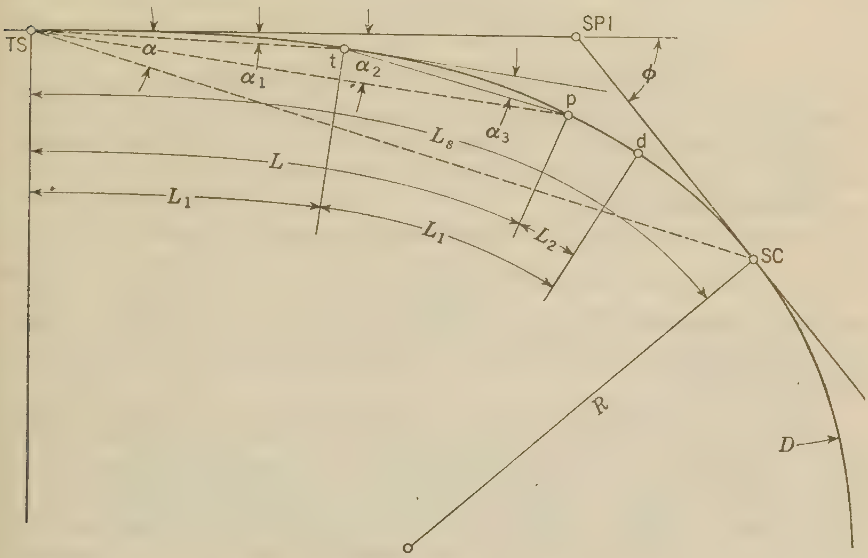

FIG. 16.—DEFLECTION ANGLES ON A SPIRAL CURVE

Derivations will not be given here; but the deflection angle α_2 (in minutes) from the beginning of the spiral (TS, Fig. 16) to any point p is:

$$\alpha_2 = \frac{D\,L^2}{10\,L_s} - c \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (93)$$

in which D is the degree of circular curve connected to the spiral curve at a distance L_s (feet) from the TS; and L is the distance in feet along the spiral curve from the TS to point p. A table of corrections c, in minutes, corresponding to the given spiral angles ϕ, in degrees, at 0.1 increments of the total spiral length, beginning at 0.3 and ending at 1.0 of the spiral length, is available (59).

The deflection angle from the tangent to the spiral curve at any transit point, t, to any point, p, is equal to the deflection calculated from the TS to that point, plus a straight-line correction. This correction is:

$$C' = \frac{D\,L_1\,L_2}{10\,L_s} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (94)$$

The constant $\frac{D}{10\,L_s}$, as used in the formula for the deflection from the TS to point p, is also used in this expression. The length L_1 is the distance in feet from the TS to the transit, and L_2 is the distance, in feet, from a point d to the deflection point p. Point d is at a distance L_1, in feet, from the transit in direction of the sharpest curvature. When distance L_2 to point p is measured from point d toward the TS it is negative, and when measured from point d in a direction away from TS the distance L_2 is positive. This fact must be remembered when calculating deflections for any transit position not on the TS.

The simple formula—

$$\alpha_3 = \frac{D\,L^2}{10\,L_s} + \frac{D\,L_1\,L_2}{10\,L_s} - c \qquad (95)$$

—can be used to solve the minutes of deflection from any transit setup to any deflection point. In field work, it is customary first to calculate the α_2-deflections from the TS to all spiral curve points, and to record them in the field notebook. When it is necessary to move the transit forward the simple corrections are easily made.

If the length of spiral L_s is divisible into the degree of circular curve D an even number of times the constant $\frac{D}{10\,L_s}$ and the constant $\frac{D\,L_1}{10\,L_s}$ are simple decimal fractions with definite digit endings, which is of considerable advantage to the transitman. This point can be easily kept in mind when the spiral curve is designed.

The paper has served to assemble, in one place, many of the salient points regarding the clothoid (Euler's spiral), which is a curve that follows an exact law. Approximations should be avoided as much as practicable because the inexperienced engineer will eventually be embarrassed when he uses approximate formulas where more exact results are required. Once tables have been prepared on an exact basis, the labor of calculating geometric parts (functions) of the spiral curve by the use of long-series equations, or by using approximations of such equations, has been eliminated. Then the office and field work of designing and staking spiral curves as transitions in highway alinement becomes simple and easy.

STRUCTURAL SKEW PLATES

BY F. L. EHASZ,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOHN W. ALLEN, WILLIAM A. CONWELL, JULIUS SIGMAN, AND F. L. EHASZ

SYNOPSIS

In the theory of elasticity it is sometimes feasible by means of approximate methods to obtain analyses of problems which do not lend themselves readily to exact treatment. This is true in the study of the structural behavior of plates and slabs. It is particularly valid for skew plates and slabs which, so far as the writer knows, have not been analyzed by other than approximate methods in technical literature. The object of this paper is to present a comparison of results acquired for certain skew plates by means of approximate methods involving finite differences, trigonometric series, and power series.

INTRODUCTION

Some consideration has been given by various investigators in the United States and abroad to the analysis and design of skew plates and slabs. In the field of reinforced concrete these studies have been of considerable interest and practical importance, especially in the case of highway bridge slabs that cross streams, railways, or other highways below at an oblique angle. It is common knowledge that modern traffic and speed requirements in the United States stipulate the construction of many skew structures. Whereas bridge slabs usually are provided with integral curbs and rails, which tend to make the structural behavior more complex, it is nevertheless of interest to ascertain the manner in which the more simple slabs perform. Structural engineers have been studying the skew plate, simply supported on all four sides, the clamped skew plate, and skew slabs simply supported on two sides with two free edges, in addition to the more practical bridge slabs with the integral curbs mentioned previously.

A skew plate or slab may be defined as one having the shape of a parallelogram which is not a rectangle nor a square. Some engineers designate the

---

NOTE.—Published in June, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Engr., O. H. Ammann, Cons. Engr., New York, N. Y.

rectangular or square plate as a plate with a skew angle of zero. In any case, the term "degree of skew," in this paper, is defined as the angle of distortion from the rectangular or square shape. This designation corresponds in general with the practice and the technical literature pertaining to other types of skew structures. As in the case of skew arches,[2] the skew effect in plates depends upon the ratio of the lengths of sides as well as on the angle of skew.

It was the purpose of the investigation upon which this paper was based to study theoretically the structural action of skew plates simply supported on all four sides, subjected to a uniformly distributed lateral load, and a clamped skew plate similarly loaded. In the course of these studies various systems of coordinates were used to determine whether the skew boundaries would lend themselves to treatment more readily by one system than by the others. It is to be observed, moreover, that, although the results reported herein pertain directly to metal plates (Poisson's ratio approximately 0.3), they can be modified easily to include other materials, such as concrete, in which case Poisson's ratio may be varied from 0.15 to 0.20.

In this work simply supported skew plates were investigated by the method of finite differences, by trigonometric series satisfying the plate equation throughout and the boundary conditions only at certain points, and by power series. A clamped skew plate was also treated by these methods. A preliminary review was made of solutions for triangular plates with a view to ascertaining the effect of the density of difference-equation networks and to determining some measure of the accuracy to be expected for similar meshes in the case of skew plates.

PREVIOUS STUDIES

The structural behavior of skew plates and slabs has been investigated mainly by the method of finite differences. The first publication on skew plates that has come to the writer's attention is a paper by Cecilia Vittoria Brigatti.[3] Results were obtained by difference equations for uniformly loaded skew plates simply supported and clamped, the sides being of the same length. The fundamental considerations in this work appear to be open to question.

Adolf Anzelius[4] has given some attention to a uniformly loaded skew plate, simply supported on two opposite sides and free on the other two. His solution is in the form of series involving hyperbolic and trigonometric functions, which yield an infinite system of linear equations. The method is approximate and appears to be quite cumbersome. As in other similar approaches, the accuracy of the method depends upon the number of coefficients taken in the series. Mr. Anzelius gave, qualitatively, only twisting moments for a 45° skew slab.

A summary of results obtained by difference equations for uniformly loaded skew slabs, in particular, with two opposite sides simply supported and the other two edges free, has been abstracted from the doctoral work of Helmut Vogt[5] and promulgated in a paper[6] by the same author. Professor Vogt has given particular attention to the arrangement of the reinforcement in bridge slabs. Brief mention was made of skew slabs simply supported on four sides and uniformly loaded.

Studies of skew slabs by means of difference equations have also been made by V. P. Jensen,[7] M. Am. Soc. C. E. Uniformly loaded skew slabs simply supported on four sides, and similarly loaded skew slabs simply supported on two opposite edges and free on the other two sides, were analyzed by use of difference equations developed in a form readily applicable to networks made up of lines parallel to the sides, regardless of the degree of skew. In these slabs the ratio of the length of the long side to that of the short span was kept nearly constant and equal to a value of 2.0. Poisson's ratio was taken to be 0.2. Particular attention was given by Professor Jensen to a simple-span slab bridge with curbs and a 45° skew. The method of obtaining influence surfaces by means of difference equations as recommended by Nathan Newmark,[7] Assoc. M. Am. Soc. C. E., proved to be useful in these studies. Also, Professor Jensen considered the effectiveness of reinforcement for various arrangements of the main and transverse steel.

ORDINARY THEORY OF PLATES

Notation.—The letter symbols in this paper are identified in the text, or by diagram, where they first appear and, for convenience of reference, are assembled alphabetically in the Appendix.

Assumptions and Limitations.—In the ordinary theory of plates several simplifying assumptions are made, resulting in concomitant limitations. As a matter of convenience the plate is considered to be horizontal, homogeneous, elastic, isotropic, uniform in thickness, and subjected to lateral loads only. In addition to being uniform, the thickness must be small compared with the lateral dimensions. The deflections and the energy of deformation in the medium-thick plate are not affected by the vertical stresses (tensions, compressions, and shears) as they are in the case of thick plates. Likewise, the energy due to shortening and stretching of the middle surface may be neglected, which is tantamount to stating that the deflections are small relative to the thickness of the plate. This work of deformation, naturally, must be considered in the theory of thin plates. It is taken for granted, furthermore, that Hooke's law applies to the horizontal strains. In the theory of beams, it will be recalled, plane cross sections before bending are assumed to remain plane after bending. Similarly, in the ordinary theory of plates, straight lines normal to the middle surface of the plate before bending remain straight and normal after bending. Analogous to the concept of straight-line variation of tensile and compressive stresses in the cross section of the beam, there follows in the case of the plate the postulation that horizontal unit stresses (tensions, compressions, and shears) in vertical sections are distributed linearly.

Fundamental Differential Equations.—The derivation of the differential equations for the ordinary theory of plates in Cartesian coordinates has been given by various writers in the technical literature[8,9,10,11] and therefore will not be given in this paper. It is pertinent, however, to outline the basic equations for later reference.

The bending and twisting moments in the distorted plate (see Fig. 1) are given by the expressions

$$M_x = -N\left(\frac{\partial^2 w}{\partial x^2} + \mu\frac{\partial^2 w}{\partial y^2}\right) \qquad \text{(1a)}$$

$$M_y = -N\left(\frac{\partial^2 w}{\partial y^2} + \mu\frac{\partial^2 w}{\partial x^2}\right) \qquad \text{(1b)}$$

and

$$M_{xy} = -(1-\mu)\,N\,\frac{\partial^2 w}{\partial x\,\partial y} \qquad \text{(1c)}$$

[9] "An Introduction to the Theory of Elasticity for Engineers and Physicists," by R. V. Southwell, Oxford Univ. Press, 1936, p. 228.

[10] "Die elastischen Platten," by A. Nadai, Julius Springer, Berlin, 1925, p. 18.

[11] "Die Theorie elastischer Gewebe und ihre Anwendung auf die Berechnung biegsamer Platten," by H. Marcus, 2d Ed., Julius Springer, Berlin, 1932.

The Lagrange equation for the flexure of plates produced by a uniformly distributed lateral load p may be shown to be

$$\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2\,\partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{p}{N} \qquad (3)$$

or

$$\nabla^4 w = \nabla^2\nabla^2 w = \frac{p}{N} \qquad (4)$$

in which

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \qquad (5)$$

is the Laplace operator. From Eqs. 1 it is clear that the moment sum is expressible in the form

$$M_x + M_y = -(1+\mu)\,N\,\nabla^2 w \qquad (6)$$

The vertical shears are given by the equations

$$V_x = -N\frac{\partial}{\partial x}\nabla^2 w \qquad (7a)$$

and

$$V_y = -N\frac{\partial}{\partial y}\nabla^2 w \qquad (7b)$$

Maximum stresses, occurring at the surface, are

$$\sigma_x = \pm\frac{6\,M_x}{h^2} \qquad (8a)$$

$$\sigma_y = \pm\frac{6\,M_y}{h^2} \qquad (8b)$$

and

$$\tau_{xy} = \pm\frac{6\,M_{xy}}{h^2} \qquad (8c)$$

From the shears and the twisting moments it is possible to deduce the vertical reactions

$$R_x = V_x + \frac{\partial M_{xy}}{\partial y} = -N\left[\frac{\partial^3 w}{\partial x^3} + (2-\mu)\frac{\partial^3 w}{\partial x\,\partial y^2}\right] \qquad (9a)$$

and

$$R_y = V_y + \frac{\partial M_{xy}}{\partial x} = -N\left[\frac{\partial^3 w}{\partial y^3} + (2-\mu)\frac{\partial^3 w}{\partial x^2\,\partial y}\right] \qquad (9b)$$

These reactions are defined in the same manner as the vertical shears.

Polar Coordinates.—The differential equations for the bending of plates may be readily placed into polar form by some simple transformations. It will be necessary later to use the concept of average curvature at a point of the distorted plate and, consequently, it is introduced here. Curvatures in the xz-plane and the yz-plane are

$$\frac{1}{r_x} = \frac{\partial}{\partial x}\left(\frac{\partial w}{\partial x}\right) = \frac{\partial^2 w}{\partial x^2} \qquad (10a)$$

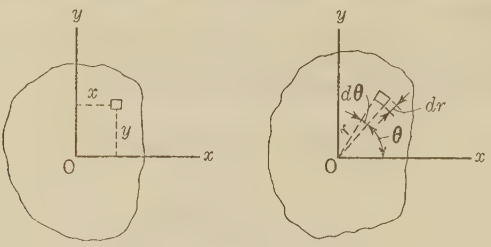
and

$$\frac{1}{r_y} = \frac{\partial}{\partial y}\left(\frac{\partial w}{\partial y}\right) = \frac{\partial^2 w}{\partial y^2} \qquad (10b)$$

respectively. It can be shown that at the same point the sum of the curvatures in any two perpendicular directions n and t is equal to the sum of Eqs. 10 or, symbolically,

$$\frac{1}{r_n} + \frac{1}{r_t} = \frac{\partial^2 w}{\partial n^2} + \frac{\partial^2 w}{\partial t^2} = \frac{1}{r_x} + \frac{1}{r_y} = \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} \qquad (11)$$

r_n and r_t are defined in a manner similar to r_x and r_y. The invariant sum defined by Eq. 11 has been designated as the average curvature of the plate's surface at a point. Transformation from Cartesian to polar coordinates (see Fig. 2) yields the result



(a) CARTESIAN (b) POLAR

FIG. 2.—TRANSFORMATION TO POLAR COORDINATES

$$\nabla^2 w = \frac{\partial^2 w}{\partial r^2} + \frac{1}{r}\frac{\partial w}{\partial r} + \frac{1}{r^2}\frac{\partial^2 w}{\partial \theta^2} \qquad (12a)$$

By repetition of this operation it is possible to obtain the Lagrange plate equation in the form

$$\nabla^2\nabla^2 w = \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \theta^2}\right)\left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r}\frac{\partial w}{\partial r} + \frac{1}{r^2}\frac{\partial^2 w}{\partial \theta^2}\right) = \frac{p}{N} \qquad (12b)$$

Eqs. 12 will be used subsequently in the approximate trigonometric-series solution for a skew plate.

From simple transformation equations, expressions for moments in polar form may be deduced by stipulating that the x-axis coincides with the radius r. If t is the direction (tangential) perpendicular to the radial direction r, M_r and M_t are the moments per unit length acting in sections perpendicular to r and t, respectively. These moments and the corresponding twisting moments, M_{rt}, may be shown to be

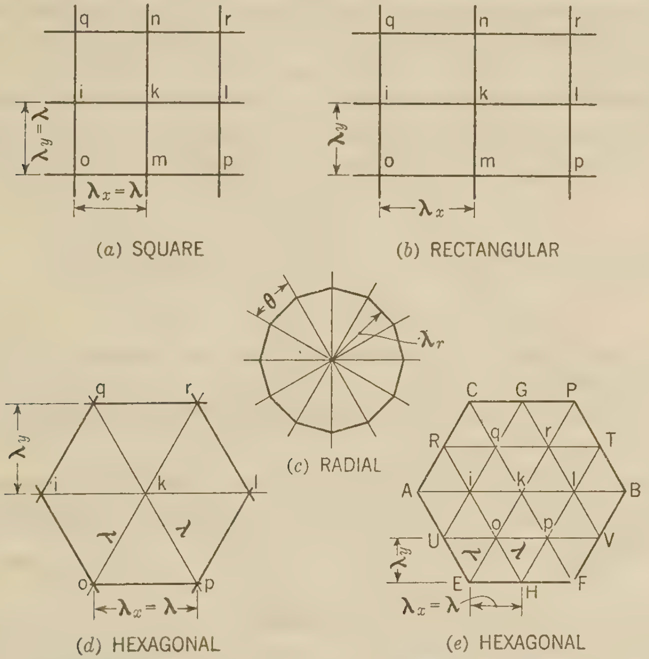
$$M_r = -N\left[\frac{\partial^2 w}{\partial r^2} + \mu\left(\frac{1}{r}\frac{\partial w}{\partial r} + \frac{1}{r^2}\frac{\partial^2 w}{\partial \theta^2}\right)\right] \qquad (13a)$$

$$M_t = -N\left(\mu\frac{\partial^2 w}{\partial r^2} + \frac{1}{r}\frac{\partial w}{\partial r} + \frac{1}{r^2}\frac{\partial^2 w}{\partial \theta^2}\right) \qquad (13b)$$

and

$$M_{rt} = -(1-\mu)\,N\left(\frac{1}{r}\frac{\partial^2 w}{\partial r\,\partial\theta} - \frac{1}{r^2}\frac{\partial w}{\partial\theta}\right) = -(1-\mu)\,N\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial w}{\partial\theta}\right) \quad ..(13c)$$

It is possible to obtain a power series in quadrilinear form that would yield an approximate solution of skew plate problems. Since this procedure would have entailed considerably more work than a similar series approach in Cartesian form, solutions were not sought by quadrilinear coordinates. In this work the power-series approach, useful for attacking a wide variety of plate problems, was dealt with only in Cartesian coordinates and was applied to a few plate problems which were treated also by other methods.



(*a*) SQUARE (*b*) RECTANGULAR (*c*) RADIAL (*d*) HEXAGONAL (*e*) HEXAGONAL

FIG. 3.—TYPES OF NETWORKS FOR DIFFERENCE EQUATIONS

Difference Equations.—By means of difference equations it is possible to obtain approximate solutions for many plate problems which cannot be treated easily by exact methods. Skew plates and slabs fall into this category. Many writers have applied this method to plate problems.[8–17] Since finite squares, rectangles, and triangles (hexagons) (see Fig. 3) are used in the formation of

difference-equation networks, rather than the corresponding infinitesimal elements associated with differential equations, only approximate results are obtained. The approximations become better as the elements become smaller. An attempt was made in this investigation to ascertain the effect of the density of the networks for triangular plates as well as skew plates.

The procedure for the method of finite differences as presented by H. Marcus,[11] M. Am. Soc. C. E., was followed throughout this work. According to Mr. Marcus, the elastic web is said to consist of a network of elastic strings attached to the edges of the plate in such a way as to conform with the boundary conditions of the actual plate or slab. In the case of a plate that supports a concentrated load, it is desirous to arrange a network that has a point of intersection at the position of the load. If the load is uniformly distributed, it is replaced by a statically equipollent system of concentrated forces applied at the intersection points contiguous to the loaded area. The difference equations relating the deflections of the web usually yield a system of simultaneous linear equations in normal form. A function of the moment sum can be written

$$\bar{M} = -N\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right) \dots\dots\dots\dots\dots\dots (14)$$

From Eqs. 4 and 14 the equation of the elastic surface becomes

$$\nabla^2 \bar{M} = -p \dots\dots\dots\dots\dots\dots\dots\dots (15)$$

The sum of the moments in the x-direction and the y-direction is

$$M_x + M_y = -N(1+\mu)\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right) = (1+\mu)\,\bar{M} \dots\dots (16)$$

The deflections, $\bar{w}$, of a membrane subjected only to fiber stresses parallel to the surface, are related to the horizontal component, S, of the surface stresses by the differential equation

$$\nabla^2 \bar{w} = \frac{\partial^2 \bar{w}}{\partial x^2} + \frac{\partial^2 \bar{w}}{\partial y^2} = -\frac{p}{S} \dots\dots\dots\dots\dots\dots (17)$$

Manifestly, S must be constant over the entire membrane because of conditions of static equilibrium. If $S = 1$, comparison of Eqs. 15 and 17 suggests the theorem:[16]

> "The deflection of a membrane subjected to loads proportional to those on a given plate may be considered as the sum of the principal moments of the actual plate."

Similar to the procedure in the case of beams, it is possible to derive another theorem:

> "A second membrane may be loaded with elastic weights proportional to these moment sums and, subject to appropriate boundary conditions, the deflections of the latter membrane will be proportional to the deflections of the actual plate under the given loading system."

The elastic weights in the second theorem are actually $\frac{\bar{M}}{N}$.

It is obvious that the solution of the plate problem is manifested by the equations

$$\nabla^2 \bar{M} = -p \qquad (18a)$$

and

$$\nabla^2 w = -\frac{\bar{M}}{N} \qquad (18b)$$

By analogy and equilibrium considerations one may obtain the relations

$$\bar{M}_k = S_1 \bar{w}_k \qquad (19)$$

in which S_1 is the quantity S referred to the first membrane, and

$$w_k = \bar{z}_k \frac{S_1 S_2}{N} \qquad (20)$$

in which $\bar{z}_k$ designates the deflection of the nodal point k in the second membrane. Equations relating the web deflections for the square mesh may be written as follows:

$$4\,\bar{w}_k - (\bar{w}_i + \bar{w}_l + \bar{w}_m + \bar{w}_n) = \frac{p_k \lambda^2}{S_1} \qquad (21a)$$

and

$$4\,\bar{z}_k - (\bar{z}_i + \bar{z}_l + \bar{z}_m + \bar{z}_n) = \frac{\bar{M}_k \lambda^2}{S_1 S_2} \qquad (21b)$$

in which the subscripts refer to the points in Fig. 3(*a*). For the hexagonal network, the following expressions apply (see Figs. 3(*d*) and 3(*e*)):

$$4\,\bar{w}_k - \frac{2}{3}(\bar{w}_i + \bar{w}_l + \bar{w}_o + \bar{w}_p + \bar{w}_q + \bar{w}_r) = \frac{p_k \lambda^2}{S_1} \qquad (22a)$$

and

$$4\,\bar{z}_k - \frac{2}{3}(\bar{z}_i + \bar{z}_l + \bar{z}_o + \bar{z}_p + \bar{z}_q + \bar{z}_r) = \bar{M}_k \frac{\lambda^2}{S_1 S_2} \qquad (22b)$$

From the simultaneous linear equations the values of $\bar{w}_k$ and $\bar{z}_k$ are obtained. Once these are found the $\bar{M}_k$-functions and deflections of the actual plate result from Eqs. 19 and 20.

Bending moments and twisting moments in the case of rectangular meshes (see Fig. 3(*b*)) are given by the expressions[18]

$$M_x = S_1 S_2 \left[\frac{2\,\bar{z}_k - \bar{z}_i - \bar{z}_l}{\lambda^2_x} + \mu \frac{2\,\bar{z}_k - \bar{z}_m - \bar{z}_n}{\lambda^2_y} \right] \qquad (23a)$$

$$M_y = S_1 S_2 \left[\frac{2\,\bar{z}_k - \bar{z}_m - \bar{z}_n}{\lambda^2_y} + \mu \frac{2\,\bar{z}_k - \bar{z}_i - \bar{z}_l}{\lambda^2_x} \right] \qquad (23b)$$

and

$$M_{xy} = (1 - \mu)\, S_1 S_2 \left[\frac{(\bar{z}_p + \bar{z}_q) - (\bar{z}_o + \bar{z}_r)}{4\,\lambda_x \lambda_y} \right] \qquad (23c)$$

---

[18] "Die Theorie elastischer Gewebe und ihre Anwendung auf die Berechnung biegsamer Platten," by H. Marcus, 2d Ed., Julius Springer, Berlin, 1932, p. 18.

values of λ being defined in Fig. 3. The vertical shearing forces are to be found from the equations

$$V_x = S_1 \frac{\partial \bar{w}}{\partial x} = \frac{S_1}{2\,\lambda_x} (\bar{w}_l - \bar{w}_i) \qquad (24a)$$

and

$$V_y = S_1 \frac{\partial \bar{w}}{\partial y} = \frac{S_1}{2\,\lambda_y} (\bar{w}_n - \bar{w}_m) \qquad (24b)$$

Bending moments in the directions 1, 2, and 3 (in which $M_2 = M_x$ and directions 1 and 3 are −60° and +60°, respectively) may be obtained from the following:

$$M_{1k} = (1 - \mu)\, S_1\, S_2 \frac{2\,\bar{z}_k - \bar{z}_p - \bar{z}_q}{(\lambda_y \sec \alpha)^2} + \mu\, S_1\, \bar{w}_k \qquad (25a)$$

$$M_{2k} = (1 - \mu)\, S_1\, S_2 \frac{2\,\bar{z}_k - \bar{z}_i - \bar{z}_l}{\lambda^2_x} + \mu\, S_1\, \bar{w}_k \qquad (25b)$$

and

$$M_{3k} = (1 - \mu)\, S_1\, S_2 \frac{2\,\bar{z}_k - \bar{z}_o - \bar{z}_r}{(\lambda_y \sec \alpha)^2} + \mu\, S_1\, \bar{w}_k \qquad (25c)$$

in which $2\,\alpha$ equals 60°. Vertical shearing forces are given by the terms

$$V_{1k} = S_1 \frac{\bar{w}_p - \bar{w}_q}{2\,\lambda_y \sec \alpha} \qquad (26a)$$

$$V_{2k} = S_1 \frac{\bar{w}_l - \bar{w}_i}{2\,\lambda_x} \qquad (26b)$$

and

$$V_{3k} = S_1 \frac{\bar{w}_r - \bar{w}_o}{2\,\lambda_y \sec \alpha} \qquad (26c)$$

The twisting moments result from the expression (see Fig. 4(*a*)):

$$M_{xy} = -(1 - \mu)\, N \frac{\partial^2 w}{\partial x\, \partial y} = (1 - \mu) \frac{S_1\, S_2}{2\,\lambda_x\, \lambda_y} [(\bar{z}_p + \bar{z}_q) - (\bar{z}_o + \bar{z}_r)] \qquad (27)$$

As stated previously, $M_x = M_2$. In order to find M_y, it is possible to use the simple equation (from Eq. 16):

$$M_y = (1 + \mu)\, \bar{M} - M_x \qquad (28)$$

The maximum and minimum bending moments may be shown to be

$$M_{\max} = \frac{M_x + M_y}{2} + \frac{1}{2} \sqrt{(M_x - M_y)^2 + 4\, M^2_{xy}} \qquad (29a)$$

and

$$M_{\min} = \frac{M_x + M_y}{2} - \frac{1}{2} \sqrt{(M_x - M_y)^2 + 4\, M^2_{xy}} \qquad (29b)$$

The maximum value of the twisting moment is

$$M_t = \frac{1}{2} \sqrt{(M_x - M_y)^2 + 4\, M^2_{xy}} \qquad (30)$$

To obtain the trajectories of the principal moments (see Fig. 2(*b*)), use is made of the equation

$$\tan 2\,\theta = \frac{2\,M_{xy}}{M_x - M_y} \qquad (31)$$

PRELIMINARY SURVEY OF TRIANGULAR PLATES

A brief preliminary study of the effect of density of difference-equation networks on certain deflections and moments was made for the equilateral triangular plate, the 30°–60°–90° triangular plate, and an isosceles triangular plate having a right angle, all plates being simply supported and subjected to a uniformly distributed load. Comparison with published results obtained by more exact methods indicated that a relatively small number of nodal points gives values that are in fair agreement with those of the more accurate solutions. This is especially true in the case of bending moments. In general, moments and deflections for points nearer the center of gravity of the plates showed better agreement than those for points nearer the boundaries. Net works considered involved from two to twenty-one coefficients. Because of lack of space, however, detailed observations for triangular plates are not given herein.

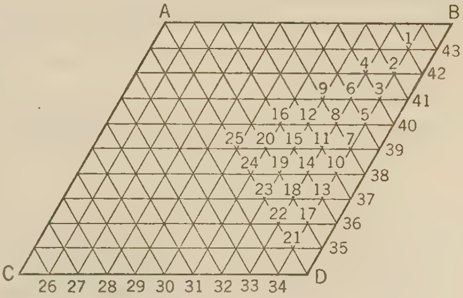
(*b*) SIXTEEN COEFFICIENTS



(*c*) TWENTY-FIVE COEFFICIENTS

FIG. 4.—NETWORKS FOR 30° SKEW PLATES (AB = AC = 2 *c*)

SIMPLY SUPPORTED 30° SKEW PLATE WITH EQUAL SIDES SUBJECTED TO A UNIFORMLY DISTRIBUTED LOAD

Analysis by Method of Finite Differences.—The most convenient network for the analysis of a 30° skew plate by the difference-equation method is a triangular (hexagonal) arrangement formed by drawing lines parallel to the sides and the shorter diagonal of the plate (see Figs. 3(*d*) and 4). To determine the effect of the mesh intervals on the results for deflections and moments in the case of the uniformly loaded, simply supported, 30° skew plate having equal sides (length = 2 c), three networks of varying density ($\lambda = c/2, c/4, c/5$) were analyzed by this method.

The difference equations relating the $\bar{w}$-values and $\bar{z}$-values at the intersections of the lines forming the networks result in a system of simultaneous linear equations. The number of those equations depends upon the number of intersection points or nodal points. In the particular plate under consideration, there is symmetry about both diagonals and, consequently, only one quarter of the plate need be analyzed.

If the length of the sides is divided into four parts ($\lambda = c/2$), it is apparent that four nodal points result (some of them are repeated), and, therefore, four simultaneous linear equations must be written and four coefficients are to be found. For $\lambda = c/4$ and $\lambda = c/5$, sixteen and twenty-five equations, respectively, must be written. As stated previously, the equations relating the deflections of the membranes involved in this method are usually in normal form, and they may be solved conveniently by the "Doolittle Method" of solving simultaneous equations.[19] The boundary conditions for the membranes associated with simply supported plates are indicated in Table 1. It is to be noted that the relations given for $\bar{z}$ in this table are also valid for $\bar{w}$.

TABLE 1.—BOUNDARY CONDITIONS FOR SKEW PLATES

Condition	 (a) SQUARE MESH		 (b) HEXAGONAL MESH	
	$\bar{z}_s$	$\bar{z}_q$	$\bar{z}_u$	$\bar{z}_R$
Simply supported edge	$\bar{z}_s = \bar{z}_n = 0$	$-\bar{z}_k$	$\bar{z}_i = \bar{z}_q = 0$	$-\bar{z}_k$
Clamped edge	$\bar{z}_i = \bar{z}_n = 0$	$+\bar{z}_k$	$\bar{z}_i = \bar{z}_q = 0$	$+\bar{z}_k$

Substitution in Eqs. 22 gives the following equations for the sixteen-coefficient solution—

$$\left.\begin{aligned} 4\,\bar{w}_1 - \frac{2}{3}\,(2\,\bar{w}_2) &= \frac{p\,\lambda^2}{S_1} \\ 4\,\bar{w}_2 - \frac{2}{3}\,(\bar{w}_1 + \bar{w}_2 + \bar{w}^3 + \bar{w}_4) &= \frac{p\,\lambda^2}{S_1} \end{aligned}\right\}\ldots\ldots\ldots\ldots\ldots(32)$$

—etc.; and

$$\left.\begin{aligned} 4\,\bar{z}_1 - \frac{2}{3}\,(2\,\bar{z}_2) &= \bar{w}_1\,\frac{\lambda^2}{S_2} \\ 4\,\bar{z}_2 - \frac{2}{3}\,(\bar{z}_1 + \bar{z}_2 + \bar{z}_3 + \bar{z}_4) &= \bar{w}_2\,\frac{\lambda^2}{S_2} \end{aligned}\right\}\ldots\ldots\ldots\ldots\ldots(33)$$

etc. Eqs. 32 and 33 may be put into the form given in Table 2. The last two columns in this table are the terms that appear on the right side of Eqs. 32 and 33. Hence, it is to be remembered that after each numerical value in these two columns (Table 2) there are actually an equal sign and zero, since a minus sign precedes each one. The "Doolittle Method" was adopted for simultaneous equations that happened to occur in normal form.[19]

TABLE 3.—SOLUTION OF EQS. 32 AND 33 WITH REFERENCE TO TABLE 2

Point number:	$\bar{w}$	$\bar{z}$	Point number:	$\bar{w}$	$\bar{z}$
1	0.618631 A	0.811050 B	9	3.214962 A	8.697569 B
2	1.105895 A	1.969178 B	10	1.646262 A	3.956232 B
3	1.461449 A	3.107640 B	11	2.870206 A	7.690210 B
4	1.949388 A	4.268346 B	12	3.518332 A	9.904091 B
5	1.682575 A	3.949917 B	13	1.220346 A	2.718592 B
6	2.530822 A	6.266184 B	14	2.529533 A	6.568515 B
7	1.757560 A	4.290623 B	15	3.423915 A	9.605294 B
8	2.845728 A	7.511201 B	16	3.736860 A	10.738709 B

The solution yields the values for $\bar{w}_1$, $\bar{w}_2$, $\bar{z}_1$, $\bar{z}_2$, etc., given in Table 3, in which, to simplify typography,

$$A = \frac{p\,\lambda^2}{S_1} \qquad (34a)$$

and

$$B = \frac{p\,\lambda^4}{S_1\,S_2} \qquad (34b)$$

When all the $\bar{w}$-coefficients and $\bar{z}$-coefficients are found, it is an easy matter to obtain the deflections and moments. These are indicated for the sixteen-coefficient solution in Table 4. It is necessary to refer to Figs. 3(*d*) and 4(*b*) in the preparation and interpretation of these results. Similar analyses were made for the uniformly loaded, simply supported, 30° skew plate or slab, having equal sides, by utilizing four-coefficient and twenty-five-coefficient difference-equation networks (see Figs. 4(*a*) and 4(*c*)).

Table 5 affords a comparison of the moments and deflections at the center of the equal-sided, uniformly loaded, simply supported, 30° skew plate for three different networks. It is seen that the moments M_1, M_2, M_3, M_x, and M_y are in fairly good agreement even in the four-coefficient case. The twisting moments, M_{xy}, are in fair agreement only for the sixteen-coefficient and twenty-

five-coefficient solutions. The deflections at the center of the plate agree fairly well again only for the sixteen-coefficient and twenty-five-coefficient cases.

Solutions in Trigonometric Series.—Another approximate method for determining deflections and moments in a plate is one in which the deflection function is set up in the form of a trigonometric series, satisfying the plate equation. This series contains a set of arbitrary constants that can be computed in such a manner as to satisfy the boundary conditions at an arbitrary number of points. The degree of approximation, naturally, depends upon the number of points selected on the boundary, but it has been found that in many cases a relatively small number of points is sufficient to give fairly reliable results. There is reason to believe that the use of approximate methods is justified, since the assumptions made in theories are very seldom entirely true in practice.

The approximate determination of the stress function for the prismatic bar in torsion and the deflection function in a clamped square plate has been indicated by J. Barta.[20] These problems had been solved previously by more exact methods, and the agreement found by Mr. Barta was fairly good.

The trigonometric-series approach may be used quite readily in the solution of both simply supported and clamped skew plates. Both of these cases are treated for a 30° skew in this paper. It is to be noted (see Fig. 5) that a new set of Cartesian-coordinate axes is chosen in order to take advantage of symmetry.

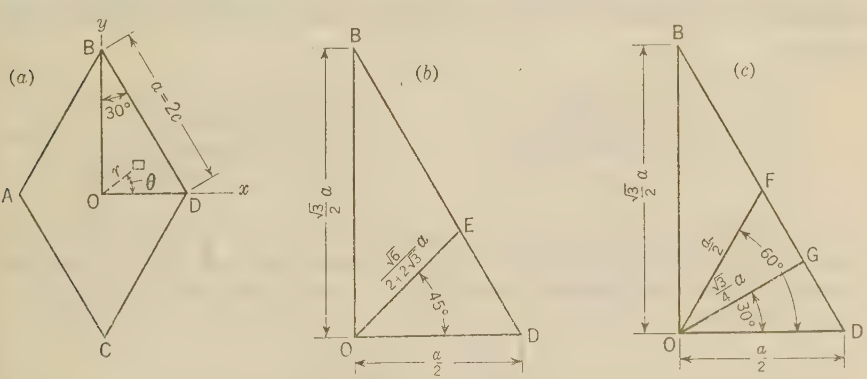

FIG. 5.—DIAGRAMS FOR TRIGONOMETRIC-SERIES ANALYSES OF SKEW PLATES (AB = AC = BD = CD)

In Fig. 5(*c*) it is seen that the number of points chosen along the entire boundary is 12. It is sufficient, therefore, to satisfy the boundary conditions at points B, D, F, and G. Because of symmetry, the assumed deflection function is taken to be

$$w = \frac{p\,r^4}{64\,N} + a_0 + r^2\,a_2\cos 2\,\theta + r^2\,c_2 + r^4\,a_4\cos 4\,\theta + r^4\,c_4\cos 2\,\theta$$
$$+ r^6\,a_6\cos 6\,\theta + r^6\,c_6\cos 4\,\theta + r^8\,c_8\cos 6\,\theta \ldots\ldots\ldots\ldots (35)$$

---

[20] "Über die näherungsweise Lösung einiger zweidimensionaler Elastizitätsaufgaben," by J. Barta, *Zeitschrift für Angewandte Mathematik und Mechanik*, Vol. 17, No. 3, 1937, pp. 184–185.

The boundary conditions for a simply supported edge (length of side = a) are: $w = 0$; and

$$\nabla^2 w = \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} = 0 \qquad (36)$$

which, in polar form, becomes Eq. 12a equated to zero.

From Eqs. 35, 36, and 12a it is clear that, at the boundary points, the following relations must be valid:

$$w = \frac{p\,r^4}{64\,N} + a_0 + r^2 a_2 \cos 2\,\theta + r^2 c_2 + r^4 a_4 \cos 4\,\theta + r^4 c_4 \cos 2\,\theta$$
$$+ r^6 a_6 \cos 6\,\theta + r^6 c_6 \cos 4\,\theta + r^8 c_8 \cos 6\,\theta = 0 \qquad (37a)$$

and

$$\nabla^2 w = \frac{p\,r^2}{4\,N} + 4\,c_2 + 12\,r^2 c_4 \cos 2\,\theta$$
$$+ 20\,r^4 c_6 \cos 4\,\theta + 28\,r^6 c_8 \cos 6\,\theta = 0 \qquad (37b)$$

It may be shown easily that the assumed deflection function (Eq. 35) satisfies the plate formula, Eq. 4.

By substituting the values of r and θ for points B, D, F, and G in Eqs. 37, and allowing a and its powers to equal unity, it is possible to obtain eight simultaneous equations, the solution of which yields the values of the arbitrary constants:

$$\left.\begin{array}{ll} a_0 = 0.0027059329\,p/N & c_4 = 0.0057873004\,p/N \\ a_2 = -0.0038678560\,p/N & a_6 = 0.0041150544\,p/N \\ c_2 = -0.0148808677\,p/N & c_6 = -0.0138895211\,p/N \\ a_4 = 0.0131565067\,p/N & c_8 = -0.0068034953\,p/N \end{array}\right\} \qquad (38)$$

These values, multiplied by the corresponding powers of a (length of side), may be inserted in Eq. 35 to give the approximate solution for the deflection function. From the resulting expression the maximum value of deflection may be obtained by letting $r = 0$:

$$w_{\max} = 0.0432949264\,\frac{p\,c^4}{N} \qquad (39a)$$

in which $a = 2\,c$. The corresponding value obtained by the method of finite differences is

$$w_{\max} = 0.041583\,\frac{p\,c^4}{N} \qquad (39b)$$

which indicates a difference of about 4%, based upon the difference-equation value.

From Eqs. 13 and 35, expressions may be deduced which, for the center of the plate ($r = 0$ and $\theta = 0$), reduce to:

$$M_r = -2\,N\,[a_2 + c_2 + \mu\,(c_2 - a_2)] \qquad (40a)$$

and

$$M_t = -2\,N\,[\mu\,(a_2 + c_2) - a_2 + c_2] \qquad (40b)$$

At the center of the plate these moments are found to be

$$M_r = 0.1764210176\, p\, c^2 \tag{41a}$$

and

$$M_t = 0.1331010304\, p\, c^2 \tag{41b}$$

which compare fairly well with the corresponding difference-equation moments

$$M_r = 0.169566\, p\, c^2 \tag{42a}$$

and

$$M_t = 0.133894\, p\, c^2 \tag{42b}$$

The differences based upon the difference-equation values for these radial and tangential moments are 4% and 0.6%, respectively. The agreement for the deflections and moments in this case is fairly good.

Power-Series Method.—Several power-series approaches may be found for the approximate solution of plate problems. One of these is presented in this paper, whereas others studied in the investigation are given in a more detailed report filed in the Engineering Societies Library. In the detailed report plates with unequal sides are also treated.

In the case of the uniformly loaded, simply supported, 30° skew plate having equal sides, it is desirable to establish a set of Cartesian-coordinate axes as shown in Fig. 6(*a*). This enables one to take advantage of the symmetry prevailing about both axes. The deflection function may be written in the form

FIG. 6.—POWER-SERIES NETWORKS FOR SKEW PLATES

$$w = \frac{p}{N}\left(y + \sqrt{3}\,x + \frac{\sqrt{3}}{2}a\right)\left(y - \sqrt{3}\,x - \frac{\sqrt{3}}{2}a\right)\left(y + \sqrt{3}\,x - \frac{\sqrt{3}}{2}a\right) \times \left(y - \sqrt{3}\,x + \frac{\sqrt{3}}{2}a\right)\sum_{m=0,2,\ldots}^{\infty}\ \sum_{n=0,2,\ldots}^{\infty} C_{m,n}\left(\frac{x}{a}\right)^m\left(\frac{y}{a}\right)^n \tag{43}$$

Since Eq. 43 involves the product of expressions for the sides, it is apparent that one of the boundary conditions, $w = 0$, is already satisfied.

Other conditions to be imposed on Eq. 43 are that $\nabla^4 w = \frac{p}{N}$ (Eq. 4) throughout the entire plate, and that $\nabla^2 w = 0$ (see Eq. 36) along the boundary.

It is to be expected that an approximate solution of the deflection function should result, if Eqs. 4 and 36 are satisfied only at certain points within the plate and certain other points along the boundary, respectively. One particular case involving points B, D, and E, along the boundary, and points 1, 2, 4, and 5 (see Fig. 6(*c*)) yielded the following values for the center of the plate ($a = 2\,c$):

$$w = 0.045007 \frac{p\,c^4}{N} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

$$M_x = 0.196316\,p\,c^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45a)$$

and

$$M_y = 0.110744\,p\,c^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45b)$$

which are about 8%, 16%, and 17% different from the corresponding difference-equation values.

Clamped 30° Skew Plate with Equal Sides Subjected to a Uniformly Distributed Load

Analysis by Method of Finite Differences.—In solving the problem of the clamped plate, it is convenient to relate the membrane deflections in such a manner that only one set of simultaneous equations need be solved. From Eqs. 19, 22*b*, and Fig. 3(*e*),

$$4\,\bar{z}_k - 2/3\,(\bar{z}_i + \bar{z}_l + \bar{z}_o + \bar{z}_p + \bar{z}_q + \bar{z}_r) = \bar{w}_k\,\lambda^2/S_2 \ldots\ldots (46a)$$

$$4\,\bar{z}_i - 2/3\,(\bar{z}_A + \bar{z}_k + \bar{z}_R + \bar{z}_q + \bar{z}_U + \bar{z}_o) = \bar{w}_i\,\lambda^2/S_2 \ldots\ldots (46b)$$

$$4\,\bar{z}_l - 2/3\,(\bar{z}_k + \bar{z}_B + \bar{z}_r + \bar{z}_T + \bar{z}_p + \bar{z}_V) = \bar{w}_l\,\lambda^2/S_2 \ldots\ldots (46c)$$

$$4\,\bar{z}_q - 2/3\,(\bar{z}_R + \bar{z}_r + \bar{z}_C + \bar{z}_G + \bar{z}_i + \bar{z}_k) = \bar{w}_q\,\lambda^2/S_2 \ldots\ldots (46d)$$

$$4\,\bar{z}_r - 2/3\,(\bar{z}_q + \bar{z}_T + \bar{z}_G + \bar{z}_D + \bar{z}_k + \bar{z}_l) = \bar{w}_r\,\lambda^2/S_2 \ldots\ldots (46e)$$

$$4\,\bar{z}_o - 2/3\,(\bar{z}_U + \bar{z}_p + \bar{z}_i + \bar{z}_k + \bar{z}_E + \bar{z}_H) = \bar{w}_o\,\lambda^2/S_2 \ldots\ldots (46f)$$

$$4\,\bar{z}_p - 2/3\,(\bar{z}_o + \bar{z}_V + \bar{z}_k + \bar{z}_l + \bar{z}_H + \bar{z}_F) = \bar{w}_p\,\lambda^2/S_2 \ldots\ldots (46g)$$

From Eqs. 22*a* and 46 the more convenient form is found as follows:

$$42\,\bar{z}_k - 10\,(\bar{z}_i + \bar{z}_l + \bar{z}_o + \bar{z}_p + \bar{z}_q + \bar{z}_r) + (\bar{z}_A + \bar{z}_B + \bar{z}_C + \bar{z}_D + \bar{z}_E + \bar{z}_F)$$
$$+ 2\,(\bar{z}_R + \bar{z}_T + \bar{z}_U + \bar{z}_V + \bar{z}_G + \bar{z}_H) = \frac{9}{4}\frac{p\,\lambda^4}{S_1\,S_2} \ldots\ldots\ldots (47)$$

For this particular clamped plate, sixteen coefficients were used (see Fig. 4(*b*)). Table 6 contains the deflections and moments at the intersection points of the network and at certain boundary points.

Solutions in Trigonometric Series.—The trigonometric-series approach, as mentioned previously, applies to the clamped skew plate as well as to the simply supported case. Again, a plate having a 30° skew is selected, the sides being clamped and the lengths equal to *a*. The assumed function for the deflections must satisfy the plate formula, Eq. 4, throughout the entire plate and the boundary conditions, as before, are to be met at an arbitrary number of points (twelve in this case).

TABLE 6.—UNIFORMLY LOADED, CLAMPED, 30° SKEW PLATE HAVING EQUAL SIDES

Boundary conditions at points B, D, F, and G (see Fig. 5(*c*)), which must be satisfied are: $w = 0$; $\partial w/\partial r = 0$; and $\partial w/\partial \theta = 0$.

Because of symmetry the deflection function may be put in the form

$$w = \frac{p\,r^4}{64\,N} + a_0 + r^2\,a_2\cos 2\,\theta + r^2\,c_2 + r^4\,a_4\cos 4\,\theta + r^4\,c_4\cos 2\,\theta + r^6\,a_6\cos 6\,\theta + r^6\,c_6\cos 4\,\theta + r^8\,a_8\cos 8\,\theta + r^8\,c_8\cos 6\,\theta + r^{10}\,c_{10}\cos 8\,\theta \ldots\ldots\ldots\ldots\ldots\ldots \quad (48)$$

Differentiation of Eq. 48 results in

$$\frac{\partial w}{\partial r} = \frac{p\,r^3}{16\,N} + 2\,r\,a_2\cos 2\,\theta + 2\,r\,c_2 + 4\,r^3\,a_4\cos 4\,\theta + 4\,r^3\,c_4\cos 2\,\theta + 6\,r^5\,a_6\cos 6\,\theta + 6\,r^5\,c_6\cos 4\,\theta + 8\,r^7\,a_8\cos 8\,\theta + 8\,r^7\,c_8\cos 6\,\theta + 10\,r^9\,c_{10}\cos 8\,\theta \ldots\ldots\ldots \quad (49a)$$

and

$$\frac{\partial w}{\partial \theta} = -2\,r^2\,a_2 \sin 2\,\theta - 4\,r^4\,a_4 \sin 4\,\theta - 2\,r^4\,c_4 \sin 2\,\theta$$
$$- 6\,r^6\,a_6 \sin 6\,\theta - 4\,r^6\,c_6 \sin 4\,\theta - 8\,r^8\,a_8 \sin 8\,\theta$$
$$- 6\,r^8\,c_8 \sin 6\,\theta - 8\,r^{10}\,c_{10} \sin 8\,\theta \quad \text{(49b)}$$

By substituting values of r and θ for points B, D, F, and G (see Fig. 5(*c*)) and setting a equal to unity, it is feasible to derive ten simultaneous equations, the solution of which gives the values

$$\left.\begin{array}{ll} a_0 = 0.0007979061\,p/N & a_6 = -\,0.0168885960\,p/N \\ a_2 = -\,0.0022057884\,p/N & c_6 = -\,0.0493657788\,p/N \\ c_2 = -\,0.0065078196\,p/N & a_8 = 0.0177867736\,p/N \\ a_4 = 0.0128847660\,p/N & c_8 = 0.0297909016\,p/N \\ c_4 = 0.0057365111\,p/N & c_{10} = 0.0276254724\,p/N \end{array}\right\} \quad (50)$$

These values, it must be remembered, are to be multiplied by appropriate powers of a before they are inserted in Eq. 48 to give the approximate solution for the deflection function. The maximum deflection for this plate occurs at the center ($r = 0$), and its value is found to be

$$w_{\max} = 0.0127664976\,\frac{p\,c^4}{N} \quad \text{(51a)}$$

The corresponding value obtained by means of difference equations is

$$w_{\max} = 0.014384\,\frac{p\,c^4}{N} \quad \text{(51b)}$$

which indicates a difference of about 11% based on the latter value. Referring to Eqs. 13, it is possible to deduce expressions for the radial and tangential moments, which for the center of the plate ($r = 0$ and $\theta = 0$) reduce to the same form as that found for the simply supported plate, Eqs. 40, except that the values of the constants are different. Substitution of the values obtained for a_2 and c_2 in Eqs. 40 gives:

$$M_r = 0.0800337388\,p\,c^2 \quad \text{(52a)}$$

and

$$M_t = 0.0553289088\,p\,c^2 \quad \text{(52b)}$$

The corresponding difference-equation values are

$$M_r = 0.082470\,p\,c^2 \quad \text{(53a)}$$

and

$$M_t = 0.065211\,p\,c^2 \quad \text{(53b)}$$

indicating, for the radial and tangential moments at the center, a difference of about 3% and 15%, respectively, based on the difference-equation moments. Obviously, in the case of the clamped plate, the boundary conditions should be satisfied for a greater number of points (for the same degree of approximation) than in the case of the simply supported skew plate.

For the equal-sided clamped 30° skew plate with the boundary conditions being satisfied at only eight points along the entire boundary (see Fig. 5(*b*)), the results are naturally less reliable than those obtained when twelve points are taken into consideration.

The maximum deflection of the plate obtained by the trigonometric-series approach for this case (eight boundary points considered) is approximately 17% too low based on the difference-equation result. The difference between the radial and tangential moments as obtained by the trigonometric and difference-equation methods average about 20%. Clearly, the degree of approximation in this case is not satisfactory.

Power-Series Method.—The clamped 30° skew plate having equal sides and subjected to a uniformly distributed load may also be analyzed by power-series methods. The deflection function may be written in the form (see Fig. 6),

$$w = \frac{p}{a^4 N}\left(y + \sqrt{3}\,x + \frac{\sqrt{3}}{2}a\right)^2\left(y - \sqrt{3}\,x - \frac{\sqrt{3}}{2}a\right)^2\left(y + \sqrt{3}\,x - \frac{\sqrt{3}}{2}a\right)^2$$

$$\times\left(y - \sqrt{3}\,x + \frac{\sqrt{3}}{2}a\right)^2 \sum_{m=0,2,4,\ldots}^{\infty}\ \sum_{n=0,2,4,\ldots}^{\infty} C_{m,n}\left(\frac{x}{a}\right)^m\left(\frac{y}{a}\right)^n \ldots (54)$$

from which it is apparent that the boundary conditions $w = 0$, $\partial w/\partial x = 0$, and $\partial w/\partial y = 0$ are valid. The plate formula, Eq. 4, must also be satisfied. By doing this for only a certain number of interior points, it is possible to solve the problem approximately. It is convenient to select the number of points to correspond to the number of constants, $C_{m,n}$, chosen for the series; in this manner one obtains as many equations as there are unknowns in the series. Eq. 4 may be satisfied for a larger number of points by normalizing the resulting equations. This process yields a system of linear equations in normal form (symmetry about the diagonal) which may easily be solved by the Doolittle Method.[19]

Six points are now selected within the plate (see Fig. 6(*c*)) and, correspondingly, six coefficients are taken in the power series. Obviously, from symmetry, these are $C_{0,0}$, $C_{2,0}$, $C_{0,2}$, $C_{4,0}$, $C_{2,2}$, $C_{0,4}$. From Eq. 54, by a few simple operations, one may derive the differential equation presented (for compactness) in Table 7.

Substitution of values of x and y in Table 7 for the six points gives rise to a system of equations, the solution of which yields the values

$C_{0,0} = 2.6184138565 \times 10^{-3}$ $C_{4,0} = 20.1633240889 \times 10^{-3}$
$C_{2,0} = 11.8165756479 \times 10^{-3}$ $C_{2,2} = -10.3051787620 \times 10^{-3}$
$C_{0,2} = -2.6453532509 \times 10^{-3}$ $C_{0,4} = -1.1029769807 \times 10^{-3}$

The maximum deflection of the plate is found to be

$$w_{\max} = 0.0008284825\,\frac{p\,a^4}{N} \ldots\ldots\ldots\ldots (55a)$$

which is about 7.8% less than the difference-equation value—

$$w_{\max} = 0.000899\,\frac{p\,a^4}{N} \ldots\ldots\ldots\ldots (55b)$$

From Eqs. 1 and 54 it is possible to determine the bending moments at the center of the plate

$$M_x = 0.084732\, p\, c^2 \qquad (56a)$$

and

$$M_y = 0.051492\, p\, c^2 \qquad (56b)$$

TABLE 7.—DIFFERENTIAL EQUATION DERIVED FROM EQ. 54, WITH $a = 1$

$$\frac{N}{p}\nabla^4 w =$$

$$\begin{aligned}

\end{aligned}$$

$$= 1$$

These are about 3% and 21% different from the corresponding difference-equation values.

SUMMARY AND CONCLUSIONS

In this paper a theoretical study of uniformly loaded, simply supported, and clamped skew plates has been made by means of approximate methods. No exact solution of skew plate problems has come to the attention of the writer, and consequently comparisons were made between approximate methods.

A survey was made of a few systems of coordinates in order to ascertain their convenience in the treatment of triangular and skew plates. The trilinear and quadrilinear systems appear to have no particular advantages, except possibly as regards the question of symmetry. Both seem to require more effort than the Cartesian-coordinate system in the solution of the same problems. The trilinear system has been suggested by an investigator who solved plate problems that have also been analyzed by Cartesian coordinates. The quadrilinear system, in the case of power-series methods, would definitely involve more work. Polar-coordinate equations, on the other hand, have been very useful in the trigonometric-series solutions.

From a preliminary survey of triangular plates and a more extensive investigation of the uniformly loaded, simply supported, 30° skew plate having equal sides, a measure of the reliability of difference-equation results for various densities of networks was obtained. In general, it may be stated that a relatively small number of nodal points gives values which are in fair agreement with those of more dense and, hence, more accurate networks. This is especially true in the case of bending moments. More specifically, in this connection, the following observations are noteworthy:

(1) In the case of simply supported equilateral, triangular plates, subjected to uniformly distributed loads, reasonably good results are obtainable by the method of finite differences even for a relatively small number of coefficients—say, five. The maximum deflection given by the five-coefficient solution and the eight-coefficient solution varied from the exact solution by 2.7% and 1.2%, respectively.

(2) A comparison of deflections at certain points of the simply supported, 30°-60°-90° plate subjected to a uniformly distributed load obtained by networks having three and twenty-one nodal points showed a difference of about 6% or 7%.

(3) For the simply supported isosceles, right triangular plate subjected to a uniformly distributed load, the deflections as obtained by A. Nadai's approximation and a difference-equation network having twelve coefficients are in fair agreement at points near the center of gravity of the plate, but nearer the boundaries there is considerable disagreement.

(4) A comparison of bending moments and twisting moments at similar points of the uniformly loaded, simply supported, 30° skew plate (equal sides) obtained by the four-coefficient solution and the sixteen-coefficient solution indicated reasonably good agreement. At one pair of corresponding points the results agreed well within 1%. Two other pairs, for which a comparison was made, showed a maximum difference of about 5% for bending moments, whereas the twisting moments varied by about 10% in one case and by about 22% in the other. The deflections differed by about 8% or 9% for the three points investigated.

(5) At the center of the uniformly loaded, simply supported, 30° skew plate having equal sides, the bending moments and deflections resulting from the networks having twenty-five and sixteen coefficients agreed well within 1%. The corresponding twisting moments differed by only 2%.

(6) A similar comparison (see conclusion (5)) between these results as obtained by the twenty-five-coefficient and the four-coefficient solutions showed good agreement (within 3%) for the bending moments. The twisting moments and deflections at the center differed by 19% and 9%, respectively.

The uniformly loaded, simply supported, 30° skew plate with equal sides was analyzed by the trigonometric-series and power-series methods, as well as by the difference-equation method, and certain deflections and moments were compared. The following comparisons may be enumerated:

(*a*) The maximum deflection given by the trigonometric-series method for this case (eight coefficients) differs by about 4% from the difference-equation value. At the center of the plate, the radial and tangential moments differ by 4% and 0.6%, respectively, for these same two methods. The agreement here is seen to be good.

(*b*) At the center of the plate, the deflection, w, and the moments M_x and M_y, as obtained by the method using power series (only three terms and seven points considered), differed by 8%, 16%, and 17%, respectively, from the corresponding difference-equation values. By increasing the number of terms in the series and the number of points for which the conditions are satisfied, it would appear to be possible to increase the accuracy.

The clamped 30° skew plate with equal sides, subjected to a uniformly distributed load, was studied by similar methods, and the following observations were made:

(*A*) A difference of 11% was found between the maximum deflections as obtained by trigonometric series (ten coefficients) and by difference equations. The radial and tangential moments at the center differed (for these two methods) by about 3% and 15%, respectively.

(*B*) The values for the maximum deflection as obtained by power series (six coefficients) and difference equations differed by 7.8%. The moments M_x and M_y differed by 3% and 21%, respectively.

Structural action of skew plates and slabs in the region of corners was not treated. Singularities prevailing in these sections probably necessitate the use of more rigorous, mathematical methods.

ACKNOWLEDGMENT

The source of the material for this paper was a thesis by the writer, entitled "A Theoretical Study of Skew Plates," presented to Lehigh University, Bethlehem, Pa., in June, 1941, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

This investigation was conducted under the general supervision of Hale Sutherland, M. Am. Soc. C. E., Director of the Fritz Engineering Laboratory of Lehigh University, while the writer served as Instructor in Theoretical and Applied Mechanics at the University of Illinois, Urbana, Ill. The suggestions and criticisms of Professors Newmark and Jensen, previously mentioned, are gratefully acknowledged.

APPENDIX

NOTATION

The following letter symbols conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932) prepared by a Committee of the American Standards

Association, with Society representation, and approved by the Association in 1932:

A = a substitution coefficient in Table 2;
a = a horizontal dimension of plate (for example, see Fig. 5);
a_n = a coefficient in a trigonometric series;
B = a substitution coefficient in Table 2;
C = coefficient; $C_{m,n}$ = a coefficient in a power series;
c = a horizontal dimension of a plate (for example, see Fig. 5);
c_n = a coefficient in a trigonometric series;
E = the modulus of elasticity of a material in tension and compression;
G = the modulus of elasticity of a material in shear;
h = thickness of plate;
M = moment (positive directions shown in Fig. 1):

- M_x, M_y = bending moments per unit of length in sections perpendicular to the x-axis and the y-axis, respectively;
- M_{xy} = twisting moment per unit of length in sections perpendicular to the x-axis;
- M_r, M_t = bending moments per unit of length in sections perpendicular to radial and tangential directions (positive when producing compression in the top fibers of a plate);
- $M_{r,t}$ = twisting moments per unit of length in sections perpendicular to radial directions;
- M_1, M_2, M_3 = bending moments per unit of length in sections perpendicular to directions 1, 2, and 3, respectively;
- M_t = maximum value of a twisting moment (Eq. 30);

$\bar{M}$ = a function of the moment sum (Eq. 14); $\bar{M}_k$ = value of $\bar{M}$ at the nodal point k (Eq. 19);
N = flexural rigidity of the plate (Eq. 2);
n = a direction in any given plane, perpendicular to direction t (n = "normal" and t = "tangential");
p = uniformly distributed lateral unit load;
R = reactions; R_x and R_y = vertical reaction per unit of length in sections normal to the x-axis and the y-axis, respectively;
r = radius = polar coordinate with angular displacement θ; r_x, r_y = radii of curvature of the middle surface of a plate in planes parallel to the xz-plane and the yz-plane, respectively;
S = horizontal component of the surface stresses; S_1 = S referred to the first membrane, etc. (Eq. 19);
t = a direction perpendicular to n;
u = displacement in the x-direction;
V = vertical shear:

- V_x, V_y = vertical shear per unit of length in sections normal to the x-axis and the y-axis, respectively;

V_{1k} = vertical shear referring to the nodal point k and the plane 1;

v = displacement in the y-direction;

w = displacement in the z-direction; $\bar{w}$ = deflection of first membrane ($\bar{w}_k$ = values of $\bar{w}$ referred to the nodal point k);

x = distances in the x-direction;

y = distances in the y-direction;

z = distances in the z-direction ($\bar{z}_k$ = the deflection of the nodal point k in the second membrane);

θ = angular displacement; polar coordinate with the radius r;

λ = intervals in difference-equation networks (see, for example, Fig. 3), subscripts x and y referring to respective axes;

μ = Poisson's ratio (lateral contraction to longitudinal elongation);

σ = bending stress; σ_x, σ_y = normal components of bending stress in the x-direction and the y-direction, respectively;

τ = shear stress; τ_{xy}, τ_{xz}, τ_{yz} = shearing components of stress, the first subscript in each case indicating the axis to which the plane (in which the stress is acting) is normal, and the second subscript indicating the direction of the shearing stress;

∇ = the Laplace operator.

DISCUSSION

JOHN W. ALLEN,[21] JUN. AM. SOC. C. E.—An interesting comparison of three approximate methods of solving the problem of skew plates is presented in this paper. For the average engineer the difference-equation solution is the most direct of the three. The physical meaning of the difference equations can be understood readily and applied to various structures. This method often provides a powerful tool when exact solutions are not available.

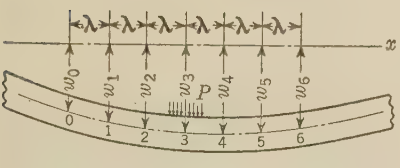

FIG. 7.—DEFLECTED BEAM

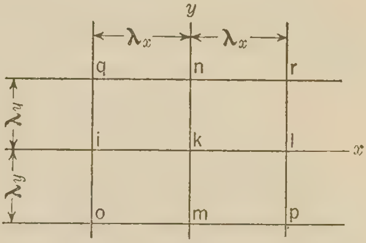

FIG. 8.—NETWORK OF POINTS IN A SLAB

If the structure under consideration were to deflect in only one direction such as the beam in Fig. 7, these equations can be set up in simplified form. The basic equations can then be transposed easily to a structure that is deflecting in two directions.

The difference equations are merely approximate expressions for the slope, and the rate of change of slope, of a curve such as a deflected surface or a moment curve. The theorem is basic, in ordinary structural analysis, that:

(I) The moment in a structure is proportional to the rate of change of slope of the deflected structure; and

(II) The load applied to a structure at a point is proportional to the rate of change of the slope of the moment curve.

The corresponding difference equations for the foregoing theorems can be written as follows: The rate of change of slope of a structure, at point 3, Fig. 7, is proportional to—

$$\frac{\text{(Slope midway between points 2 and 3)} - \text{(slope midway between points 3 and 4)}}{\text{Distance between the midpoints}}.$$

In other words,

$$\left(\frac{d^2w}{dx^2}\right)_3 \cong \frac{1}{\lambda}\left(\frac{w_2 - w_3}{\lambda} - \frac{w_3 - w_4}{\lambda}\right) \cong \frac{w_2 - 2\,w_3 + w_4}{\lambda^2} \ldots\ldots (57)$$

---

[21] Engr., Chicago Bridge & Iron Co., Chicago, Ill.

but $\frac{d^2w}{dx^2} = -\frac{M}{E\,I}$; and therefore

$$\left(\frac{M}{E\,I}\right)_3 \overset{\frown}{=} -\frac{w_2 - 2\,w_3 + w_4}{\lambda^2} \qquad (58)$$

These same equations can be written similarly for the second theorem. For example, let P = the load on the structure at the point under consideration. Then $P = \frac{d^2M}{dx^2}$; and:

$$(P)_3 \overset{\frown}{=} \frac{M_2 - 2\,M_3 + M_4}{\lambda^2} \qquad (59)$$

By combining Eqs. 58 and 59 load P can be expressed in terms of the deflection w:

$$\left(\frac{P}{E\,I}\right)_3 \overset{\frown}{=} -\frac{w_1 - 4\,w_2 + 6\,w_3 - 4\,w_4 + w_5}{\lambda^4} \qquad (60)$$

From the foregoing it can be seen that difference equations involve finite distances to express approximately that which differential equation expresses in minute distances. With difference equations the expressions are solved simultaneously for a few points instead of a complete solution for an infinite number of points.

It is also interesting to note the geometrical meaning of the twisting moment in the slab. Referring to Fig. 8, the following expression for the twisting moment can be obtained. Since the twisting moment is proportional to the rate of change of slope in the x-direction with respect to the y-direction, it can be expressed approximately for point k as follows:

$$\frac{(\text{Slope at point } n \text{ in the } x\text{-direction}) - (\text{slope at point } m \text{ in the } x\text{-direction})}{\text{Distance between the points } n \text{ and } m \text{ in the } y\text{-direction}}.$$

In other words,

$$-\left[\frac{M_{xy}}{(1-\mu)N}\right]_k \overset{\frown}{=} \frac{1}{2\,\lambda_y}\left(\frac{w_q - w_r}{2\,\lambda_x} - \frac{w_o - w_p}{2\,\lambda_x}\right) \overset{\frown}{=} \frac{w_q + w_p - w_r - w_o}{4\,\lambda_x\,\lambda_y} \qquad (61)$$

The foregoing demonstrates that difference equations supply a direct, even though approximate, method of computing quantities that are important in the design of a structure. An equation must be written for each point on the network selected, and solved simultaneously.

Application of these equations and tests of models of structures[22] proves that the conclusions concerning the number of points on a network required to obtain reasonable accuracy are substantially correct.

William A. Conwell,[23] M. Am. Soc. C. E.—In cataloging and demonstrating the various methods available for the solution of plate problems, the author has performed a remarkable service to the profession. In particular, the presentation of the method for applying difference equations to a determination of the bending moments in a plate, whether skew or rectilinear, will be appreciated by most engineers, who prefer physical concepts to involved mathematics. The paper will serve, without doubt, as a text for future study by those engineers who have long been disturbed by rule-of-thumb, semitheoretical, and semi-empirical methods and have sought a practical analytical approach.

[22] "Analysis of Skew Slabs with Curbs," by John W. Allen, thesis presented to the Univ. of Illinois, Urbana, Ill., in 1941, in partial fulfilment of the requirements for the degree of Master of Science in Theoretical and Applied Mechanics.

[23] Pittsburgh, Pa.

The writer wishes to call attention to some of the properties of the square network as shown in Fig. 3(*a*) and Eqs. 21*a* and 21*b*. The simplicity of the equations becomes more apparent when the equations are solved for $\bar{w}_k$ and $\bar{z}_k$, respectively. The values of $\bar{w}_k$ and $\bar{z}_k$ are then evidently merely the averages of the four adjacent values in the network, adjusted by one fourth of the quantity appearing on the right-hand side of Eqs. 21*a* and 21*b*.

This property of simplicity permits the use of numerical methods[24] in the solution of the problem. Reasonable values for $\bar{w}$ and $\bar{z}$ are first assumed for each nodal point on the network and then adjusted by the application of the equations to each point in turn. When a value thus computed differs from the assumed or previously computed value, it is substituted for the assumed or previously computed value and used in all the computations which follow until another application of the equation results in a further adjustment. Each assumed value is thus adjusted and readjusted until the equations are satisfied at each point. For large networks, this process would be a laborious one if it were not for the fairly quick convergence which may be secured by a method outlined by George H. Shortley, Royal Weller, and Bernard Fried.[25]

There is an old engineering practice of using an even number for the last digit in a dividend when the division results in a fraction of a half. Used strictly in numerical procedures, this practice assures accuracy in the results even though only a few significant figures are used in the computations. Because of this fact, elaborate machine computations are avoided and the calculations are reduced to simple arithmetical procedures and slide-rule work. Furthermore, it is possible to obtain values rapidly, which are correct to two significant figures, for rough designs or estimates. The use of such values is fully justified by the fact that the values represent a considerable improvement over values obtained from rule-of-thumb or pseudo-analytical processes. In its final form, furthermore, a slab or plate does not ordinarily fulfil all the assumed conditions of homogeneity, elasticity, "isotropicity," uniformity of thickness, etc.; and, hence, more elaborate computations may be warranted only for detailed analysis or research.

In addition to its simplicity, the square network can be applied universally to either rectilinear plates or those having any degree of skew. The hexagonal network, as demonstrated by the author, is convenient in the solution of plates having a 30° skew. Not only is the square network the natural one to use for a 45° skew but, again because of its simplicity, it is a good choice for any skew. Its application results in a solution in which two irregular edges are substituted for two straight-line edges; but, as the writer will demonstrate, this has little effect on the final results. Values adjacent to the irregular edge are in error, of course; but, for an equal-sided symmetrical plate, this error presents no problem as accurate values are available along the straight edge, symmetrical to the irregular edge. For other than symmetrical, equal-sided plates two solutions may be necessary—one with the network based on one of the edges and another with the network based on the edge that was irregular in the first solution. The solution of such plates by other than the square network would also result in a considerably more complicated procedure than that required for symmetrical equal-sided plates.

$7 @ \lambda = 1.75c$
$\lambda_y = \lambda = \frac{c}{4}$
$2.02c$
29°45′
$\lambda_x = \lambda = \frac{c}{4}$
$8 @ \lambda = 2c$

FIG. 9.—SQUARE NETWORK FOR THE SOLUTION OF A 30° SKEW PLATE WITH EQUAL SIDES

To demonstrate the foregoing statements, the writer has prepared a solution of the simply supported, equal-sided 30° skew plate supporting a uniform load. Fig. 9 shows the square network used in the solution, with its irregular edges and its span of 1.75 c (as against the actual 1.73 c) in the direction of Y—with the resulting discrepancies of 15 min in skew and 0.02 c in the length of the irregular edges. That these irregularities do not influence results beyond the accuracy required for engineering design is evident from comparison of the results with those of the author's sixteen-coefficient solution, as shown in Table 8. Inasmuch as the network used did not have a nodal point at the center of the plate, the values there were obtained by means of a supplementary network which included the six points adjacent to the center and which permitted direct computation of the center values.

TABLE 8.—COMPARISON OF MOMENTS AND DEFLECTIONS AT THE CENTER OF A UNIFORMLY LOADED, SIMPLY SUPPORTED, 30° SKEW PLATE FOR VARIOUS NETWORKS

Network	λ	Moment M_x	Moment M_y	Moment M_{xy}	Deflection w
Hexagonal........	$c/4$	$0.143095\ p\,c^2$	$0.160524\ p\,c^2$	$-0.015095\ p\,c^2$	$0.041948\ p\,c^4/N$
Square............	$c/4$	$0.144\ p\,c^2$	$0.159\ p\,c^2$	$-0.0144\ p\,c^2$	$0.0420\ p\,c^4/N$
Square............	$c/3$	$0.12\ p\,c^2$	$0.14\ p\,c^2$	$-0.016\ p\,c^2$	$0.038\ p\,c^4/N$

Prior to the more accurate computation (in general, to three significant figures), the writer made a rough calculation using only two significant figures and taking a network in which $\lambda = c/3$. In that instance, the span of the network in the direction of Y was 1.667 c; the skew, 31°; and the length of the irregular edge, 1.94 c. That such rough computations, which produce results very quickly, have engineering value is again evident from a comparison of the results given in Table 8.

Julius Sigman,[26] Esq.—Various methods of analysis are used in this interesting study of skew plates. These methods involve solution by finite differences, by trigonometric series, and by power series. It is very evident that the author has done some painstaking research, and the results obtained seem to agree fairly closely.

When practical considerations are taken into account, it becomes apparent that, because of the limitations of the basic assumptions, skew slabs and structures present a vast field still to be explored. Such an exploration would help in connection with many problems that commonly occur in practice.

Five general methods of studying the structural action of concrete slabs and frames may be listed:

1. Experimental tests of prototypes;
2. Laboratory tests of large-scale models;
3. Model analyses (plaster models and photoelastic tests);
4. Semi-empirical analyses such as those developed by C. Bach,[27] and John R. Nichols; [28] and
5. Theoretical analyses utilizing (a) differential equations, (b) difference equations, (c) "single-infinite" series of hyperbolic functions, (d) "doubles-infinite" Fourier series, (e) power series, (f) trigonometric series, (g) W. Ritz's [29,30] approximate energy method involving the principle of energy minimum, (h) Bessel [31] functions, and (i) short series of polynomials.

In ordinary theory, the plates are assumed to be uniform in thickness and the thickness is assumed to be small compared with the superficial dimensions. In the case of skewed reinforced concrete rigid frame bridges, the thickness of the deck cannot be considered small compared with the lateral dimensions; and the depth, furthermore, is variable so that ordinary theory does not apply.

In addition, the deflections and energy of deformation are assumed not to be affected by the vertical stresses. In the rigid frame bridge deck, deflections and strain energy are markedly affected by the vertical tensions, compressions, and shears.

The following problems with practical value, suggested for future investigation, are worthy of theoretical treatment as thorough as that presented by the author: (1) Skew plates with large deflections; (2) skew slabs with variable thickness; (3) continuous skew slabs; (4) effect of partial fixity of edges; (5) effect of curbs, sidewalks, and parapets on deck action in rigid frame bridges;

[30] *Ann. Physik* (4), Vol. 28, 1909, p. 737.

[31] "The Theory of Sound," by J. W. Strutt, Baron Rayleigh, Dover Publications, New York, N. Y., 2d Ed., 1945.

(6) structural action at corners of skew slabs—a possible approach to the solution would be one using the theory of functions of complex variables; and (7) variable depth skewed slabs with curbs.

Also, since authorities do not agree as to proper procedure for skewed reinforced concrete rigid frame bridge analysis, a solution involving the theory of elasticity might accomplish much toward clarifying certain questions concerning which opinion differs.

F. L. Ehasz,[32] Jun. Am. Soc. C. E.—Discussion of the paper has served to emphasize the usefulness of approximate methods in the analysis of difficult slab and plate problems. In general, the comments made by the various discussers were favorable, and the writer is grateful for their contributions.

The directness and simplicity of difference-equation solutions are discussed by Mr. Allen. From his presentation it is clear that the method is a powerful one in cases not easily dealt with by so-called exact methods. The geometrical significance of structural functions as expressed by difference equations seems to be particularly lucid.

Mr. Conwell states that most engineers prefer physical concepts to purely mathematical treatment in his illuminating remarks. The writer agrees with Mr. Conwell's statements concerning the number of significant figures required for rough design and estimating purposes and the extent to which practice satisfies the ideal assumptions made in analysis. Mr. Conwell's study of the equal-sided 30° skew plate, uniformly loaded and simply supported, by difference equations applied to a square network is interesting. The close agreement between results for the networks given in Table 8 is to be expected, to the extent indicated, in regions near the center of the plate. In the case of the plate fixed at its edges, furthermore, the agreement at the various points throughout the plate would be less. As Mr. Conwell states, however, the engineering value of relatively rough computations is satisfactory for practical purposes. On the other hand, research investigations must be conducted with greater accuracy, since they serve as a basis for deciding the extent to which practicing engineers may abbreviate their studies.

Several interesting problems for future research have been listed by Mr. Sigman. The suggestion that the skewed reinforced concrete rigid frame bridge be analyzed by the theory of elasticity is one that has been in the minds of several investigators. It is common knowledge that this task would be a prodigious one. Admittedly, if such a problem could be thus analyzed successfully, it would go a long way toward clarifying the true structural behavior. Present methods of analysis appear to be satisfactory from a practical viewpoint, considering the uncertain loading and boundary conditions in this type of structure. The writer agrees, however, that such a solution would be a welcome one, even though the assumptions of restraint and loading (action of earth pressure, for example) would still be open to question. Extensive field tests of bridges under actual operation would be of much value in clarifying some of the uncertainties to which Mr. Sigman referred in his discussion. This type of research has found considerable favor in Europe.

THE MECHANISM OF ENERGY LOSS IN FLUID FRICTION

By Boris A. Bakhmeteff,[1] M. Am. Soc. C. E., and
William Allan,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. George R. Rich, J. C. Stevens, Leon Beskin, Hunter Rouse and A. A. Kalinske, and Boris A. Bakhmeteff and William Allan.

Synopsis

An account of the inner processes, by which the energy of fluid flow is lost through friction, is presented in this paper. Previous investigations have dealt largely with bulk appraisals, relating to over-all losses of head. The internal mechanism was investigated in pioneer fashion by Sir G. G. Stokes,[3] who first expressed the internal energy balance for motion in viscous media and formulated the so-called "dissipation function." Horace Lamb[4] broadened the Stokes reasoning, applying it to laminar motion in general. More recently, an attempt to interpret energy exchange in turbulent motion was made by G. I. Taylor.[5,6]

Although it is unimpeachable from a formal mathematical point of view, the traditional treatment does not elucidate the physical aspect of the problem, failing in particular to reveal the fundamental fact that the withdrawal of energy from the flow and its final dissipation into molecular heat do not coincide spatially and that they constitute the initial and the ultimate phase of a manifold process.

The paper reveals these consecutive phases, explaining their dynamic significance and the nature of the losses involved in the different stages. The facts disclosed are especially pertinent for gaining a more comprehensive understanding of the mechanism of turbulent flow. The analysis begins with friction in

uniform established motion and subsequently is extended to boundary layer flow. The fundamental relations are established first for the simpler case of laminar motion, and subsequently are applied to the more complex turbulent flow.

NOTATION

The letter symbols in this paper, defined in the text where they first appear, conform essentially to American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942.

1. INTRODUCTION TO UNIFORM RECTILINEAR MOTION

Fluid friction is revealed outwardly by the resistance slope $S = h_f/l$, or the pressure gradient

$$-\frac{dp}{dx} = \frac{p_1 - p_2}{l_{1,2}} = \gamma \frac{h_1 - h_2}{l_{1,2}} = \gamma S \left(\frac{\text{lb} \times \text{ft}}{\text{ft}^3 \text{ per ft}} \right) \qquad (1)$$

in which: p = pressure intensity; l = distance measured in the direction of flow; γ = specific weight (weight per unit volume); and h = head, measured from a datum line. In this instance Eq. 1 measures the rate of energy per unit volume lost equally by each and every element of a cross section, in its displacement over a unit length of the conduit. The same quantity (Eq. 1) serves to determine the mean wall friction stress

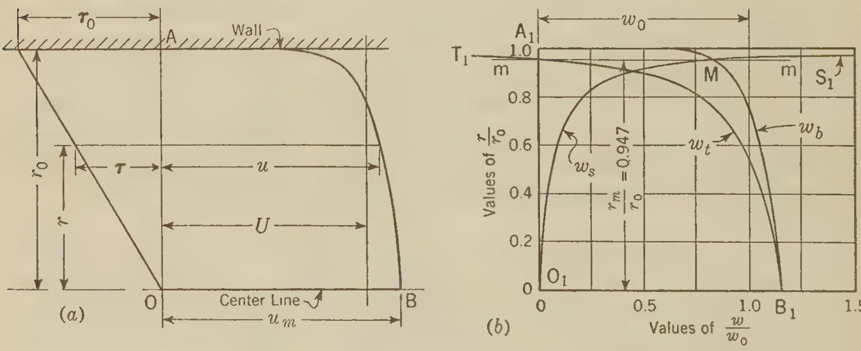

FIG. 1.—TURBULENT FLOW IN SMOOTH PIPE

$$\bar{\tau}_o = -\gamma S R = \frac{dp}{dx} R \left(\frac{\text{lb}}{\text{ft}^2} \right) \qquad (2)$$

and, with that, the internal shearing stress structure. The latter, in uniform motion, is linear.[7] Thus, for a pipe (Fig. 1)—

$$\tau = \tau_o \frac{r}{r_o} \qquad (3a)$$

---

[7] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 1936, p. 3.

and, for two-dimensional motion (Fig. 2)—

$$\tau = \tau_o \frac{y'}{y'_o} \qquad (3b)$$

In Eqs. 2 and 3, r = the distance from the axis to an inner filament; A = the cross-sectional area; P_w = the wetted perimeter; $R = A/P_w$ the hydraulic radius; and y', in two-dimensional motion, will designate specifically the distance from the free surface (Fig. 2) or from the central axis as against y, which exemplifies a transverse coordinate in general.

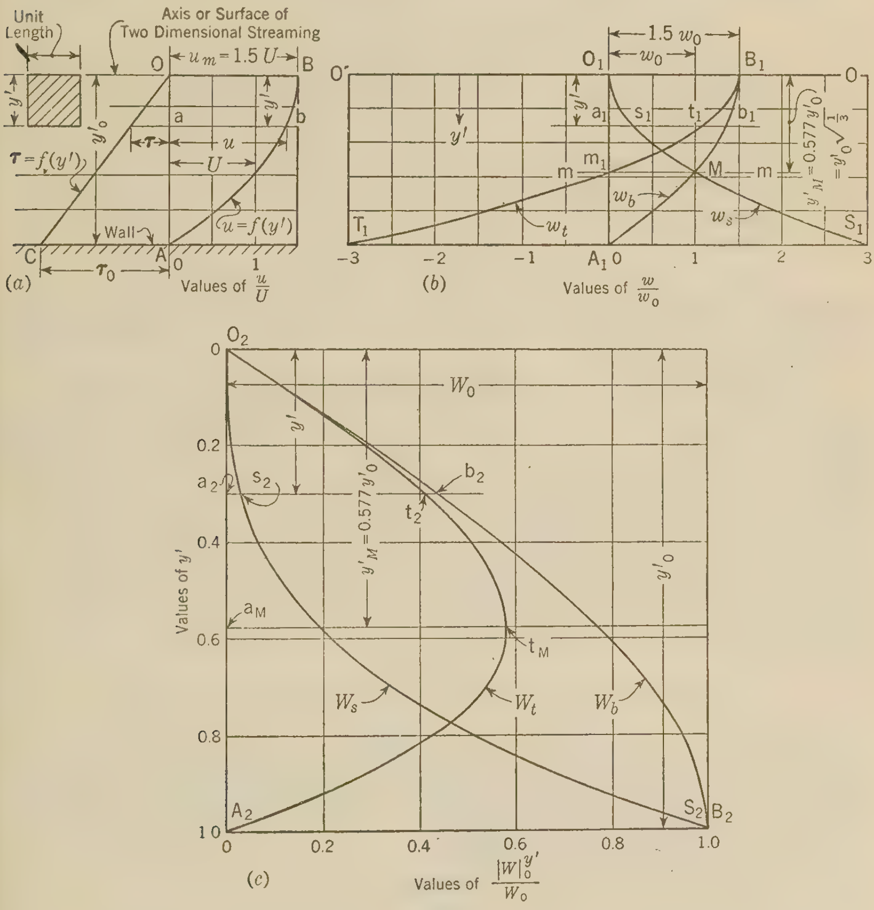

FIG. 2

Another familiar concept is the bulk loss of power:

$$W_o = \gamma S Q = -\frac{dp}{dx} Q \left(\frac{\text{lb} \times \text{ft}}{\text{sec per ft}} \right) \qquad (4)$$

or the total work done by the flow in overcoming frictional resistances during unit time and over a unit length of the conduit. In Fig. 3, the discharge Q enters the unit length block and subsequently leaves it, in the interim unit time suffering the loss W_o; or, one may state that within the unit length block, and during each second, mechanical energy at the rate of W_o is withdrawn from the flow and is spent to overcome resistances, by way of ultimate dissipation into molecular heat. Since the velocities do not change, all of W_o is withdrawn from the potential energy store carried by the flow, thereby causing a reduction of the piezometric head by $h_f = S \times 1$. The foregoing may be symbolized by writing

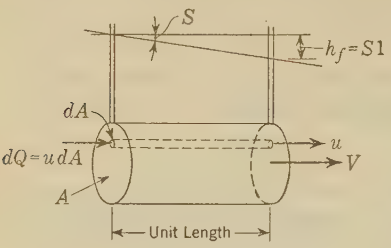

FIG. 3

$$W_o = (W_b)_o = (W_s)_o \qquad (5)$$

with the subscript b designating the process of withdrawal or the "borrowing" of the energy from the flow, and the subscript s indicating the spending of the energy on resistances.

The equality shown in Eq. 5 holds for bulk relations only. In fact, contrary to Eq. 5, the local values of w_b and w_s are generally not equal and do not balance each other. Indeed, the cardinal fact which dominates the entire energy loss mechanism is that the cross-sectional distribution of the local borrowing quantity w_b and the local spending rate w_s manifest altogether different, and in a sense opposite, outlines, and that for such reason the borrowing and the spending phases are necessarily linked by an intermediate process, the function of which is to transmit energy withdrawn at one part of the cross section to other parts, where the mechanism of energy exchange calls for its spending.

2. The Energy Withdrawing or Borrowing Function

The distribution of the local borrowing rate w_b is determined by noting that the energy withdrawn per unit time within an elementary tube dA (Fig. 3) is $\gamma\ S\ dQ = \gamma\ S\ u\ dA$, with u the local velocity. Dividing by the volume $dA \times 1$, one obtains the unit rate (that is, the work over a unit time interval, apportioned to a unit volume of fluid):

$$w_b = \gamma\, S\, u = -\frac{dp}{dx}\, u \left(\frac{\text{lb} \times \text{ft}}{\text{ft}^3 \times \text{sec}}\right) \qquad (6)$$

which shows that the spatial distribution of w_b follows the local velocity profile, copying the latter to the scale $\gamma\, S$ (curves BA and B_1A_1 in Figs. 2(a) and 2(b)).

In two-dimensional flow, for a block of unit width normal to the plane (Fig. 2), the total borrowed energy will be

$$(W_b)_o = \gamma\, S \int_0^{y'_o} u\, dy' = \gamma\, S\, U\, y'_o = \gamma\, S\, q_o = W_o \qquad (7)$$

and the average cross-sectional unit rate will be

$$w_o = \frac{W_o}{y'_o} = \gamma\, S\, U = -\frac{dp}{dx}\, U \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Furthermore, the aggregate energy amount "withdrawn" during a unit time from a partial cross-sectional block, such as that shown in Fig. 2(*a*) by the hatched area, is

$$\Big|W_b\Big|_0^{y'} = \int_0^{y'} w_b\, dy' = \gamma\, S \int_0^{y'} u\, dy' = \gamma\, S \Big|q\Big|_0^{y'} \ldots\ldots\ldots (9)$$

constituting the "cumulative" borrowing rate between the transverse limits, as indicated. The quantity $|q|_0^{y'}$, measured by the area OBba in Fig. 2(*a*), will be termed the "cumulative discharge." The corresponding quantities $|W_b|_0^{y'}$ are defined in Fig. 2(*c*) by curve $O_2b_2B_2$, with the coordinate $a_2\, b_2$ representing the area $O_1B_1b_1a_1$ under the part B_1b_1 of the local w_b-curve in Fig. 2(*b*). Obviously, for $y' = y'_o$, $|W_b|_0^{y'}$ equals W_o as defined in Eq. 7.

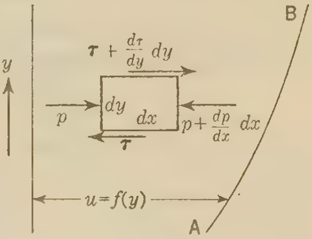

FIG. 4

Differential Form.—To express the energy borrowing process mathematically, note that for a two-dimensional element (Fig. 4), the resulting friction force is $\left(\tau + \frac{d\tau}{dy}\, dy\right) dx - \tau\, dx = \frac{d\tau}{dy}\, dx\, dy$. In uniform established motion frictional traction is in balance with the pressure resultant $\left(-\frac{dp}{dx}\, dx\right) dy$ which, apportioned to a volume unit, defines the equilibrium premises:

$$-\frac{dp}{dx} + \frac{d\tau}{dy} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

and

$$\frac{d\tau}{dy} + \gamma\, S = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10b)$$

The sign of the stress gradient $d\tau/dy$ is necessarily negative, for the friction resultant opposes the motion and compensates the positive pressure, or the gravity force, actuating the flow. The stress τ is essentially an internal agency. Action on the interfaces n and m of adjoining filaments (Fig. 5(*b*)) is equal in size, but opposite in direction. In determining which sign (plus or minus) is to be used for τ in Eqs. 10 and subsequently, one is guided by the direction of the traction on the face of a fluid block (Fig. 5(*a*)), terminated by the positive ordinate y. As is evident, the sign of τ will coincide appropriately with that of du/dy.

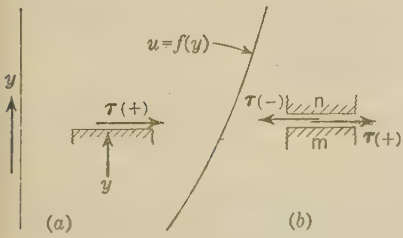

FIG. 5

The unit time work performed by friction on the element (Fig. 4) is $\frac{d\tau}{dy}\,dx\,dy\,u$, which is also a negative quantity to be compensated by the positive work of the pressure resultant $[(-\,dp/dx)\,dx\,dy\,u]$. The latter, in turn, is equal to the positive unit rate at which energy is withdrawn locally from the flow. Hence

$$w_b = -\frac{dp}{dx}u = -u\frac{d\tau}{dy} \qquad \text{(11)}$$

Note that, thus far, no limitations have been imposed on the particular nature of the stress-generating agencies. Therefore, Eq. 11 is quite general and will apply to all cases of two-dimensional flow, whether laminar or turbulent.

3. The Energy Spending Phase

It is expedient to consider first purely viscous (laminar) patterns, in which the mechanism is relatively simple. Indeed, in accord with Stokes,[3] the spending of energy has been identified with the work involved in viscous deformation. For two-dimensional motion (Fig. 6), when the element abcd is deformed into ab′c′d, during the time dt, the work done is the product of the shearing force $\tau\,dx$ and the displacement $du\,dt = \frac{du}{dy}\,dy\,dt$, and the local unit time rate of deformation work per unit volume is equal to

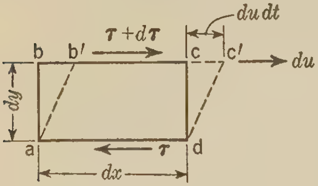

Fig. 6

$$w_s = \tau\frac{du}{dy} \qquad \text{(12}a\text{)}$$

or for laminar motion, with $\tau = \mu\frac{du}{dy}$:

$$w_s = \mu\left(\frac{du}{dy}\right)^2\left(\frac{\text{lb} \times \text{ft}}{\text{ft}^3 \times \text{sec}}\right) \qquad \text{(12}b\text{)}$$

Energy spending is thus concentrated in the region of high velocity gradients, which is principally near the walls of a conduit. In fact, at the axis, where $du/dy = 0$, the local loss is nil. The outline of the local energy spending curve w_s (curve $o_1\,s_1$, Fig. 2(*b*)) is thus "opposite" to that of w_b.

By analogy to Eq. 9, the cumulative spending rate—

$$\left|W_s\right|_0^{y'} = \int_0^{y'} w_s\,dy' \qquad \text{(13}a\text{)}$$

—is the aggregate work spent on resistances per unit time in the shaded block of Fig. 2(*a*), being represented in Fig. 2(*c*) by curve $O_2s_2S_2$, in which the coordinate a_2s_2 measures the area $O_1s_1a_1$ in Fig. 2(*b*). For the total reach $0 - y'_o$ obviously—

$$\left|W_s\right|_0^{y'_o} = \int_0^{y'_o} w_s\,dy' = \left|W_b\right|_0^{y'_o} = W_o \qquad \text{(13}b\text{)}$$

the cumulative curves W_b and W_s (Fig. 2(*c*)) terminating at the same point B_2. Naturally the areas $O_1B_1A_1$ and $O_1S_1A_1$ under curves w_b and w_s in Fig. 2(*b*) are equal. For any intermediary position, however, such as y', the cumulative values $|W_b|_0^{y'}$ and $|W_s|_0^{y'}$ shown in Fig. 2(*c*) by a_2b_2 and a_2s_2, do not coincide. Neither do the local values w_b and w_s represented in Fig. 2(*b*) by a_1b_1 and a_1s_1. Indeed in the central region of Fig. 2(*b*), between the axis and the intersection point M, the borrowed energy w_b exceeds the rate w_s at which energy is spent locally, whereas, nearer to the wall beyond M, the local energy rates, required for compensating the deformation work, exceed by far the comparatively small quantities w_b, available locally by borrowing. It follows, accordingly, that, between the "borrowing" and the "spending" phase, there must necessarily be an intermediate "transmittance" function, by means of which the excess of borrowed energy, available in the central region $0 - y'_M$, is conveyed to the wall zones to cover the requirements for spending.

4. The Energy Balance Equation

The local energy balance can be expressed by

$$w_b = w_s + w_t \quad \text{(14)}$$

with $w_t = w_b - w_s$ designating the local "transmittance energy rate." In the central reach, with $w_b > w_s$, w_t is positive, exemplifying the excess of energy subject to transmittance. In the wall region, where w_s exceeds the local supply of w_b, w_t becomes negative, signifying that the deficiency in locally borrowed energy is supplied from the store accumulated by transmittance from the central zone.

In Fig. 2(*b*), the (B_1T_1)-curve is obtained by subtracting O_1S_1 from B_1A_1, so that the local value for y' is $s_1b_1 = a_1t_1$. The resulting curve crosses the axis ($w_t = 0$) at the intersection ordinate y'_M, reaching its maximum negative value A_1T_1 at the solid boundary.

In Fig. 2(*c*), the curve $O_2t_MA_2$ features the corresponding cumulative quantity

$$|W_t|_0^{y'} = |W_b|_0^{y'} - |W_s|_0^{y'} \quad \text{(15)}$$

obtained by deducting $O_2s_2S_2$ from $O_2b_2B_2$. Obviously the coordinate $a_2t_2 = a_2b_2 - a_2s_2$ measures the area $O_1B_1b_1s_1 = O_1B_1t_1a_1$ in Fig. 2(*b*), indicating the aggregate excess energy, transmitted from the block toward the wall region. The maximum cumulative value a_Mt_M in Fig. 2(*c*), corresponding in position to the intersection point M of the local w_b-curve and w_s-curve, is the total excess energy, accumulated over the reach $0 - y'_M$ and made available through transmittance for spending in the wall zone. Obviously the coordinate a_Mt_M in Fig. 2(*c*) represents the positive excess area $O_1B_1MO_1$ in Fig. 2(*b*), equal to the negative deficiency area MS_1A_1M. The decline of W_t beyond point M signifies the gradual consumption in the wall region of the energy accumulated by transmittance. At the solid boundary the transmittance energy exhausts its functions. Accordingly, the cumulative W_t-curve goes through zero.

5. THE TRANSMITTANCE FUNCTION

To grasp the "transmittance" concept consider, in two-dimensional flow, an element A (Fig. 7) in its relation to the adjacent layers B and C (for clarity the interfaces are shown separated). In its motion relative to layer B, element A exercises a positive traction, performing work on layer B at the unit time rate of $\tau\,dx\,u$. In turn, element A receives work from layer C at the rate $(\tau + d\tau)\,dx\,(u + du)$. The resulting positive work performed by the element on the adjoining fluid, over what it receives, is $\tau\,dx\,u - (\tau + d\tau)(u + du)\,dx$ which, after omitting quantities of higher order of smallness, becomes

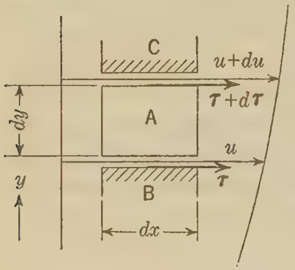

FIG. 7

$$-\,dx\,(\tau\,du + u\,d\tau) = -\frac{d}{dy}(\tau\,u)\,dy\,dx.$$

Dividing by the volume $dx\,dy$, the unit local rate of work transmitted to the adjacent fluid or the transmittance unit rate is

$$w_t = -\frac{d}{dy}(\tau\,u) = \frac{d}{dy}(-\,\tau\,u)\left(\frac{\text{lb}\times\text{ft}}{\text{ft}^3\times\text{sec}}\right)\dots\dots\dots\dots(16)$$

With Eqs. 11 and 12*a*, the local energy balance, Eq. 14, for two-dimensional laminar flow, takes the basic differential form

$$\underset{(w_b)}{-\,u\frac{d\tau}{dy}} = \underset{(w_s)}{\tau\frac{du}{dy}} - \underset{(w_t)}{\frac{d}{dy}(\tau\,u)}\dots\dots\dots\dots\dots\dots\dots(17)$$

Formally, by transposing the members, Eq. 17 may be changed into a complete differential of $\tau\,u$, which furnishes the starting point in the Stokes[3] analysis. However, to give Eq. 17 the proper physical significance, the members must be presented in the algebraic sequence as written. Note that, for established uniform motion, with $\frac{d\tau}{dy}$ necessarily negative (see Eq. 10), the quantity $-\,u\frac{d\tau}{dy} = w_b$ is positive. The quantity w_s is also positive, for in $\tau\frac{du}{dy}$ both members are of the same sign (see paragraph following Eqs. 10). The only quantity that changes in sign is the local transmittance rate w_t (Eq. 16).

Since w_t is the derivative of $-\,(\tau\,u)$, the latter must feature the cumulative transmittance rate W_t. In fact, for the block $0 - y'$ in Fig. 2(*a*), by Eq. 16,

$$\left|W_t\right|_0^{y'} = \int_0^{y'} w_t\,dy' = \int_0^{y'}\frac{d}{dy'}(-\,\tau\,u)\,dy' = \left|-\,u\,\tau\right|_0^{y'}\dots\dots(18)$$

represents the work done by the shaded block on the adjacent flow. The quantity $u\,\tau$ is negative, being the product of a positive velocity and a stress, which in terms of Fig. 8 is negative. Hence $(-\,\tau\,u)$ is positive, as indicated by curve $O_2t_MA_2$ in Fig. 2(*c*). The sign of the local value w_t, on the other hand, conditioned by the tangent to the W_t-curve, changes from positive to negative at point t_M.

As a matter of procedure, when dealing with the transmittance phase, it is expedient to start with the cumulative curve which, according to Eq. 18, is the product of the velocity curve (BA in Fig. 2(*a*)) and the stress line (OC in Fig. 2(*a*)). The maximum value of $-u\,\tau$ is reached at the intersection point M in Fig. 2(*b*) corresponding to $w_t = w_b - w_s = 0$. Point M is to be referred to as the "reversal point."

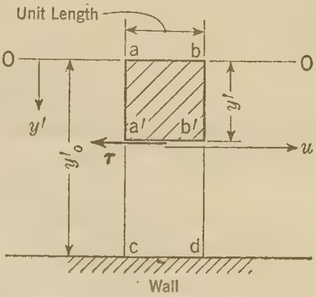

Fig. 8

Cumulative Energy Balance Equation.—The local equation (Eq. 17) is complemented for two-dimensional uniform flow by the cumulative expression

$$-\int_{y_1}^{y_2} u\,\frac{d\tau}{dy}\,dy = \int_{y_1}^{y_2} \tau\,\frac{du}{dy}\,dy - \int_{y_1}^{y_2} \frac{d}{dy}\,(\tau\,u)\,dy \,\ldots\ldots\ldots (19)$$

or, in relation to Fig. 2:

$$\int_0^{y'} \left(-\,u\,\frac{d\tau}{dy}\right) dy' = \int_0^{y'} \tau\,\frac{du}{dy}\,dy' + \Big|-\tau\,u\Big|_0^{y'} \,\ldots\ldots\ldots\ldots (20)$$

and

$$\gamma\,S\Big|q\Big|_0^{y'} = \int_0^{y'} w_s\,dy' \quad + \Big|-\tau\,u\Big|_0^{y'} \,\ldots\ldots\ldots\ldots (21)$$

all the members (see Fig. 2(*c*)) being positive.

Again, as in the case of Eq. 11 and Eq. 9, no restrictions were imposed on the nature of the stress-forming agency. The "transmittance" phase formulas, Eqs. 16 and 18, apply to all forms of flow, laminar or turbulent.

6. Mechanical Analogy

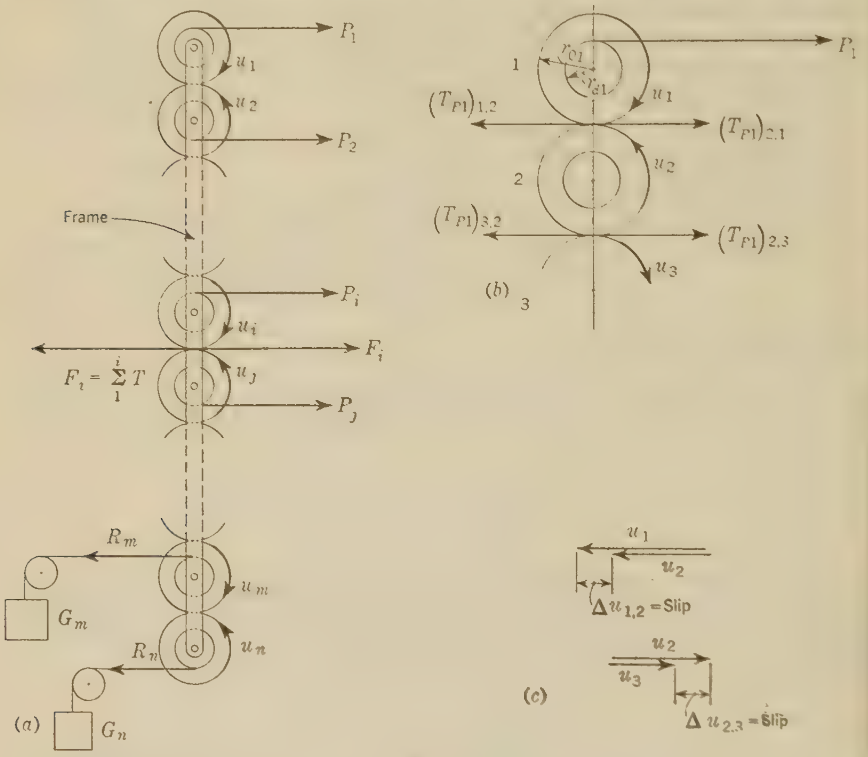
The essence of the "transmittance function" may be demonstrated by a mechanical model. In Fig. 9 a sequence of wheels is mounted on a common frame, with adequate friction between the contacting surfaces. Because of this friction, energy derived from the "driving" agencies $P_1, P_2, \ldots,$ is transmitted to where it is spent on the resistances R. Slipping between successive wheels will mean that, although the friction components such as $|T_{p1}|_{1,2} = P_1\,\frac{r_d}{r_e}$ and $|T_{p1}|_{2,1}$ (Fig. 9(*b*)) are equal, the velocities u_1 and u_2 differ, and thus only a part of the power $|T_{p1}|u_1$ derived from P_1 (namely, $|T_{p1}|u_2$) will be transmitted to the next wheel. The difference

$$|T_{p1}|u_1 - |T_{p1}|u_2 = |T_{p1}|\Delta u_{1,2} \,\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

represents a local mechanical "energy loss," an amount dissipated directly into molecular heat. The work done cumulatively by all the preceding driving agencies (P_1 to P_i) through wheel i is

$$F_i u_i = u_i \sum_1^i |T_p| \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

Of this work, however, only $F_i u_j$ is passed to the next wheel (j), the amount $F_i (u_i - u_j)$ being dissipated locally in the slip between (i) and (j). As a result, the "cumulative" energy balance for the wheel sequence is expressed by



P_1
u_1
u_2
P_2

Fig. 9

$$\sum_1^i |T_p| u = \sum_1^i (F \Delta u) + u_j F_i \ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Eq. 24 is analogous to Eq. 21. The friction resultant F_i is the simile of the stress τ in Fig. 8; $\sum_1^i |T_p| u$ is equivalent to the borrowed energy $|W_b|_0^{y'}$; the local "slip" loss (Eq. 22) compares with w_s in Eq. 12a; and $\sum (F \Delta u)$ in Eq. 24 is the analogue of $|W_s|_0^{y'}$. Finally, the "transmittance" member $u_j F_i$ is the equivalent, both in meaning and form, of the product $|\tau u| = |W_t|_0^{y'}$.

7. ENERGY "SPENDING" AND "DISSIPATION"

Loss of energy signifies ultimate dissipation into molecular heat. Energy borrowed from the flow changes its mechanical aspects and is transformed into thermal form. Such transformation is caused finally by viscous attrition, which enhances intermolecular activity. The ultimate dissipation develops thus on an ultramicroscopic molecular scale.

In laminar patterns the process of dissipation is assumed to coincide with viscous deformation (see Section 3). Mechanical energy spent in deformation is dissipated through transformation into heat in loco.

In turbulent flow, "spending" and "dissipation" coincide only partly. The term "spending" will be used to signify only the idea that energy borrowed from the flow has lost, irretrievably, its original flow form; and "dissipation," under all circumstances, will designate the ultimate "degradation" of mechanical energy into heat.

8. EXAMPLES OF ENERGY BALANCES IN LAMINAR MOTION

In some of the simpler laminar patterns, the stress and velocity quantities can be expressed in definite mathematical form, permitting an appraisal of the energy exchange process by purely analytical procedure.

(*a*) *Two-Dimensional Motion, Between Parallel Plates* (*Fig. 2*).—With $q_o = U\,y'_o$ as the unit width discharge between the axis and the wall, the local velocity is

$$u = u_M \left[1 - \left(\frac{y'}{y'_o} \right)^2 \right] \qquad (25)$$

in which $u_M = \frac{3}{2}\,U$. Furthermore,

$$-\frac{dp}{dx} = \frac{3\,\mu\,U}{(y'_o)^2} \qquad (26a)$$

and

$$\tau_o = -\frac{3\,\mu\,U}{y'_o} \qquad (26b)$$

Accordingly in Eqs. 7 and 8,

$$W_o = \frac{\tau^2_o\,y'_o}{3\,\mu} \qquad (27a)$$

and

$$w_o = \frac{\tau^2_o}{3\,\mu} \qquad (27b)$$

By elementary algebraic procedure (which is omitted), one arrives at the following dimensionless expressions for the local and cumulative unit rates that appear in Eqs. 17 and 20:

$$w_b = \tfrac{3}{2}\,w_o \left[1 - \left(\frac{y'}{y'_o} \right)^2 \right]; \qquad w_s = 3\,w_o \left(\frac{y'}{y'_o} \right)^2;$$

$$w_t = \tfrac{3}{2}\,w_o \left[1 - 3 \left(\frac{y'}{y'_o} \right)^2 \right] \qquad (28a)$$

and

$$\left|W_b\right|_0^{y'} = \tfrac{3}{2}\, W_o \left[\frac{y'}{y'_o} - \frac{1}{3}\left(\frac{y'}{y'_o}\right)^3\right]; \qquad \left|W_s\right|_0^{y'} = W_o \left(\frac{y'}{y'_o}\right)^3;$$

$$\left|W_t\right|_0^{y'} = \tfrac{3}{2}\, W_o \left[\frac{y'}{y'_o} - \left(\frac{y'}{y'_o}\right)^3\right] \qquad (28b)$$

The curves of these equations are plotted in Fig. 2.

(b) *Cylindrical Pipe.*—The Poiseuille relation,

$$-\frac{dp}{dx} = \frac{8\,U\,\mu}{r^2_o} \qquad (29)$$

with $R = \dfrac{r_o}{2}$ and $u_m = 2\,U$, leads to the following expressions:

$$\tau_o = -\frac{4\,\mu\,U}{r_o} \qquad (30a)$$

$$u = -\frac{\tau_o\,r_o}{2\,\mu}\left[1 - \left(\frac{r}{r_o}\right)^2\right] \qquad (30b)$$

$$W_o = \frac{\pi\,r^2_o\,\tau^2_o}{2\,\mu} \qquad (30c)$$

and

$$w_o = \frac{\tau^2_o}{2\,\mu} \qquad (30d)$$

In establishing the local rates, it is expedient to operate with an elementary cylindrical shell. For example, the work involved in the deformation shown in Fig. 10(*a*) results in the formula:

$$w_s = \tau\,\frac{du}{dr} \qquad (31)$$

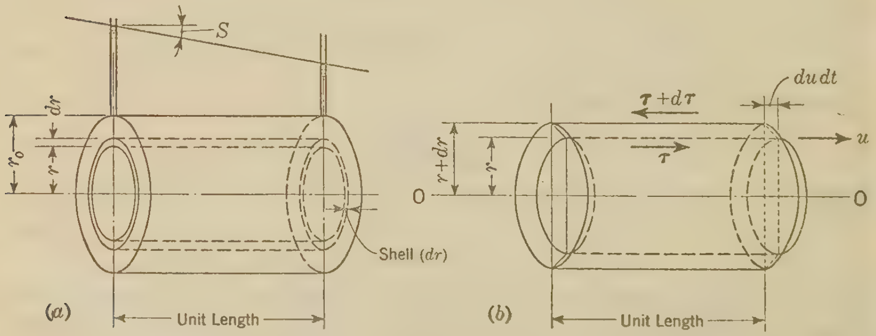

FIG. 10

The cumulative quantities should refer to an internal cylinder of radius r and unit length. The final dimensionless interrelationships are:

$$w_b = 2\,w_o\left[1 - \left(\frac{r}{r_o}\right)^2\right]; \quad w_s = 2\,w_o\left(\frac{r}{r_o}\right)^2; \quad w_t = 2\,w_o\left[1 - 2\left(\frac{r}{r_o}\right)^2\right] \qquad (32)$$

and

$$\left|W_b\right|_0^r = 2\,W_o\left(\frac{r}{r_o}\right)^2\left[1-\frac{1}{2}\left(\frac{r}{r_o}\right)^2\right]; \qquad \left|W_s\right|_0^r = W_o\left(\frac{r}{r_o}\right)^4;$$

$$\left|W_t\right|_0^r = 2\,W_o\left(\frac{r}{r_o}\right)^2\left[1-\left(\frac{r}{r_o}\right)^2\right] \quad \ldots\ldots\ldots\ldots\ldots (33)$$

The cumulative curves are reproduced for comparison, with the eventual turbulent outlines, in Fig. 11.

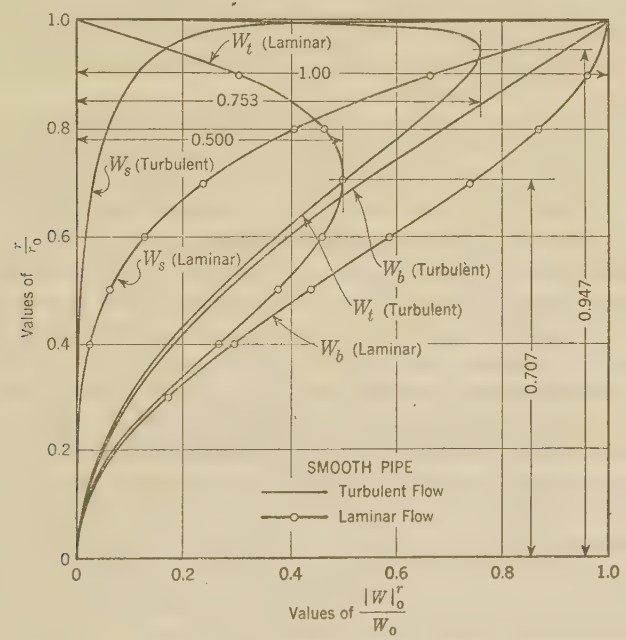

FIG. 11

9. TURBULENT FLOW PATTERNS

Since no restrictions were introduced to limit the expressions for the borrowing rate w_b (Eq. 11) and the transmittance rate w_t (Eq. 16), the equations are directly applicable to turbulent flow. Naturally, $\bar{\tau}$ will be the local Reynolds stress, and $\bar{u}$ the mean steady local velocity, whereas the quantities $\bar{w}_b = -\overline{u\frac{d\tau}{dy}}$ and $\bar{w}_t = \frac{d}{dy}(-\overline{\tau u})$ in Eq. 18 and Eq. 21 will feature the temporal average unit borrowing and transmittance rates. Because of the complex nature of turbulent motion, the spending rate w_s cannot be appraised a priori as in the case of Eq. 12*b* for laminar flow. On the other hand, from the standpoint of a complete differential, the mean local spending rate for two-dimensional turbulent flow—

$$\bar{w}_s = \bar{w}_b - \bar{w}_t = -\overline{u\frac{d\tau}{dy}} - \frac{d}{dy}(-\overline{\tau u}) = \overline{\tau\frac{du}{dy}} \ldots\ldots\ldots\ldots (34)$$

—must conserve the mathematical form of Eq. 12*a*. The w_s-quantity indicates the unit rate at which flow energy disappears under the action of agencies pertinent to the turbulent process.

Furthermore, the incumbent stress and velocity quantities cannot be derived from analytical expression as in Section 3, and must be taken directly from observation. Empirical data vary widely, depending on wall roughness, the Reynolds number, and other circumstances of the flow. Nevertheless, energy balances for turbulent flow display certain consistent characteristics, which happen to differ substantially from laminar outlines, and reflect the essence of turbulence dynamics. A typical example is given in Fig. 1, based on Göttingen data[8] relating to turbulent flow in a 10 cm smooth pipe, with $U = 876$ cm per sec, and $-dp/dx = 480$ g per cm^3.

By using in Eq. 34 the values for $\bar{\tau}$, $\bar{u}$, and $d\bar{u}/dy$ contained in the Nikuradse report, one computes the consecutive local unit rates $\bar{w}_b$, $\bar{w}_t$, and $\bar{w}_s$ as plotted in Fig. 1. The cumulative curves, obtained from the local outlines through step-by-step integration are presented, in dimensionless form, in Fig. 11, together with the comparative plottings for laminar flow.

The striking feature, characteristic of all turbulent patterns, is the intensive concentration of energy spending in a narrow zone next to the wall. For laminar flow the reversal point (M) is located at a distance 0.293 r_o from the wall, whereas in turbulent motion it is shifted to within 0.053 r_o from the solid boundary. Furthermore, over the reach $0-r_M$, constituting about 95% of the radial distance, relatively small amounts of energy are spent locally, the major part of the locally borrowed energy w_b being transmitted to the wall zone (r_M-r_o) where the accumulated energy is used to offset the unusually high requirements for spending. In fact, in Fig. 1, the calculated local values of w_s and w_t close to the solid boundary outreach by far the bounds of the figure. Accordingly, to appraise the phenomena, one must refer to the dimensionless cumulative diagram, Fig. 11, in which the specific characteristics of the energy exchange in turbulent motion become particularly lucid. Through the central region, the cumulative transmittance curve $|W_t|_0^r$ follows closely the borrowing outline $|W_b|_0^r$. In fact, over the reach $0-\text{M}$, in which more than 90% of the total energy W_o is withdrawn (borrowed) from the flow, the cumulative loss is less than 17%. By contrast over 83% of W_o is spent in the narrow (0.05 r_o) wall zone, where the quite insignificant local borrowing accounts for less than 8% of W_o. In other words, the concentrated "spending" in the wall zone takes effect principally at the expense of the transmitted energy.

One should infer, from the shape of the turbulent curves, that the energy exchange in the central zone and in the border zone must be actuated by entirely different physical factors. Conventionally, in fact, one may accept the premise that the "reversal radius" r_M separates the fluid body into two parts, of which the central cylindrical block $(0-r_M)$ will be called the "transmittance region," whereas the annular space near the wall (r_M-r_o) will be referred to as the "conversion zone" (see Section 12).

10. The Mechanics of Turbulent Friction Loss

Turbulent motion is characterized by the presence, in the flow, of an array of eddies that "swarm" in an apparently unpredictable manner and at each instant add their rotary components to the respective local velocities of the main motion. The ever-fluctuating turbulent pattern, superimposed over the steady flow structure, devolves thus from the composite action of a multitude of individual vorticing units.

The energy of a fluid in turbulent motion is compounded from the energy of the main flow, characterized locally by the energy head

$$e = z + \frac{p}{\gamma} + \frac{u^2}{2g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

and by the kinetic energy of the superimposed turbulent structure. The latter, being essentially the composite energy of the swarming eddies, is defined locally by value of $\rho\overline{(u'_t)^2}/2$, where

$$\overline{(u'_t)^2} = \overline{(u')^2} + \overline{(v')^2} + \overline{(w')^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

is the temporal mean square of the local turbulent fluctuations in the three coordinate directions.

A statistically permanent state of turbulence implies the maintenance of a steady average eddying structure, which means that new vorticing units must be generated incessantly to replace the eddies "extinguished" by attrition in the course of their swarming motion through the flow. The generation of eddies infers that they are endowed with energy, which must necessarily be supplied from the energy store of the main flow. Indeed, the primary characteristic of the turbulence mechanism is that energy, at an apportioned rate, is withdrawn continuously from the main flow, and is "invested" into turbulent eddies, such "investment" involving the conversion of the borrowed flow energy into vortical eddying form. The generation of turbulence is thus synonymous with the producing of the turbulent eddies. Turbulent energy, manifest in turbulent fluctuations, is originally flow energy, transformed into vortical form. By its very nature the conversion is an irreversible process, because energy, once converted into eddies, can by no means be restored to the flow. For such reason, so far as the main flow is concerned, when energy withdrawn from the latter is "spent" in the creation of turbulent eddies, it may be considered "lost." Actually the "lost" flow energy reappears, at least partially, in the converted vortical form, which animates the turbulent structure. The final dissipation of such energy takes place after conversion, and at the time when, in the course of swarming, the mechanical energy with which the eddies were initially endowed is transformed (degraded) through viscous attrition into molecular heat.

According to prevailing views, the generation of turbulent eddies in established "friction" flow is largely concentrated in a narrow zone near the solid boundaries of a conduit. L. Prandtl[9] most appropriately qualifies his definition of such boundary zones as "the actual eddy producing mill," whereas the "spreading" of the eddies toward the central region is said to take place "rather passively." Indeed, the faculty of generating eddies seems to be a specific property, inherent to discontinuity "vortex sheets" that are subjected to exexcessive strain. Whenever they are overstrained, such vortex sheets, or layers of concentrated vorticity, become unstable; and after passing through a cycle of ever-increasing self-induced pendulations, they terminate by eventually "curling," or being "rolled" up, into "chains" of eddies or a sequence of intermittent lumps of condensed vorticity. The process is comparatively well defined in the case of "free" discontinuity sheets caused in the interior of a fluid by "separation." As illustrated by Fig. 12, the formation of the eddies, in such instances, may be observed visually. (In these observations by L. Schiller and his associates,[10] the original vortex sheet was made visible by the injection of dye.) In friction flow, past solid surfaces, the reach of excessive strain is supposedly associated with the boundary zone near the wall where, over an exceedingly thin "sublayer," the velocity drops abruptly to zero. Thus far, existing techniques have not permitted the direct observation of turbulence generation near solid boundaries. There is ample indirect evidence, nevertheless, pointing to the essential similarity of the case with that of "free" separation sheets. (For further information in this generally still obscure and mysterious realm, the reader is referred to the general literature in this field.)[11,12]

[11] "Fundamentals of Hydro- and Aeromechanics," based on lectures of L. Prandtl, by O. G. Tietjens, translated by L. Rosenhead, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1934, p. 222.

[12] "The Formation of Vortices from a Surface of Discontinuity," by L. Rosenhead, *Proceedings*, Roya Soc. of London, Series A, Vol. CXXXIV, 1931-1932, pp. 170-192.

The pivotal phase in the sequence of events is conversion, in the course of which turbulent eddies are generated incessantly in the conversion zone. The preconversion phases (Section 9) deal with energy of the main flow. As illustrated by Fig. 11, flow energy is borrowed largely in the middle regions of a cross section and through transmittance is concentrated near the wall, being made available for conversion. In the post-conversion phase, the remainder of the originally borrowed mechanical energy is in turbulent eddying form. Individual vorticing units, assumedly of the Fig. 12 type, are "cast off" or "shed" from the generating zone into the adjacent flow, and as the eddies spread across the conduit on generally oblique paths, their initial energy is gradually dissipated into molecular heat. The possible interreaction between a vortical unit and the surrounding flow is illustrated by Fig. 13. On the top of the eddy, the rotary component u_t adds to the local velocity u_1, whereas at the bottom it subtracts from u_2. The resulting difference in velocity heads results in a transverse pressure differential, prompting the eddy to move in a crosswise direction away from the wall. The "shedding" of the eddies from the seat where they are originally generated may be thus considered as caused by a "Magnus effect," similar in nature to the "lift" of an airfoil or to the propelling force in a rotor ship. The transverse motion, prompted by such induced pressure forces, combines with the drag of the current which tends to wash the eddy downstream.

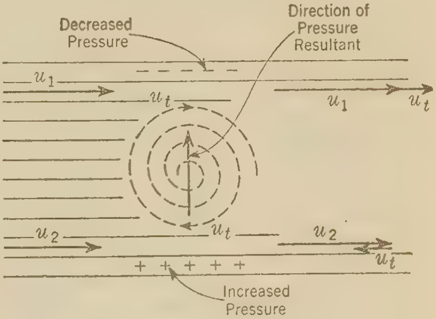

FIG. 13

The transformation of the mechanical vortical energy into thermal state is by viscous attrition. Indeed, the local dissipation rate may be expressed in terms of the Taylor formula[13,14]

$$w_d = \kappa\,\mu\,\frac{\overline{(u'_t)^2}}{\lambda^2} \qquad (37)$$

in which κ is a numerical coefficient, and λ is a characteristic dimension of the small-size eddying group in the vorticing composite. In an eddying composite, energy is dissipated in large part through the instrumentality of the smallest size eddies, or the so-called micro-turbulence fringe. Large eddies, in turn, are responsible for producing the turbulent stress and more generally for actuating convective transfer. The large eddies, accordingly, enhance turbulent diffusion, and their direct contribution to dissipation is comparatively small. It is surmised that, in the course of swarming, the larger eddies are subject to a process of "grinding," by which they are split continuously into smaller

units. G. I. Taylor has treated this general subject and has presented a bibliography.[15,16]

The sequence involved in the mechanism of turbulent friction loss is presented schematically in Fig. 14. Of the total borrowed flow energy W_o, the amount W_c is made available in the conversion zone. Energy W_c is less than W_o by about the cumulative loss $\left|W_s\right|_0^M$ in the transmittance zone. In the absence of adequate experimental knowledge, one cannot judge as to what part of W_c is dissipated locally in the course of conversion. No doubt, however (see Section 12), the conversion process is accompanied by a considerable inherent loss. The latter, in Fig. 14, is symbolized by the ordinate CB. The remaining W (turbulent) = BA represents the part of the original W_o which survives conversion and which, liberated in eddying form, furnishes the "animating" source by which the state of turbulence, as revealed in its outward manifestations, is actuated and maintained. Finally, curve B′ − O portrays the gradual extinction of the eddying structure or the transverse "decay of turbulence," by the dissipation of mechanical energy into molecular heat (Eq. 37).

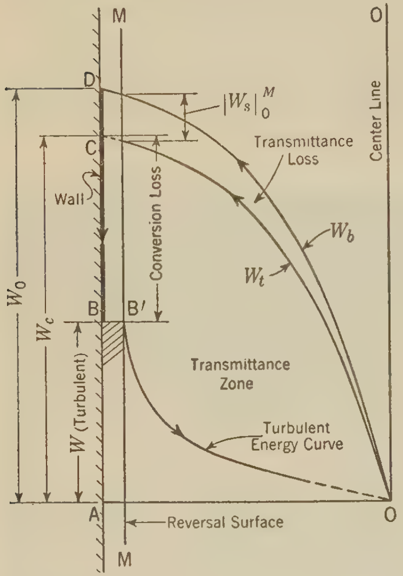

FIG. 14

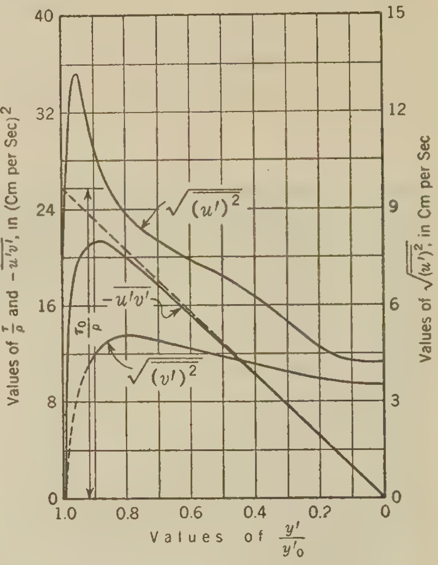

FIG. 15

An exact quantitative appraisal of the sequence would require experimental data of the type presented in Fig. 11 complemented by detailed records showing reliably, in three-dimensional fashion, the distribution of turbulence intensity across the cross section. No complete data of this nature are available. Fig. 15 shows, in part, the distribution of the axial and transversal turbulent com-

ponents in a rectangular conduit.[17] As seen, the axial intensity of turbulence, measured by the root mean square $\sqrt{\overline{(u')^2}}$, reaches a sharp maximum in the immediate proximity of the wall, readily corresponding to the outward boundary of the conversion region. From there on, the intensity recedes rapidly toward the center of the conduit.

11. EFFECT OF WALL ROUGHNESS

A basic premise underlying the Prandtl-von Kármán turbulence theory is the organic link between the stress structure and the shape of the velocity curves.[18] Experiments reveal that, if the roughness of the walls of a given conduit of radius r_o is modified consecutively, the flow Q being adjusted to yield in each instance the same resistance slope S, and hence the same stress structure (Eqs. 3 and 4), then the respective velocity profiles in the central "turbulent"

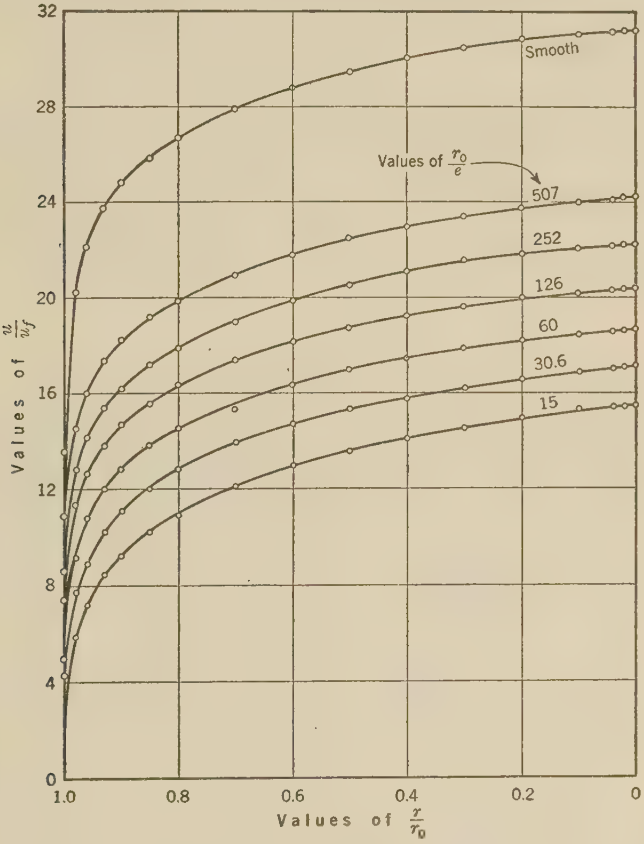

FIG. 16

---

[17] "Beitrag zum Turbulenz Symposium," by L. Prandtl, *Proceedings*, 5th International Cong. for Applied Mechanics, Cambridge, Mass., John Wiley & Sons, Inc., New York, N. Y., 1939, p. 345.

[18] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 1936, p. 55.

zone will follow identically shaped parallel outlines (see Fig. 16). In fact, if the observed velocities were plotted from a common maximum point, the curves for the different roughnesses would coincide over the greater part of the cross section, the eventual differences becoming apparent only in the comparatively narrow boundary zones.[19]

In regard to the energy balances, an unvarying resistance slope makes the total energy loss $W_o = \gamma\, Q\, S$ proportional to the respective average velocity. Furthermore, congruent velocity profiles signify that the velocity gradients $d\bar{u}/dy$ in the central turbulent zone are the same for all degrees of roughness, and that therefore in such a zone the local losses w_s by Eq. 34 will be identical in all instances. The same obviously will pertain to the cumulative values $|W_s|_0^r$, as long as one does not transgress to a point where the velocity profiles cease to be congruent.

The inescapable conclusion is that the spending of energy in the transmittance region, the latitude of which may be broadly said to coincide with the central "turbulent" zone, is solely dependent on the stress structure, and that the spending process in the transmittance zone is implemented by the same agencies that shape the stress patterns (see Section 12). Deducting the common loss in the transmittance zone $|W_s|_0^M$ from the respective W_o-quantities (which are proportional to the varying bulk velocities), one obtains the energy quantities

$$W_c = W_o - |W_s|_0^{r_M} = \gamma\, S\, A\, U_. - |W_s|_0^{r_M} \ldots\ldots\ldots\ldots (38)$$

which for one or another degree of wall roughness are to be spent in the conversion (boundary) zones. Paradoxically, the largest value of W_c occurs in the case of a smooth surface. The rougher the walls, the smaller the value of W_o and therefore of W_c, always assuming an unvarying resistance slope.

The relation between the velocities and the wall roughness is summarized in terms of dimensionless ratios in Fig. 16.[20,21] Velocity profiles for pipes of different size and different relative roughness are plotted versus r/r_o in terms of the so-called "friction velocity"

$$u_f = \sqrt{\frac{\tau_o}{\rho}} = U\sqrt{\frac{c_f}{2}} = U\sqrt{\frac{f}{8}} \ldots\ldots\ldots\ldots\ldots\ldots (39)$$

c_f is the conventional turbulent friction factor in

$$\tau_o = \rho\, c_f\, \frac{U^2}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40a)$$

and f is the coefficient of friction in the pipe formula

$$S = \frac{f}{D}\frac{U^2}{2\,g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40b)$$

---

[19] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 1936, p. 56.

[20] "Strömungsgesetze in rauhen Rohren," by J. Nikuradse, *Forschungsheft*, Verein Deutscher Ingenieure, No. 361, 1933, p. 8.

[21] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press., Princeton, N. J., 1936, p. 97.

(Fig. 16 refers to flow in pipes ranging from 1 in. to 4 in. in diameter, D, the walls of which were roughened artifically by uniform sand grains of different sizes. The inverse ratios of relative roughness r_o/e are the quotients of the radius of the pipe by the grain size. The shape of the roughness grains is assumed to be "similar.")

In the central reaches the velocity profiles in Fig. 16 show congruence in outline, which is to be anticipated, since reducing the velocities to the term u_f is equivalent to referring the velocity pattern to a common stress structure. Since the curves are dimensionless and imply no restrictions with regard to the absolute dimensions of the conduit or the size of the roughness grains, the diagram typifies universal velocity patterns for the "standard" Göttingen sand roughness type. Accordingly the experimental data, underlying Fig. 16 and explicitly tabulated in the Göttingen Report,[22] may be used for disclosing, in equally generalized manner, the comparative features of the internal energy exchanges for pipes of the respective relative wall roughnesses. In fact, in terms of the "friction" velocity (Eq. 39) the pressure gradient is

$$-\frac{dp}{dx} = \gamma S = \left|\frac{2\,\tau_o}{r_o}\right| = \frac{2\,\rho\,u^2_f}{r_o} \qquad (41)$$

and the total energy loss and the average spending rate are

$$W_o = 2\,\pi\,r_o|\tau_o|U = 2\,\pi\,r_o\,\rho\,u^3_f\,\frac{U}{u_f} \qquad (42a)$$

and

$$w_o = \frac{W_o}{\pi\,r^2_o} = \frac{2\,\rho\,u^3_f}{r_o}\,\frac{U}{u_f} \qquad (42b)$$

The analysis may be confined to the cumulative quantities only. In expressing borrowed energy, replace the pressure gradient in w_b (Eq. 11) by Eq. 41; substitute $u_f\,\dfrac{u}{u_f}$ for u; and $r_o\,\dfrac{r}{r_o}$ for r. Then:

$$\Big|W_b\Big|_0^r = -\frac{dp}{dx}\int_0^r 2\,\pi\,r\,u\,dr = 2\,\pi\,r_o\,\rho\,u^3_f\int_0^{r/r_o} 2\,\frac{r}{r_o}\,\frac{u}{u_f}\,d\left(\frac{r}{r_o}\right) \qquad (43a)$$

The subintegral quantity is twice the static moment, with regard to the axis, of the area bounded by the velocity curve u/u_f in Fig. 16, between the limits 0 and r/r_o.

The cumulative transmittance rate, for a cylinder of radius r, takes the form

$$|W_t|_0^r = 2\,\pi\,r(-\,\tau\,u)_0^r = 2\,\pi\,r_o\,\rho\,u^3_f\left[\left(\frac{r}{r_o}\right)^2\frac{u}{u_f}\right] \qquad (43b)$$

in which the quantity in brackets equals the product of the squared relative distance (r/r_o) in Fig. 16 by the corresponding u/u_f.

After the curves for the borrowing and for the transmittance phases are computed and plotted, the cumulative spending rate

$$|W_s|_0^r = |W_b|_0^r - |W_t|_0^r \qquad (44)$$

---

[22] "Strömungsgesetze in rauhen Rohren," by J. Nikuradse, *Forschungsheft*, Verein Deutscher Ingenieure, No. 361, 1933, p. 12.

is determined by subtracting the outline for W_t from that of W_b. Eqs. 43*a* and 43*b* contain the quantity $2\,\pi\,r_o\,\rho\,u^3_f$ which, with Eq. 42*a*, becomes equal to $W_o \frac{u_f}{U}$; and this value is used as a reference basis in plotting the curves. The resulting diagrams (Fig. 17), of which Fig. 17(*b*) is reduced to dimensionless terms, are most instructive. The reversal M point is closest to the boundary in the instance of a smooth wall. As the roughness increases, the transverse latitude of the conversion zone also grows; in the extreme case for which

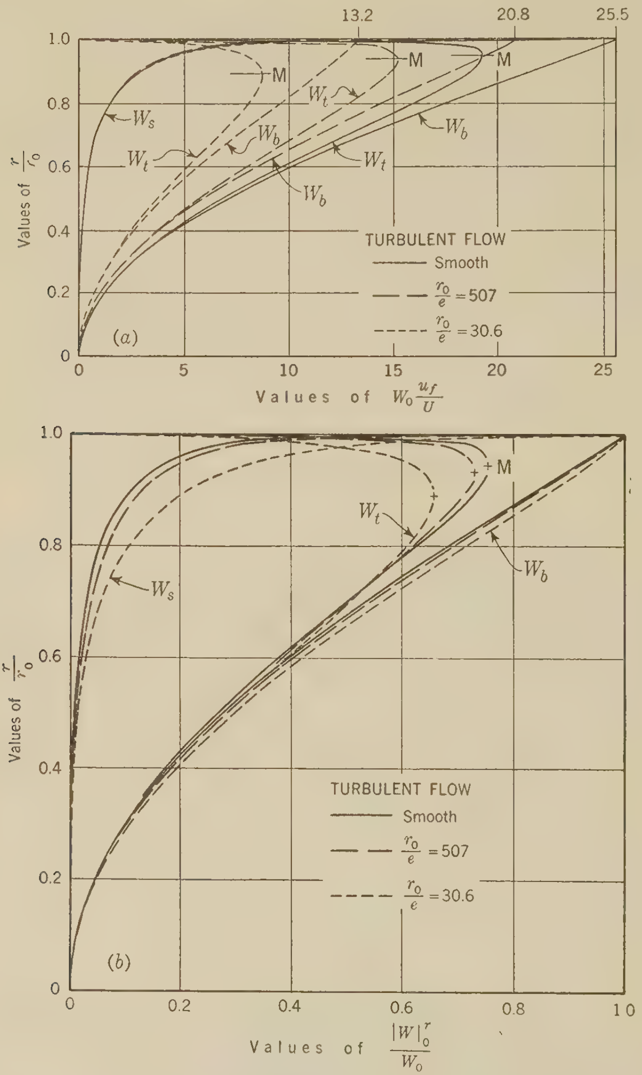

Fig. 17.—Cumulative Energy Balance in Turbulent Flow in Pipes

$r_o/e = 30.6$, it is about 10% of r_o. As expected, within the transmittance zones, the cumulative loss is shown by a single outline. In fact, W_s shows no appreciable discrepancies, up to the closest observable range ($r = 0.98\, r_o$) from the wall, which means that conversion is actually concentrated in a very narrow layer, the thickness of which is only a small portion of the reach $r_M - r_o$. In the case of the smooth pipe, the energy destined for conversion constitutes nineteen $\left(W_e \frac{u_f}{U}\right)$-units of a total of 25.5, or about 75%. For the roughest surface, the corresponding energy is 8.75 units of a total of 13.2, or 66%. On the whole, however, the dimensionless curves of Fig. 17 are a rather compact set, suggesting that, over a great variety of circumstances, energy exchange patterns in turbulent flow exhibit generically similar characteristics.

12. THE NATURE OF THE ENERGY SPENDING PROCESS

In treating the factors that shape the stress structure in turbulent patterns, it is customary to distinguish between the "viscous" and the "turbulent" agencies. Thus in

$$\tau = \mu \frac{d\bar{u}}{dy} - \left| \rho\, l^2 \left(\frac{d\bar{u}}{dy} \right)^2 \right| \qquad (45)$$

the quantity between the vertical bars represents (according to Prandtl) the effect of the Reynolds "momentum transfer," produced by transverse turbulent mixing.[23] One could expect that the same agencies would be instrumental in determining the manner in which energy, withdrawn from the flow, is "spent" in the different regions of a cross section.

Conversion Zone.—Paradoxically the function of conversion, which was said to be synonymous with the generation of turbulence (Section 10) reverts primarily to viscous action. The "casting off" of eddies appears to be the ultimate phase in a sequence of cyclic transformations suffered by viscous vortex sheets subjected to excessive strain. The intensity of the latter is affected by the fact that, in the immediate vicinity of the wall, the boundary stress by Eq. 40*a*, corresponding in magnitude to the general turbulent structure, must be "carried across" the laminar sublayer by viscous shear. This results in an extremely sharp velocity gradient

$$\left(\frac{du}{dy} \right)_{y \to 0} = \left| \frac{\tau_o}{\mu} \right| = \frac{\rho\, u^2{}_f}{\mu} = \frac{c_f}{\nu} \frac{U^2}{2} \qquad (46)$$

which exceeds by hundreds, if not by thousands, the ordinary "laminar" strain underlying the appraisal of deformation work in Fig. 6. The extreme character of the ensuing deformation is suggested by Fig. 18(*a*); Fig. 18(*b*) shows in turn the ultimate phase of the cyclic transformation, with the original viscous sheet rolled up into interspaced eddies, ready to be detached and "cast off" into the main flow.[11,12]

The deformation work involved in the initial straining of the vortex sheet can be appraised by means of Eqs. 12. Indeed, it is viscous deformation work, in the first instance, which absorbs the energy made available through transmittance and is destined for conversion.

---

[23] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 1936, p. 44.

In the case of laminar motion, as stated in Section 7, all the deformation energy is dissipated in loco. In the generation of turbulence, on the other hand, part of the energy absorbed in deformation reappears in converted eddying form. Such an apparent difference in behavior can be explained at present only by hypothetical conjecture. The answer may lie in the dimensional scales of the respective phenomena. In laminar motion the action of viscosity, when one layer slides past another, is on a molecular scale. Any eddies formed in the interface between layers, which constitute the vortex sheets, would be of ultramicroscopic size and therefore (Eq. 37) would become subject to a most intensive dissipative action. As a result the tiny "molecular" eddies become extinguished in loco without having a chance of breaking away as individual units.

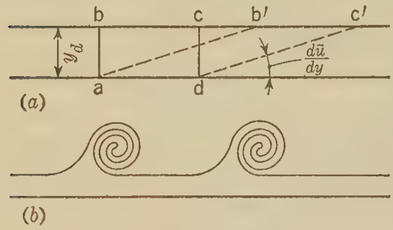

Fig. 18

By contrast in the boundary zone of Fig. 18, the pendulations, induced by the instability of the initial sheet, result in concentrated lumps of vorticity of a molar, macroscopic size. In accordance with Eq. 37, the very scale of the eddies militates against instantaneous dissipation in loco, giving the energy quantums invested into the vorticing units a certain period of life, before they are "ground up," in the process of swarming, and finally extinguished.

The nature of the phenomena involved in the deformation work during the conversion may be appraised quantitatively. Since, with Eq. 2, the energy loss in Eq. 4 equals $\frac{\tau_o}{R} A\, U = \tau_o\, P_w\, U$ the energy available in the conversion zone, per unit of wall surface, may be expressed as

$$\frac{W_c}{P_w} = |\alpha\, \tau_o\, U| \qquad (47)$$

in which $\alpha = W_c/W_o$, a fractional coefficient on the order of 0.8. The rate of deformation work per unit volume in the strained boundary vortex sheet (Fig. 18(*a*)), appraised on the basis of Eq. 12*b*, is

$$\mu \left(\frac{du}{dy}\right)^2_{\to 0} = \mu \left(\frac{\tau_o}{\mu}\right)^2 = \frac{\tau^2_o}{\mu} \qquad (48)$$

Since deformation work at such rate is called to absorb the energy amount indicated by Eq. 47, the volume of the deformable layer (Fig. 18) must measure transversely

$$y_d = \frac{\alpha\, \tau_o\, U}{\frac{\tau^2_o}{\mu}} = \frac{\alpha\, \mu\, U}{\tau_o} = \frac{\alpha\, U\, \nu}{u^2_f} = \frac{\nu}{u_f}\, \alpha \sqrt{\frac{2}{c_f}} \qquad (49a)$$

Eq. 49a acquires a special significance when reduced to the terms of the so-called "friction distance" similitude parameter[24]

$$y_f = \frac{y\, u_f}{\nu} \quad\quad (49b)$$

For smooth surfaces, flow is wholly shaped by the aforesaid similitude parameter. Indeed the thickness of the laminar sublayer δ corresponds to a parametrical value of $y_{f\delta} \approx 8$, and the transverse latitude of the entire boundary zone, between the wall and the fully turbulent inner region, to $y_{fb_z} \approx 30$. The in-between reach $(8 < y_f < 30)$ constitutes a "transitory" zone. The physical significance of this zone, which lies outward from the strictly laminar sublayer and inward from the turbulent reach where flow is fully "infested" with eddies, would be that of a turbulence generating region, within which eddies are formed and from which they are intermittently released.

In Eq. 49a, the thickness of the deformable viscous sheet, required for absorbing the convertible energy W_c in Eq. 47, corresponds to

$$y_{fd} = \frac{y_d\, u_f}{\nu} = \alpha \sqrt{\frac{2}{c_f}} \quad\quad (50a)$$

For smooth pipes, with c_f between 0.0015 and 0.0025, and $\alpha \approx 0.8$,

$$y_{fd} = 0.8 \sqrt{\frac{2 \cdot 10^4}{15 - 25}} \approx 29 - 23 \quad\quad (50b)$$

commensurate with the thickness of the boundary zone. About a third of y_{fd} in Eq. 50b is assignable to the laminar sublayer, in which dissipation occurs in loco in accord with Eq. 12b. This leaves about two thirds, or slightly more, of W_c to be spent in the transitory zone for actual conversion into turbulence. Again a portion of this remaining energy must be dissipated locally in the course of rolling up the eddies, which means that only the smaller part of the flow energy W_c, first available in the conversion zone, finally reappears in turbulent eddying form.

Transmittance Losses.—In the central "turbulent" region the contributions of the viscous shear $\mu \dfrac{d\bar{u}}{dy}$ in Eq. 45 are practically nil. Equally negligible are the energy losses $\mu \left(\dfrac{d\bar{u}}{dy} \right)^2$, computed from Eq. 12$b$ by using for $\dfrac{d\bar{u}}{dy}$ the observed local values of the main flow. It would be natural, on the other hand, to gage the w_s-rates, as they actually appear in Figs. 17 and 11, in terms of the same "mixing" agencies, which shape the "turbulence" stress. For example, one may appraise the "mixing action" in the "Prandtl" manner,[25] assuming that a molar element m_1 (Fig. 19(a)), initially belonging to filament (1) and traveling at a velocity u_1, is moved by a transverse impulse over a "mixing distance"

---

[24] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 1936, pp. 43 and 47.

[25] *Ibid.*, p. 40.

l' into filament (2), where it becomes "embedded" acquiring the velocity u_2 and suffering a velocity change:

$$|\Delta u| = |u_1 - u_2| = \left| l' \frac{d\bar{u}}{dy} \right| \tag{51}$$

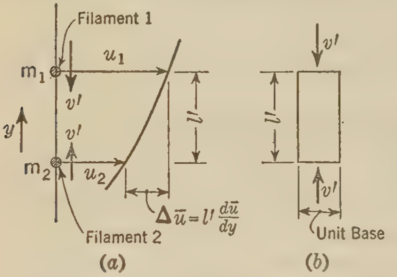
Using the latter for u' in the expression for Reynolds "momentum transfer"—

$$\tau = \rho \left| \overline{u' v'} \right| \tag{52}$$

—assuming further that the transverse exchange intensity v' is of the same order and indeed is proportional to u'; and finally absorbing the proportionality factor by a proper adjustment of the mixing scale, one ends with

$$\tau = \rho\, l' \frac{d\bar{u}}{dy} \times C\, l' \frac{d\bar{u}}{dy} = \rho\, l^2 \left(\frac{d\bar{u}}{dy} \right)^2 \tag{53}$$

in which l is the Prandtl "mixing length" and C is the proportionality factor.



(a) (b)

FIG. 19

Physically the change in the velocities due to the embedment is caused by viscous attrition that occurs during abrupt transverse displacements. Circumstances, in fact, are analogous to the case of impact with lasting constraints, as in the familiar instance of "inelastic bodies." Energy losses for the latter are expressed by the Carnot principle,[26] according to which the loss suffered by an element of mass m, the velocity of which is altered from u_1 to u_2, equals $m(u_1 - u_2)^2/2$.

In applying the Carnot principle to the block in Fig. 19(b), the aggregate mass exchanged per unit time across the upper and lower base is $2\,\rho|v'|$, and the lost velocities equal $\left| l' \frac{d\bar{u}}{dy} \right|$, thus making the energy loss (by substituting Eq. 53):

$$2\,\rho|v'|\,\frac{1}{2}\left(l' \frac{d\bar{u}}{dy} \right)^2 = \rho\, l^2 \left| \frac{d\bar{u}}{dy} \right|^3 l' = \tau \frac{d\bar{u}}{dy}\, l' \tag{54}$$

Dividing by the volume $l' \times 1$, one obtains the unit rate:

$$w\,(\text{Carnot}) = \tau\,(\text{turbulent}) \frac{d\bar{u}}{dy} = w_s \tag{55}$$

revealing that the "Carnot" loss, involved in the "mixing activity," is expressed by the same relation, which, in Eq. 34, determines the spending rate. In this light the quantity w_s (Eq. 34) in the central turbulent transmittance region, may be qualified as constituting a "mixing" or a "stress-forming" loss. Note, in particular, that the velocities altered through attrition in transverse embedment are those of the main flow. Physically, therefore, mixing action appears to imply a direct dissipation of flow energy into molecular heat, arising from the transporting action of the large-size eddies. Such convective transfer of molar masses by the large vorticing units constitutes specifically the function of so-called "turbulent diffusion." Accordingly, the local loss of flow energy in the inner turbulent zone of a cross section, determined by Eq. 55, is a dissipation rate attendant upon "turbulent diffusion" and dependent in magnitude on the intensity of the latter.

which, with linear stress distribution, makes the unit shearing force in a plane a′b′c′d′ equal to

$$\tau = \tau_o \frac{y'}{y'_o} = \gamma S y' \quad \text{(57)}$$

In other words, the stress diagram τ is the product of the multiplier γS by the depth. The observed velocity profile $u = f(y')$ in Fig. 20(*b*) serves for plotting the cumulative discharge curve OD in Fig. 20(*c*), the ordinates of which (a″b″) for y' represent the volume of flow:

$$|q|_0^{y'} = \int_0^{y'} u\, dy' = y' U_{y'} \quad \text{(58)}$$

as indicated by the shaded area ABb′a′ in Fig. 20(*b*).

In the light of Eqs. 7 and 9, whereas the total flow energy borrowed and spent in the unit prism of Fig. 20(*a*) is

$$W_o = \gamma S |q|_0^{y'_o} = \gamma S y'_o U \quad \text{(59a)}$$

the cumulative borrowed quantity—

$$|W_b|_0^{y'} = \gamma S |q|_0^{y'} \quad \text{(59b)}$$

—is directly represented by the cumulative discharge curve OD in Fig. 20(c) to the scale $\frac{W_o}{\gamma\, S}$. Likewise, with Eqs. 18 and 57, the energy rate cumulatively transmitted from the block y' deep across a′b′c′d′ is

$$|W_t|_0^{y'} = -|\tau\, u|_0^{y'} = \gamma\, S\, y'\, u \qquad (60)$$

represented (except for a common multiplier $\gamma\, S$) in Fig. 20(c) by the curve OMC. The ordinates of this curve constitute the product of the local velocity by the respective depth, or the respective moment of the local velocity vector with regard to the surface of the streaming. The energy-spending curve W_s is obtained by subtracting, point by point, W_t from W_b, making

$$|W_s|_0^{y'} = \gamma\, S\, (|q|_0^{y'} - y'\, u) = \gamma\, S\, y'\, (U_{y'} - u) \qquad (61)$$

In Eq. 61 the quantity in parentheses represents the difference between the partial mean velocity $U_{y'}$ for the block (average ordinate of the shaded figure), and the local velocity for y' (ordinate a′b′ in Fig. 20(b)).

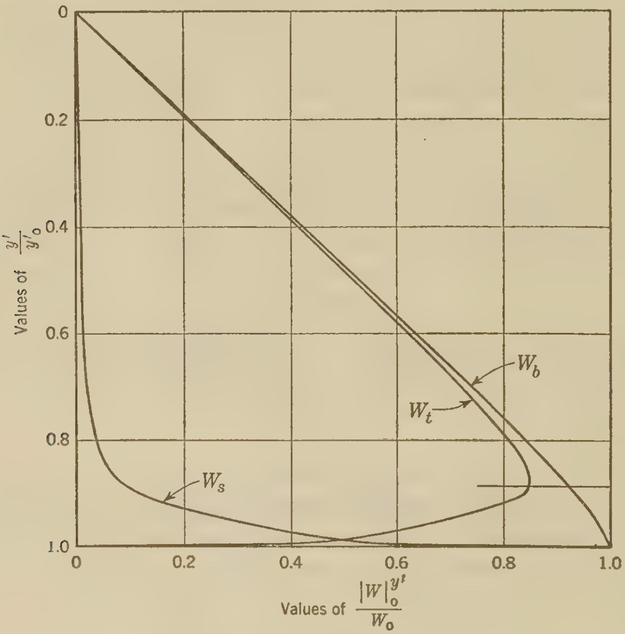

FIG. 21

The particular velocity profile, presented in Fig. 20(b), is for a large southern river during a moderately high stage. With a slope of 0.35 ft per mile, the multipler in Eqs. 57 to 61 is $\gamma\, S = 62.4 \times 0.66 \times 10^{-4} = 0.0041$; and its reciprocal is $\frac{1}{\gamma\, S} \approx 244$.

In Fig. 21, the curves of Fig. 20 are replotted in terms of dimensionless ratios. The features characteristic are typical and shed considerable light on the eventual circumstances which condition the "working" of a watercourse. In fact, the reversal point is located at a depth of 69 ft to 70 ft, or at about 11% to 12% of the total depth (78.3 ft) from the bottom. Of the total energy W_o (Eq. 59a), nearly 92% is borrowed within the transmittance zone and of this about 90% is conveyed by transmittance for spending in the lower 8 ft to 9 ft of the flow. The aggregate transmittance loss is about 8½% of the total. In fact, the relatively small "slip" loss is suggested a priori by the shape of the velocity curve. In the upper regions this curve exhibits only slight deviations from a vertical, and actually begins to show a pronounced decline of the local velocity only in the lower reaches, below $y' = 65$ ft. Actually over a depth of 70% of the total depth the cumulative loss is only 2% of W_o. It is less than 4% for $0.8\ y'_o$, and 12% for $0.9\ y'_o$. From there on, the spending increases rapidly. The most intensive exchange is in the closest proximity to the bottom, the spending in the last foot of the total $y'_o = 78.3$ ft constituting 51% of W_o. An analogous procedure applies to circular conduits.

14. General Treatment of Boundary Layers

It is assumed that the reader is familiar with the general concept and theory of flow in a boundary layer. A general account is given in several texts.[27,28,29]

To elucidate the process of energy loss in boundary layers, consider the two-dimensional motion next to a plate (see Fig. 22), under the customary premises that motion in the transverse sense is negligible, and that the pressures in a cross section do not differ from the pressure $p_b = f(x)$ at the border point b. In Fig. 22, and elsewhere in this paper, the reasoning is applied to a layer of unit width in the direction perpendicular to the plane of the figure.

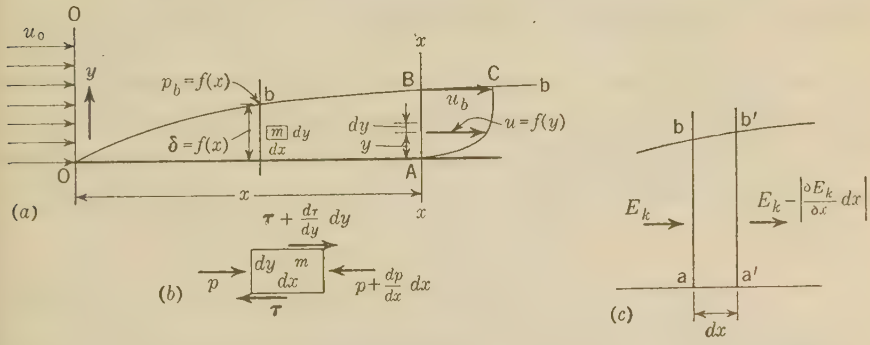

Fig. 22

The dynamic equilibrium for an element (Fig. 22(b)) is expressed by equating the mass-acceleration quantity $\rho\, dx\, dy \frac{du}{dt}$ to the resultant of the forces, of

---

[27] "Fundamentals of Hydro- and Aeromechanics," based on lectures of L. Prandtl, by O. G. Tietjens, translated by L. Rosenhead, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1934, p. 58.

[28] "The Mechanics of Viscous Fluids," Div. G in "Aerodynamic Theory," by L. Prandtl, W. F. Durand, editor in chief, Springer, Berlin, Germany, 1935, Vol. III, p. 80.

[29] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1938, p. 192 et seq.

which $-\frac{dp_b}{dx}\,dx\,dy$ is the pressure component, and $\frac{d\tau}{dy}\,dy\,dx$ is the friction resultant. Reduced to a unit volume of fluid, the equation is

$$\rho\frac{du}{dt} = -\frac{dp_b}{dx} + \frac{d\tau}{dy} \qquad \text{(62)}$$

For the usual case of u_b = constant, and $\frac{dp_b}{dx} = 0$, Eq. 62 becomes

$$\rho\frac{du}{dt} = \frac{d\tau}{dy}; \qquad \frac{d\tau}{dy} + \left(-\rho\frac{du}{dt}\right) = 0 \qquad \text{(63)}$$

indicating that, in the absence of a pressure gradient, motion in the boundary layer is sustained by the inertia of the oncoming flow. The negative friction resultant $\frac{d\tau}{dy}$ (see Eqs. 10) is offset by an appropriate retarding of the motion, with the positive "inertial force" $\left(-\rho\frac{du}{dt}\right)$ balancing the negative friction traction. Obviously the work implied in overcoming frictional resistances is performed at the expense of the kinetic energy of the flow, the initial store of which is gradually reduced. With regard to an elementary cross-sectional block (Fig. 22(*c*)), the kinetic energy E_k, entering per unit time across ab, exceeds the energy leaving the block across line a′b′ by $\left|\frac{dE_k}{dx}\right|dx$, in which the quotient $\left|\frac{dE_k}{dx}\right|$ measures the energy withdrawn (borrowed) and spent per unit time in a boundary layer block of unit length. It has the same significance for boundary layer flow as W_o (Eq. 4) has for established uniform motion, except that $\left|\frac{dE_k}{dx}\right|$ will vary from section to section. Since the quotient is essentially negative,

$$-\frac{dE_k}{dx} = f(x) = (W_\delta)_x \qquad \text{(64)}$$

the inner subscript δ suggesting that W_δ covers the entire transverse extent of the layer, whereas the outer subscript indicates specifically the location of the particular unit block under consideration. On the other hand, $|W_\delta|_0^x$ will designate the aggregate energy borrowed and spent in a unit of time in the entire body of the boundary layer OBA between O and x. Obviously for $\frac{dp}{dx} = 0$, $|W_\delta|_0^x$ is the difference between the kinetic energy $\rho\int_0^\infty u\frac{u^2}{2}\,dy$ flowing across AB and the energy $\rho\int_0^\infty u\frac{u_o^2}{2}\,dy$, originally carried by the same volume of flow in the on-coming undisturbed state, across O–O. In other words,

$$|W_\delta|_0^x = \rho\int_0^\infty u\left(\frac{u_o^2 - u^2}{2}\right)dy = \frac{\rho u_o^3}{2}\int_0^\infty \frac{u}{u_o}\left[1 - \left(\frac{u}{u_o}\right)^2\right]dy \qquad \text{(65)}$$

The quantity E_k includes energy carried across the cross section from the plate to infinity. Inasmuch as there is no appreciable change of velocity outside of the boundary layer, one may substitute for the right side of Eq. 65: $\frac{\rho u^3_o}{2}\int_0^\delta \frac{u}{u_o}\left[1-\left(\frac{u}{u_o}\right)^2\right]dy$. Eq. 65 complements the well-known von Kármán expression

$$F_x = \rho\, u^2_o \int_0^\infty \frac{u}{u_o}\left(1-\frac{u}{u_o}\right)dy \dots\dots\dots\dots (66)$$

which serves to determine the skin friction resultant over the length x in terms of the momentum lost by the flow between 0 and x. Note that Eqs. 65 and 66 are quite general and therefore are applicable to boundary layers of all types whether laminar or turbulent, subject only to the limitation $\frac{dp_b}{dx} = 0$. Unfortunately, present knowledge of turbulent boundary layers is anything but complete, and an adequate analysis of the energy exchanges is not possible. On the other hand, for the case of a laminar layer next to a flat plate with $\frac{dp_b}{dx} = 0$, detailed theoretical calculations are available, and are in excellent accord with repeated observations. For example, theoretical and experimental aspects have been presented in detail by Hugh L. Dryden,[30] whose report, as well as subsequent papers by the same author,[16] contain the more recent interpretations of boundary layer motion, particularly with regard to "transition."

15. ENERGY BALANCE IN LAMINAR BOUNDARY LAYERS WITH $\frac{dp}{dx} = 0$

Basically, the flow pattern is conditioned by the parameter

$$\sqrt{\frac{x\,\nu}{u_o}} = x\sqrt{\frac{\nu}{x\,u_o}} = \frac{x}{\sqrt{\mathbf{R}_x}} \dots\dots\dots\dots (67)$$

in which $\mathbf{R}_x = \frac{x\,u_o}{\nu}$ is the so-called "distance Reynolds number" of the boundary layer. In particular, the transverse velocity profile $u = f(y)$ at a station x (Fig. 22(*a*)) is determined by the dimensionless quantity

$$\eta = \frac{y}{\sqrt{\frac{x\,\nu}{u_o}}} = \frac{y}{x}\sqrt{\mathbf{R}_x} \dots\dots\dots\dots (68)$$

so that the ratio ϕ of a local velocity u distant y from the plate, to the constant (border) velocity u_o $\left(\phi = \frac{u}{u_o}\right)$ is solely a function of η. In any two cross sections, if the ordinates were chosen to make $\eta_1 = \left(\frac{y_1}{x_1}\right)\sqrt{\mathbf{R}_{x1}}$ and

---

[30] "Air Flow in the Boundary Layer Near a Plate," by Hugh L. Dryden, *Technical Report No. 562*, National Advisory Committee for Aeronautics, U. S. Government Printing Office, Washington, D. C., 1937, p. 339.

$\eta_2 = \left(\frac{y_2}{x_2}\right)\sqrt{\mathbf{R}_{x2}}$ identical, the respective velocity ratios $\phi_1 = \frac{u_1}{u_o}$ and $\phi_2 = \frac{u_2}{u_o}$ would be the same. Velocity profiles with such similarity of shape are said to be "affine," permitting the representation of the $u = f(y)$-curve for any cross section by the single generalized outline plotted as $\phi\left(\frac{u}{u_o}\right) = f(\eta)$ in Fig. 23. Affinity obviously applies also to the derivative quantities

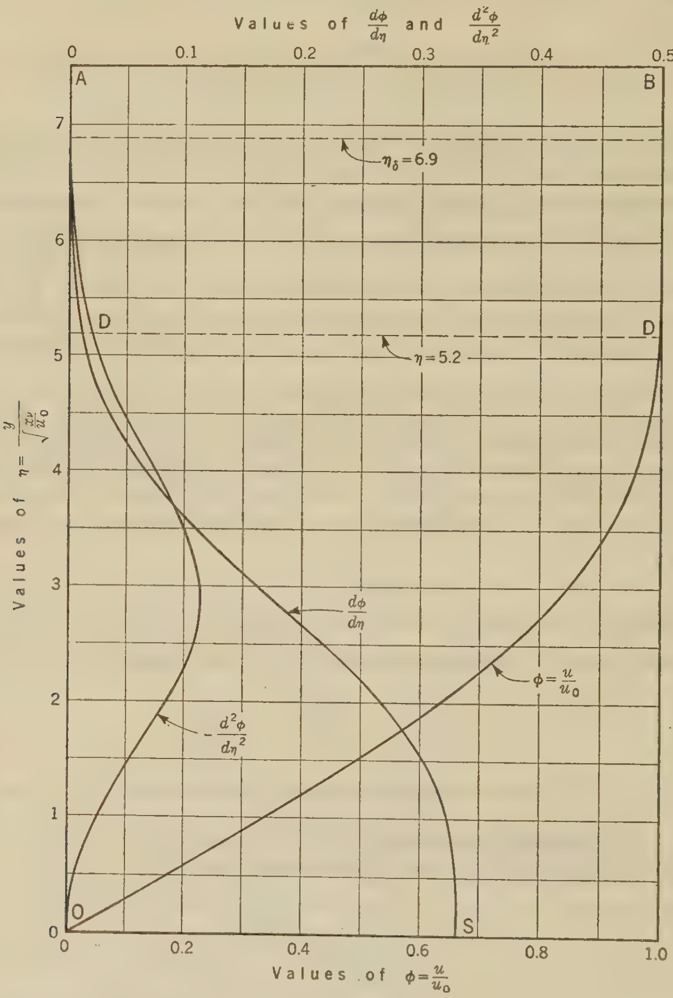

FIG. 23

$$\frac{d\phi}{d\eta} = \frac{du}{dy}\sqrt{\frac{\nu x}{u^3_o}}; \qquad \frac{d^2\phi}{d\eta^2} = \frac{d^2u}{dy^2}\frac{\nu x}{u^2_o} \quad \text{(69)}$$

the generalized outlines for which are also presented in Fig. 23 (based on a tabulation of the original Blasius data[31] included by the Dryden report.[30] The values of $\frac{d^2u}{dy^2}$ throughout the layer are negative. In Fig. 23 the positive of the curve corresponds to $-\frac{d^2\phi}{d\eta^2}$.) In particular the dotted line D–D in Fig. 23 is drawn at a transversal distance $\eta = 5.2$, suggested by Prandtl as a conventional measure for the boundary layer thickness $\delta = 5.2\sqrt{\frac{x\,\nu}{u_o}}$. At such distance, the local value of u differs from the border quantity u_o by the negligible amount of 0.5%. Fig. 23 discloses, however, that the derivative values at $\eta = 5.2$ are still quite substantial, and may weigh accordingly in the eventual energy balances. A more appropriate conventional value for the laminar boundary layer thickness would be $\eta_\delta = 6.9$ making $\delta = 6.9\sqrt{\frac{x\,\nu}{u_o}}$. The particular value of $\eta_\delta = 6.9$ is chosen, so as to give δ four times the so-called "displacement thickness" $\delta_d = 1.73\sqrt{\frac{\nu\,x}{u_o}}$. The Prandtl $\eta_\delta = 5.2$ corresponds to $\delta = 3\,\delta_d$.

For "affine" profiles, the energy equations take definite numerical form. In fact, substituting $\phi\,u_o$ for u, and $\eta\sqrt{\frac{x\,\nu}{u_o}}$ for y, the aggregate energy loss (Eq. 65) becomes

$$\left|W_\delta\right|_0^x = \frac{\rho\,u^3_o}{2}\sqrt{\frac{x\,\nu}{u_o}}\int_0^\infty \phi\,(1-\phi^2)\,d\eta = \frac{\rho\,x\,u^3_o}{2\sqrt{\mathbf{R}_x}}\,\omega = 0.522\,\frac{\rho\,x\,u^3_o}{\sqrt{\mathbf{R}_x}} \ldots (70)$$

in which ω is a dimensionless factor representing the value of the integral

$$\omega = \int_0^\infty \phi\,(1-\phi^2)\,d\eta \ldots\ldots\ldots\ldots (71)$$

Eq. 71 is dependent solely on the shape of the "affine" profile. For the laminar outline of Fig. 23, the quantity ω equals 1.044.

To obtain the local cross-sectional loss (Eq. 64), one proceeds by differentiating Eq. 70, which makes

$$(W_\delta)_x = \frac{d\left|W_\delta\right|_0^x}{dx} = \frac{\omega\,\rho\,u^3_o}{2}\,\frac{d}{dx}\sqrt{\frac{x\,\nu}{u_o}} = 0.261\,\frac{\rho\,u^3_o}{\sqrt{\mathbf{R}_x}} \ldots\ldots\ldots (72)$$

In Eqs. 70 and 72—

$$\left|W_\delta\right|_0^x = 2\,x\,(W_\delta)_x \ldots\ldots\ldots\ldots (73)$$

For establishing the interrelation between the energy loss and the skin friction resultant, note that, numerically, the von Kármán expression (Eq. 66) equals

---

[31] "Air Flow in the Boundary Layer Near a Plate," by Hugh L. Dryden, *Technical Report No. 562*, National Advisory Committee for Aeronautics, U. S. Government Printing Office, Washington, D. C., 1937, p. 361.

$$F_x = 0.664 \frac{x}{\sqrt{\mathbf{R}_x}} \rho\, u^2_o \quad \text{.......................(74)}$$

and the local wall stress (friction force per unit length of plate at the distance x) is

$$\tau_o = \frac{dF_x}{dx} = 0.332 \frac{\rho\, u^2_o}{\sqrt{\mathbf{R}_x}} = \frac{F_x}{2\,x} \quad \text{..................(75)}$$

Substituting Eq. 75 into Eqs. 70 and 72, one finds that

$$|W_\delta|_0^x = \frac{\omega\, u_o}{2} \frac{\rho\, u^2_o\, x}{\sqrt{\mathbf{R}_x}} \approx \tfrac{3}{4}\, \omega\, F_x\, u_o = 0.786\, F_x\, u_o \quad \text{.........(76a)}$$

and

$$(W_\delta)_x = \frac{\omega\, u_o}{4} \frac{\rho u^2_o}{\sqrt{\mathbf{R}_x}} \approx \tfrac{3}{4}\, \omega\, \tau_o\, u_o = 0.786\, \tau_o\, u_o \quad \text{..........(76b)}$$

16. The Local Unit Rates

Local borrowing in a boundary layer is expressed by the same formula (Eq. 11) as in uniform established motion, although, with $\frac{dp_b}{dx} = 0$, the work absorbed by the friction tractions is supplied wholly from the kinetic energy store.

In particular, for a laminar layer, using Eq. 69 in Eq. 11, one obtains

$$w_b = -\mu \frac{d^2u}{dy^2} u = \frac{\rho\, u^3_o}{x} \left(-\phi \frac{d^2\phi}{d\eta^2} \right) \quad \text{...............(77)}$$

the multiplier of the parentheses group constituting (in view of Eq. 72):

$$\frac{\rho\, u^3_o}{x} = \frac{4}{\omega} \sqrt{\frac{u_o}{\nu\, x}}\, (W_\delta)_x = 3.83 \frac{\sqrt{\mathbf{R}_x}}{x} (W_\delta)_x \quad \text{.............(78)}$$

Furthermore, dividing $(W_\delta)_x$ in Eq. 72 by the transverse dimension of the layer $\delta = 6.9 \sqrt{\frac{x\, \nu}{u_o}}$ (see paragraph containing Eq. 69), one obtains an average unit rate of

$$(w_\delta)_x = \frac{(W_\delta)_x}{\delta} = \frac{\omega}{27.6} \frac{\rho\, u^3_o}{x} = \frac{1}{26.4} \frac{\rho\, u^3_o}{x} \quad \text{.............(79)}$$

which is a quantity analogous to w_o (Eq. 8) for uniform flow. Substituting Eq. 79 into Eq. 77:

$$w_b = (w_\delta)_x \frac{27.6}{\omega} \phi \left(-\frac{d^2\phi}{d\eta^2} \right) = 26.4\, (w_\delta)_x\, \epsilon'_b \quad \text{...........(80)}$$

in which

$$\epsilon'_b = \phi \left(-\frac{d^2\phi}{d\eta^2} \right) \quad \text{........................(81)}$$

is a dimensionless function, represented in Fig. 24 by the curve AaO This curve is obtained by multiplying the ordinates of the curves Ao and Bo in Fig. 23. Obviously, ϵ'_b, in terms of 26.4 $(w_\delta)_x$, denotes the distribution of the borrowing process in all laminar boundary layers of the type $\frac{dp_b}{dx} = 0$. The

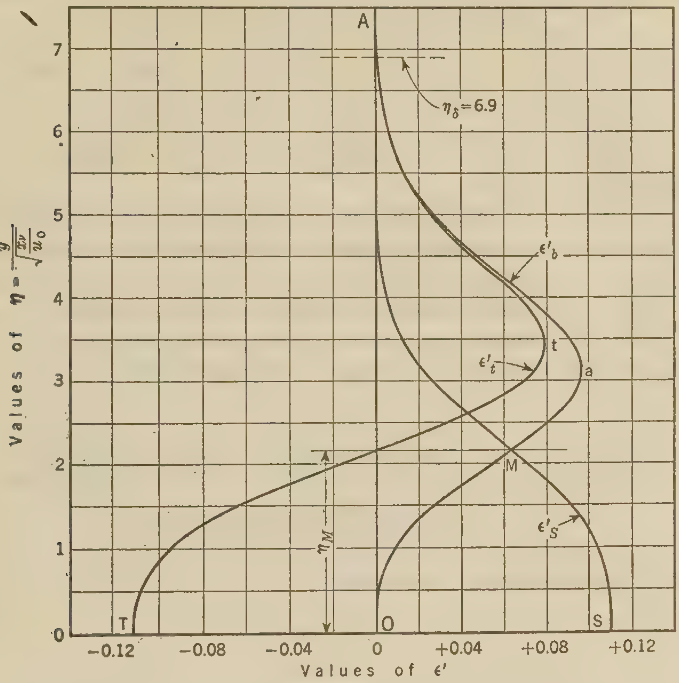

FIG. 24

local borrowing is zero near the wall, and it also declines into insignificance beyond $\eta_\delta = 6.9$. The maximum intensity of the borrowing function is reached in the intermediate region near $\eta = 3 - 3.25$.

The Spending Rate.—In a laminar layer, with the local spending measured by the work involved in viscous deformation (Eq. 12*b*), one obtains, with Eq. 69,

$$w_s = \mu \left(\frac{du}{dy}\right)^2 = \frac{\mu u^3_o}{\nu x}\left(\frac{d\phi}{d\eta}\right)^2 = \frac{\rho u^3_o}{x}\left(\frac{d\phi}{d\eta}\right)^2 = 26.4\,(w_\delta)_x\,\epsilon'_s \ldots (82)$$

Again, the dimensionless function

$$\epsilon'_s = \left(\frac{d\phi}{d\eta}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (83)$$

represented in Fig. 24 as the curve AS, describes the spending process in generalized universal terms. Similar to uniform motion, the spending of energy is concentrated near the solid boundary. With $\eta_M = y_M \sqrt{\frac{x\,\nu}{u_o}}$, the intersection point M, corresponding to $w_b = w_s$, indicates the region within which spending exceeds the energy amounts obtained by local borrowing.

The Transmittance Rate.—By subtracting curve AS (Fig. 24) from curve AaO, one obtains the outline curve AtT, or ϵ'_t which defines the local transmittance function. Expressed algebraically,

$$w_t = w_b - w_s = \frac{\rho\, u^3{}_o}{x}\left[-\phi\frac{d^2\phi}{d\eta^2} - \left(\frac{d\phi}{d\eta}\right)^2\right]$$
$$= \frac{\rho\, u^3{}_o}{x}\frac{d}{d\eta}\left(-\phi\frac{d\phi}{d\eta}\right) = 26.4\,(w_\delta)_x\,\epsilon'_t \quad\ldots\ldots(84)$$

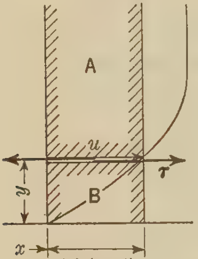

FIG. 25

Cumulative Energy Rates.—In presenting the cumulative energy quantities, it is expedient to add in the direction from the unaffected outward zone toward the plate, thus making the resulting outlines for a boundary layer directly comparable to those of Figs. 1 and 2. In fact, using Eq. 69 with Fig. 25 one obtains for the transmittance rate (compare Eq. 18):

$$|W_t|^y_\infty = \left| -u\,\tau\right|^y_\infty = \left|\phi\, u_o\, \mu\frac{du}{dy}\right|^\eta_\infty = \frac{\rho\, u^3{}_o}{x}\sqrt{\frac{x\,\nu}{u_o}}\left|\frac{d\phi}{d\eta}\phi\right|^\eta_\infty$$
$$= \frac{4}{\omega}(W_\delta)_x\left|\phi\frac{d\phi}{d\eta}\right|^\eta_\infty = 3.83\,(W_\delta)_x\,\mathrm{E}'_t \quad\ldots\ldots(85)$$

in which E'_t is a dimensionless multiplier:

$$\mathrm{E}'_t = \left|\phi\frac{d\phi}{d\eta}\right|^\eta_\infty \quad\ldots\ldots(86)$$

obtained from the data in Fig. 23, and traced as curve ATO in Fig. 26. Physically the quantity $|W_t|^y_\infty$ indicates the work performed on the block B, Fig. 25, by the overlying fluid prism A. The other cumulative quantities take the form:

$$|W_b|^y_\infty = \int_\infty^y w_b\, dy = \frac{\rho\, u^3{}_o}{x}\sqrt{\frac{x\,\nu}{u_o}}\int_\infty^\eta\left(-\phi\frac{d^2\phi}{d\eta^2}\right)d\eta$$
$$= \frac{4}{\omega}(W_\delta)_x\int_\infty^\eta \epsilon'_b\, d\eta = 3.83\,(W_\delta)_x\,\mathrm{E}'_b \quad\ldots\ldots(87a)$$

and

$$|W_s|^y_\infty = \int_\infty^y w_s\, dy = \frac{\rho\, u^3{}_o}{x}\sqrt{\frac{x\,\nu}{u_o}}\int_\infty^\eta\left(\frac{d\phi}{d\eta}\right)^2 d\eta$$
$$= \frac{4}{\omega}(W_\delta)_x\int_\infty^\eta \epsilon'_s\, d\eta = 3.83\,(W_\delta)_x\,\mathrm{E}'_s \quad\ldots\ldots(87b)$$

in which the generalized functions E'_b and E'_s are numerically equal to the areas under the curves AO and AS in Fig. 24, traced in Fig. 26 as AbB and AsB.

The Energy Balance Equation.—By analogy to Eq. 17, the local energy balance takes the generalized form

$$26.4\,(w_\delta)_x \left\{ \epsilon'_b \qquad = \epsilon'_s \qquad + \epsilon'_t \right\} \qquad (88)$$

that is,

$$\frac{\rho\, u^3_o}{x} \left\{ -\phi \frac{d^2\phi}{d\eta^2} = \left(\frac{d\phi}{d\eta} \right)^2 - \frac{d}{d\eta} \left(\phi \frac{d\phi}{d\eta} \right) \right\} \qquad (89)$$

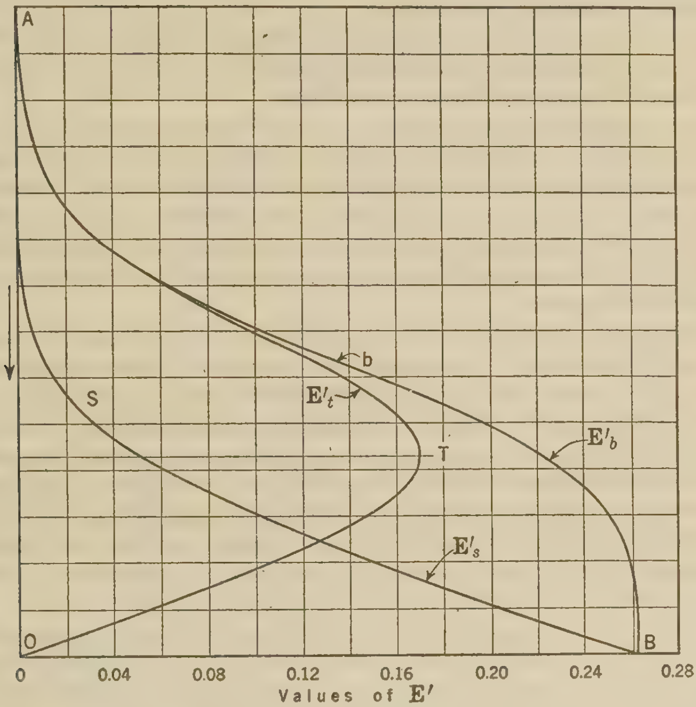

FIG. 26

The analogous symbolic formula expressing the relation between the cumulative energy quantities is:

$$3.83\,(W_\delta)_x \left\{ E'_b \qquad = E'_s \qquad + E'_t \right\} \qquad (90)$$

SUMMARY

1. In the mechanism of energy loss attendant to fluid friction, the "borrowing," or withdrawing of energy from the flow, and its spending do not coincide spacially. Spending is concentrated in the regions of high vorticity near the solid boundaries, whereas the borrowing takes effect principally in the central reaches of high local velocity.

2. The aforesaid implies an in-between "transmittance" function, by which surplus borrowed energy is transmitted to the wall region, where local borrowing is insufficient to cover the requirements for spending.

3. The aspects of the three consequent phases are determined by the internal stress structure and the concomitant velocity profile. The local energy balance equation

$$-\underset{(w_b)}{u\frac{d\tau}{dy}} = \underset{(w_s)}{\tau\frac{du}{dy}} + \underset{(w_t)}{\frac{d}{dy}(-\tau u)} \ldots\ldots\ldots\ldots\ldots\ldots (91)$$

applies equally to laminar and turbulent patterns, and serves as the basis for the reasoning presented in the paper.

4. For laminar patterns the energy exchange process can be presented wholly in analytical form. In turbulent patterns the application of the equations must rely on detailed experimental data.

5. The outstanding characteristic of all turbulent patterns is that only a small portion of the total energy is spent directly within the central turbulent zone, and that the larger part (80% to 85%) is concentrated by transmittance for spending in a narrow reach near the solid boundary. This "conversion" zone is ostensibly the seat of the pivotal process in the turbulent mechanism—namely, that of converting flow energy, concentrated by transmittance, into turbulent eddying form.

6. The function of conversion in itself reverts to viscous action. The larger part of the energy, concentrated for conversion, is ostensibly dissipated in loco in the viscous deformation of the laminar sub-layer and in the course of forming eddies in the adjacent turbulence generating zone. Thus only a smaller part of the spent flow energy reappears after conversion in the turbulent form which animates the familiar turbulent manifestations and activates the convective mass transfer instrumental in shaping the turbulent stress structure.

7. The final dissipation of the turbulent energy, continuously replenished from the generating boundary zone, is by way of viscous attrition in the course of the swarming motion of the eddies across the main flow.

8. The direct local loss of flow energy in the central transmittance zone can be accounted for dynamically by applying the Carnot impact law to the process of mass embedment in the course of transverse mixing. This loss, attributable to the convective action of the larger eddies which shape the stress structure, is concomitant to turbulent diffusion.

9. In relation to natural watercourses, the transmittance of energy and its spending in the boundary zone, shed possible light on the "working" of a river in regard to bed-load movement.

10. The analysis of boundary layer motion is extended to consider the energy aspects of the flow patterns. In the case of a laminar layer with $dp/dx = 0$, a complete account of the energy exchange mechanism is revealed in generalized dimensionless form.

Acknowledgments.—The subject matter covered by the paper forms part of a broader investigation on the "Nature of Hydraulic Resistances" conducted under the general auspices of the Society's Committee on Hydraulic Research. For the velocity profile used in Fig. 20 the writers are gratefully indebted to the Mississippi River Commission of Vicksburg, Miss.

DISCUSSION

GEORGE R. RICH,[32] M. AM. SOC. C. E.—In strikingly clear and compact form, the paper presents the spatial implications of the differential energy balance for representative problems in which the flow is directed by a wall or plate. This same differential expression also appears to afford a ready method of calculating similar energy exchanges for cases without confining walls, such as wakes behind obstacles and jets discharging into still fluid.

The requisite velocity distribution for the jet discharging into still fluid under the condition of laminar flow is given in Fig. 27 and the formula:[33]

$$u = 0.4543 \left(\frac{M^2}{\rho^2 \nu x} \right)^{1/3} \operatorname{sech}^2 \left[0.2752 \left(\frac{M}{\rho \nu^2} \right)^{1/3} \frac{y}{x^{2/3}} \right] \ldots\ldots (92)$$

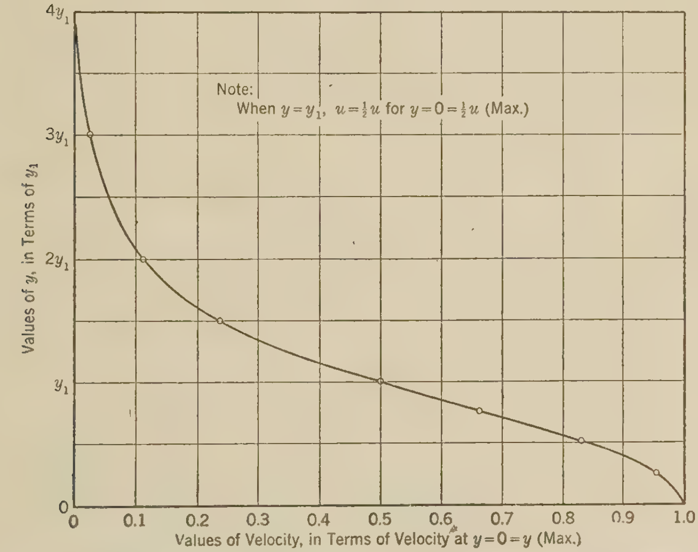

FIG. 27.—VELOCITY DISTRIBUTION FOR RECTANGULAR JET DISCHARGING INTO STILL WATER; LAMINAR FLOW

in which M, the total momentum flowing across a section, is the same for all sections x and is equal to

$$M = 2 \rho \int_0^\infty u^2 \, dy \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (93)$$

Since the present investigation is concerned only with changes in the variable y, Eq. 92 may be written:

$$u = C_1 \operatorname{sech}^2 (C_2 \, y) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (94)$$

---

[32] Chf. Design Engr., TVA, Knoxville, Tenn.

[33] "Modern Developments in Fluid Dynamics," edited by S. Goldstein, Clarendon Press, Oxford, England, 1938, Vol. I, p. 145.

By direct substitution in Eqs. 11 and 12*a* and integrating with respect to y:

$$\left|W_s\right|_0^y = 4\,\mu\, C^2_1\, C_2 \int_0^y \operatorname{sech}^4 (C_2\, y) \tanh^2 (C_2\, y)\, C_2\, dy$$

$$= 2\,\mu\, C^2_1\, C_2 \left[\frac{64}{5\,(e^{2C_2y}+1)^5} - \frac{32}{(e^{2C_2y}+1)^4} + \frac{80}{3\,(e^{2C_2y}+1)^3} - \frac{8}{(e^{2C_2y}+1)^2}\right]_0^y \quad \text{. . (95}a\text{)}$$

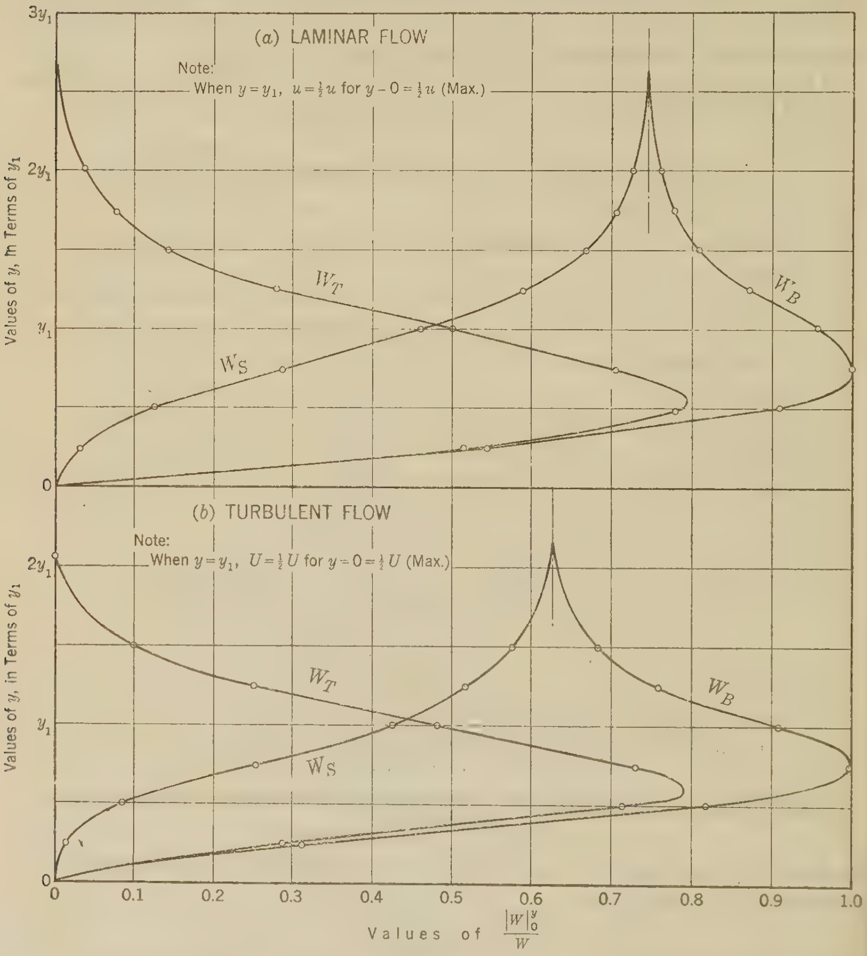

FIG. 28.—ENERGY EXCHANGES FOR RECTANGULAR JET DISCHARGING INTO STILL WATER

and

$$\left|W_B\right|_0^y = 2\,\mu\, C^2_1\, C_2 \int_0^y \left[\operatorname{sech}^6 (C_2\, y) - \operatorname{sech}^4 (C_2\, y) \tanh^2 (C_2\, y)\right] C_2\, dy$$

$$= 2\,\mu\, C^2_1\, C_2 \left[-\frac{96}{5\,(e^{2C_2y}+1)^5} + \frac{48}{(e^{2C_2y}+1)^4} - \frac{112}{3\,(e^{2C_2y}+1)^3} + \frac{8}{(e^{2C_2y}+1)^2}\right]_0^y \quad \text{. . . (95}b\text{)}$$

The resultant energy exchanges are given in Fig. 28(a), in which the characteristic shape of the borrowing curve W_B reflects the abstraction of kinetic energy from the central zone of the jet—not only for the subsequent work of viscous deformation at the particular section x, but also for imparting velocity to water at increasingly higher ordinates as the jet diverges progressively in the x-direction. This salient feature may be inferred from the curvature of the velocity distribution graph, Fig. 27; thus:

$$K = \frac{\dfrac{d^2y}{dx^2}}{\left[1 + \left(\dfrac{dy}{dx}\right)^2\right]^{3/2}} \qquad \text{(96)}$$

In the vicinity of the jet axis $y = 0$, the curvature is convex upward, changing to convex downward at a point of inflection somewhere about $y = 0.75\ y_1$. Thus, $\dfrac{d^2y}{dx^2}\left(\text{or } \dfrac{d\tau}{dy}, \text{ which measures the rate of borrowing}\right)$ must change algebraic sign near $y = 0.75\ y_1$; and, consequently, the summation of borrowed energy W_B must decrease, finally approaching, asymptotically with W_s, the value of 0.745.

The corresponding physical picture appears to be that, at low values of y, the shearing force on any element from the moving water below exceeds the opposing shear due to the inertia of the relatively slower moving water above, and the sign of the resultant increment of borrowed energy is positive. At higher values, the inertia shear from above exceeds the kinetic shear from below the element, and the algebraic sign of the increment becomes negative.

For the case of the rectangular jet discharging into still fluid under conditions of turbulent flow, the actual equation for the longitudinal velocity, although it involves only elementary functions, is exceedingly cumbersome.[34,35] Since the actual distribution of velocity is very much the same as that for the laminar condition, Fig. 27 and Eq. 92 may be assumed sufficiently accurate for present purposes in calculating energy exchanges under the turbulent condition.

Under turbulent flow let τ be the virtual viscous, or Reynolds' shearing, stress,[36] expressed in accordance with the momentum transfer theory as

$$\tau = \rho\, l^2 \left(\frac{\partial U}{\partial y}\right)^2 = \rho\, c^2\, x^2 \left(\frac{\partial U}{\partial y}\right)^2 \qquad \text{(97)}$$

in which the mixing length l is assumed to be $l = c\, x$, c being constant.

The symbol U denotes the longitudinal component of the mean velocity at ordinate y and abscissa x. Substituting in the appropriate equations of the

[34] "Berechnung Turbulenter Ausbreitungsvorgänge," by W. Tollmien, *Zeitschrift für Angewandte Mathematik und Mechanik*, Vol. 6, 1926, pp. 468–478.

[35] "Modern Developments in Fluid Dynamics," edited by S. Goldstein, Clarendon Press, Oxford, England, 1938, Vol. II, p. 594.

[36] *Ibid.*, Eqs. 52 and 53, p. 582; and Eq. 97, p. 592.

energy balance:

$$\left|W_s\right|_0^y = 8\,C^3_1\,C^2_2\,c^2\,x^2\,\rho \int_0^y \operatorname{sech}^6(C_2\,y)\,\tanh^3(C_2\,y)\,C_2\,dy$$

$$= 8\,C^3_1\,C^2_2\,c^2\,x^2\,\rho \left[\frac{\operatorname{sech}^8(C_2\,y)}{8} - \frac{\operatorname{sech}^6(C_2\,y)}{6}\right]_0^y \ldots\ldots\ldots (98a)$$

and

$$\left|\mathrm{W}_B\right|_0^y = 8\,C^3_1\,C^2_2\,c^2\,x^2\,\rho \int_0^y$$

$$\times \left[\operatorname{sech}^8(C_2\,y)\,\tanh(C_2\,y) - 2\operatorname{sech}^6(C_2\,y)\,\tanh^3(C_2\,y)\right] C_2\,dy$$

$$= 8\,C^3_1\,C^2_2\,c^2\,x^2\,\rho \left[\frac{\operatorname{sech}^6(C_2\,y)}{3} - \frac{3\operatorname{sech}^8(C_2\,y)}{8}\right]_0^y \ldots\ldots\ldots (98b)$$

Fig. 28(*b*) shows the corresponding energy exchanges. In comparison with the laminar jet, the chief difference is that a relatively greater portion of kinetic energy is convected from the zone of the central axis $y = 0$ for use in imparting velocity at the higher ordinates in sections subsequent to x and also that the spending at section x is completed at a somewhat lower ordinate, indicating greater concentration of spending in the mixing zone, as would naturally be anticipated.

J. C. STEVENS,[37] PRESIDENT, AM. SOC. C. E.—Entirely novel concepts of the internal mechanism of fluid friction have been presented in this paper. In 1942 the senior author accepted an assignment, heading a research project on the Nature of Hydraulic Friction for the Society's Committee on Hydraulic Research, of which the writer was then chairman. The research committee felt that it was high time to leave the beaten path of empiricism and to step boldly into newer fields of inquiry in fundamental concepts if further advancement in fluid mechanics was to be realized. This paper, although largely a mathematical analysis of viscous forces and their resultant effects, will serve as a beacon to direct the trend of future experimental studies in laboratory and field. From this analysis and from the physical research that it will stimulate, new methods of evaluating flow characteristics of liquids and gases are certain to be evolved.

The suggestion that the principal difference between laminar and turbulent flow may be one of vorticity scale seems to conform with observed phenomena. In pure laminar flow, the vorticity induced by viscous shear is microscopic, even molecular, for which the conversion of energy into heat is definitely confined to the shear plane. As velocities increase, flow characteristics gradually undergo a transition into a state of turbulence. One might indicate the transitional stages by such words as "pure laminar," "laminar," "mildly turbulent," "turbulent," and "shooting." Each progressive stage is characterized by a corresponding increase in the size of the vortices formed by increasing stresses induced by increasing viscous attrition following each increment in the over-all velocity. At least, this is a comforting explanation of why the losses seem to be proportional to an increasing power of the velocity exponent, from 1 for pure laminar to 2 for shooting flow.

---

[37] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

It is well to recognize that the analysis presented applies only to steady uniform flow, whether laminar or turbulent. The case of steady nonuniform flow offers a challenge that can be met only by experimentation. A. A. Kalinske,[38] Assoc. M. Am. Soc. C. E., has encountered this problem in the case of dilating tubes in which the flow is constant but in which velocities are being reduced, thus converting kinetic energy into potential energy. It is well known that, through reducers where velocities are increasing, losses from turbulence are quite low. In fact, such losses may be less than those for steady uniform flow through a corresponding length of an equivalent tube of constant diameter. Therein lies a neat little research problem. If the direction of flow is reversed, however, the losses become inordinately high. This is due to excessive turbulence in the vortex generating zone which, owing to receding boundaries, now occupies a much greater portion of the total cross-sectional area than is the case for uniform flow in a conduit of constant area.

In the example of the large river, the vertical velocity curve, Fig. 20(*b*), does not show the customary lessening of velocity at the surface. If the curve did show this typical characteristic, the cumulative curves of Fig. 20(*c*) and Fig. 21 would be slightly different. If the vertical velocity curve has a lesser surface velocity than occurs at a point below the surface, the effect is to make the "borrow" curve less than the "transfer" curve. This cannot be true for it would mean that more energy is transferred than is available.

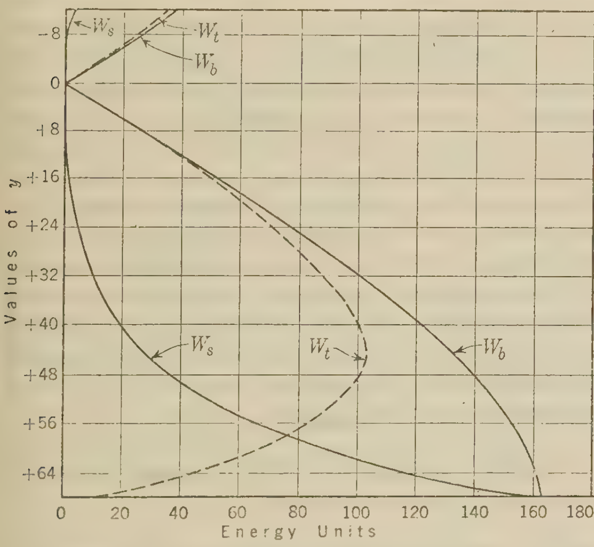

FIG. 29.—VERTICAL VELOCITY CURVE, STATION 395, AT THE DALLES, OREGON

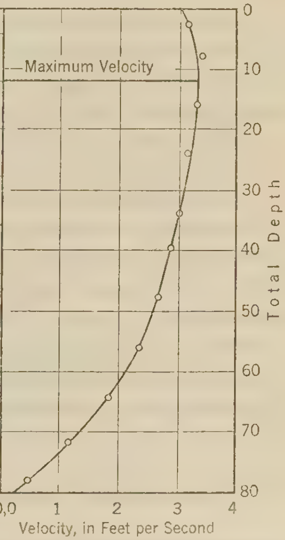

FIG. 30.—ADJUSTMENT OF NEUTRAL AXIS TO AVOID THE ANOMALY OF TRANSFERRING MORE ENERGY THAN IS AVAILABLE

---

[38] "Conversion of Kinetic to Potential Energy in Flow Expansions," by A. A. Kalinske, *Transactions*, Am. Soc. C. E., Vol. III, 1946, p. 345.

Some vertical velocity curves do not show a lessening of velocity at the surface, but many curves do evidence such a lessening.[39] The writer was curious to know what effect this would have on the "borrow," "transfer," and "spending" curves. He therefore selected one of many vertical velocity curves taken by the U. S. Geological Survey on Columbia River at The Dalles, Oregon. The curve is shown in Fig. 29. The banks of the river are steep basalt cliffs with submerged talus. The stream bed is very rough and is strewed with large boulders. Depths are great and velocities low. The vertical velocity curve is quite typical of such curves taken at this site near midstream.

To avoid the anomaly of transferring more energy than is available, the expedient of fixing the neutral axis at the depth of maximum velocity was adopted. This is exactly the procedure for flow in a pipe. The resulting curves of "borrow," "transfer," and "spending" are shown in Fig. 30. The afore-mentioned anomaly is not in evidence, which seems to indicate that instead of the surface of an open stream being considered as the neutral axis for energy transfer, it would be better to use the thread of maximum velocity.

The writer hopes that this paper is only the beginning of a searching program of study and experimentation through which the fundamental nature of fluid resistance to flow will become better known and that practicable usage of the knowledge will speedily follow.

Leon Beskin,[40] Assoc. M. Am. Soc. C. E.—A thorough description of the well-known phenomena involved in fluid friction is contained in this paper. In the writer's opinion, however, the authors have failed to propose new or more simple physical or mathematical concepts of viscous flow, in a form that would be useful to the practicing engineer, who thus could rely less on "detailed experimental data" (see item 4 of the "Summary"), and more on theory.

The authors have not translated their analysis into general mathematical expressions, since their analytical expressions are given only in the case of a two-dimensional rectilinear permanent flow and (in a somewhat less complete form) in the case of a cylindrical rectilinear permanent flow—both with constant kinetic energy. For example, Eq. 91 which is offered as a complete picture of the "local energy balance" (see item 3 of "Summary"), actually applies only to two-dimensional flow. This "balance" equation is the well-known expression for the differentiation of a product:

$$d(\tau\, u) = \tau\, du + u\, d\tau \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (99)$$

If a cylindrical flow were considered, Eq. 91 would be:

$$\underset{(w_b)}{-\frac{u}{r}\frac{d(\tau\, r)}{dr}} = \underset{(w_s)}{\tau\frac{du}{dr}} + \underset{(w_t)}{\frac{d}{r\, dr}(-\, r\, \tau\, u)} \ldots\ldots\ldots\ldots\ldots (100)$$

Thus, the mathematical expressions of the new concepts are seen to be inadequate because their validity is limited to an extremely simple case of viscous flow. It is impossible to ascertain what the consequences would be if the authors had generalized their concepts for an arbitrary three-dimensional motion, and whether new information would thus be revealed as to the phenomenon of viscous motion. To the writer it seems likely that nothing much would be gained by generalizing these concepts because, although Stokes' dissipation function has an absolute nature, the authors' borrowing and transfer functions have only a relative nature. This fact can be demonstrated by a simple inspection of Eq. 91. Velocity u is measured in reference to some axes of coordinates. If the water is flowing in a conduit which is also moving, u can be defined either in reference to the conduit, or in reference to absolute axes. This does not change the expression of w_s, but modifies both w_b and w_t. Academic as it may seem, this fact has far-reaching consequences. For instance, assuming that the same flow pattern occurs in a stationary conduit, in a turbine, or in a centrifugal pump, both terms, w_b and w_t, have different values in each of these cases; but their difference is zero when viscosity is neglected (they are both equal to zero in this case) and has a definite value when viscosity is considered. It can also be shown that the reversal point has a purely relative nature. It moves toward the center of the conduit in the case of a pump, and reaches the boundaries in the case of a turbine. Instead of "reversal point" (see Section 11) it would be more correct to use consistently the term "reversal surface" (see Fig. 14), or at least the term "reversal curve" in a section.

[39] "River Discharge," by J. C. Hoyt and N. C. Grover, John Wiley & Sons Inc., New York, N. Y., 1920, p. 52.

[40] Senior Stress Analyst, Eng. Dept., Consolidated Vultee Aircraft Corp., San Diego, Calif.

To summarize: The concepts introduced in this paper are defined in terms that are too narrow and should be generalized. The definitions have no absolute significance and change with every change in the system of coordinate axes. To justify the practical usefulness of the ideas presented in this paper, the authors need to offer a comprehensive series of illustrative examples.

HUNTER ROUSE,[41] M. AM. SOC. C. E., AND A. A. KALINSKE,[42] ASSOC. M. AM. SOC. C. E.—Energy dissipation in turbulent flow is at best an extremely complex phenomenon, and a successful investigation of the mechanics of such a process requires more ability, intuition, and courage on the part of the investigator than perhaps any other phase of fluid motion. It is for this reason that the writers have only commendation for the authors of the present paper in undertaking so broad and fundamental a treatment of the problem. No fault can be found with the mathematical derivations, and portions of the interpretive matter are considered well worthy of reading and rereading by every one interested in fluid mechanics. Section 10, for instance, which contains a detailed description of the turbulence mechanism, is particularly lucid and significant.

Because of the very complexity of fluid turbulence, a paper of this nature can be of value to only a limited number of readers if the treatment is not in itself a simple one, devoid of all ambiguous or superfluous material. The authors presumably sought to clarify the problem for more than such a limited group, through use of analogies, new concepts, and numerous charts; but the writers are inclined to question whether the goal of clarity has actually been achieved. Indeed, since the essential justification of the new concepts introduced by the authors was not properly noted, the application of these concepts to laminar and turbulent flow alike served to conceal rather than to emphasize the fundamental difference between the two types of motion.

[41] Director, Iowa Inst. of Hydr. Research, Univ. of Iowa, Iowa City, Iowa.

[42] Associate Director, Iowa Inst. of Hydr. Research, Univ. of Iowa, Iowa City, Iowa.

Perhaps the writers' thesis may best be explained by reverting to the authors' use of analogy, to emphasize the fact that analogies are, to say the least, frequently misleading in their oversimplification. Instead of the pulley system to illustrate the general flow process, one might more logically consider a uniform pile of lumber. If an equal force is applied to the end of each plank to simulate a constant pressure gradient, movement apparently comparable to that of laminar flow will result in the longitudinal direction. Thus, assuming a constant coefficient of friction (that is, "viscosity") between planks, the intensity of shear will increase linearly with depth of pile, just as—although for a different reason—the shear increases linearly with distance from the water surface or the center line of a pipe. The work done by the force acting on the end of the top plank, therefore, will evidently not be equal to the generation of thermal energy through friction with the next plank, since both planks are moving and a portion of the force will be transmitted via shear to the lumber below. However, to assume that the forces exerted upon the plank ends represent a form of potential energy (just as the pressure within a fluid is often improperly assumed to be potential energy of flow), which is then "transferred" by the shear process from one plank to another until finally dissipated in the form of heat, is hardly in accordance with accepted methods of mechanics. Moreover, it obviously would be impossible to extend either the plank analogy or the pulley analogy to the case of turbulent motion, since there is no conceivable intermixing process that the planks could undergo to simulate the well-recognized mechanism of turbulent diffusion. Neither analogy (nor, for that matter, any other) is thus capable of truly elucidating the problem under consideration.

In order to be rigorously acceptable in the mechanics sense, the authors' concept of energy borrowing and transmission must involve an actual mass exchange between neighboring zones of flow. Such an exchange is the very essence of turbulent motion, to be sure, but it appears at first glance to be no more characteristic of laminar motion than of the plank analogy. It must be recalled, nevertheless, that the large-scale or molar transfer of fluid matter produced by the mixing process of turbulence has its counterpart in the infinitesimal molecular mixing which takes place in turbulent and laminar flow alike. As a matter of fact, the kinematic molecular viscosity ν and the kinematic eddy viscosity ϵ are both products of mixing lengths and velocities, differing effectively only in scale. Just as the mixing process of turbulence is considered to produce a shear between neighboring zones of flow which is proportional to the lateral rate of momentum transfer, the viscous shear of laminar motion may be resolved into the lateral transfer of momentum through mixing on a molecular scale. Indeed, one frequently compares the rates of molecular and molar diffusion of salinity, or of heat, so that the molecular transfer of kinetic energy is actually just as real a process in laminar flow as the molar transfer is in turbulent flow.

The authors' concepts of energy transmission in both laminar and turbulent flow are therefore fully justifiable, although for reasons not brought to the attention of the reader. In the light of this justification, however, the essential difference between the two types of flow still must be properly clarified. The writers seek to accomplish the necessary distinction by assembling certain of the curves presented by the authors, together with additional functions which they have discussed only casually, in the schematic chart of Fig. 31.

In the uppermost diagrams are included the primary characteristics of laminar and turbulent flow in pipes: (1) The pressure gradient, which is constant across both sections; (2) the intensity of shear, which increases linearly with the radius in both cases; and (3) the velocity, which varies parabolically in laminar flow, and approximately logarithmically in turbulent flow. Neither these nor the remaining curves, it must be emphasized, are drawn to a particular scale, since it is the form of each function, rather than its absolute location, which is essential to the argument.

The diagrams next in order depict the mixing characteristics of the secondary motion—molecular in the laminar case and molar in the turbulent. Curve 4(*c*) represents the mean molecular velocity u'_m, and 4(*d*) the mean velocity $\sqrt{\overline{(u')^2}_t}$ of the turbulence (to which $\sqrt{\overline{(v')^2}}$ is assumed proportional); curve 4(*c*) is necessarily constant across the section, whereas curve 4(*d*) decreases markedly toward the center line. Curve 5(*c*) represents the mean free path l_m of the molecules, which is likewise constant across the section; but its molar counterpart curve 5(*d*), the mixing length or mean eddy size l, increases toward the center line. The remaining curves 6(*c*) and 6(*d*) for the mixing coefficients ν and ϵ are simply the products of the velocity and length characteristics of the respective mixing processes. Noteworthy is the fact that ν is constant across the section while ϵ reaches a maximum approximately midway between center line and wall. In either case, nevertheless, the mixing functions are related to the shear and velocity curves of the upper diagrams through the parallel expressions $\tau = \nu\,\rho\,\frac{du}{dy}$ and $\bar{\tau} = (\nu + \epsilon)\,\rho\,\frac{d\bar{u}}{dy}$.

The third pair of schematic diagrams portray the transfer and the spending of kinetic energy by the mean laminar and turbulent motion. The local rate of spending, rather than the cumulative emphasized by the authors, is used herein for the same reason that local conditions of velocity and shear rather than their cumulative effects are considered more significant in the present argument. Likewise, instead of the authors' cumulative transmission function W_t, the writers have chosen the ratio $W_t/2\,\pi\,r$, since it is the latter quantity which is directly proportional to the mixing coefficient and the velocity gradient of the foregoing diagrams. In other words, the rates of transfer of kinetic energy of the mean motion toward the walls are, in terms of the respective mixing processes: $\left(\frac{W_t}{2\,\pi\,r}\right)_{\text{lam}} = \nu\,\frac{d\left(\frac{\rho\,u^2}{2}\right)}{dy}$ and $\left(\frac{W_t}{2\,\pi\,r}\right)_{\text{turb}} = (\nu + \epsilon)\,\frac{d\left(\frac{\rho\,\bar{u}^2}{2}\right)}{dy}$.

Although it is evident from these diagrams that both the transfer and the spending of the energy of the mean motion in turbulent flow are greater in the wall region, owing to the different nature of the mixing process, the true sig-

FIG. 31.—COMPARISON OF CHARACTERISTIC FUNCTIONS FOR LAMINAR AND TURBULENT FLOW IN PIPES

nificance of these curves becomes apparent only through their correlation with the fourth pair of diagrams. The spending curve 6(*e*) for laminar flow, it must be noted, represents essentially direct dissipation into heat. The corresponding spending curve 6(*f*) for turbulent flow, on the contrary, embodies not only direct dissipation but also the conversion of energy of the mean motion into energy of turbulence through the continuous generation of new eddies.[43] As these eddies are formed, they (and their kinetic energy) become subject to the same lateral transfer as has already been discussed for the mean motion. In the case of laminar flow, the constancy of both the mixing coefficient ν and the kinetic energy $\frac{\rho(u')^2{}_m}{2}$ of the molecular motion results in a zero rate of transfer, diagram (*g*) therefore remaining blank. The rate of transfer of the kinetic energy of the turbulence, however, will be both finite and variable across the section, since—as shown by curve 8(*h*)—it must equal the product of the mixing coefficient ϵ and the negative gradient of $\frac{\rho\overline{(u')^2{}_t}}{2}$. Such transfer, in contradistinction to that of the kinetic energy of the mean flow 7(*f*), will be directed toward the center line, since that is the direction of decreasing $\overline{(u')^2{}_t}$.

The gradient of this transfer function (that is, the difference between the rates of efflux and influx of energy for a unit volume), plotted as curve 9(*h*), represents the difference between the local rate of turbulence generation and the local rate of turbulence decay. Near the wall, where the curve is positive, the generation process evidently predominates, but over the major part of the central region negative values indicate preponderant decay. The local dissipation rate, in turn, may be evaluated independently in the approximate form $\frac{\kappa\,\mu\overline{(u')^2}}{\lambda^2}$ noted by the authors and plotted as curve 10(*h*). (The length λ, it must be remarked, differs from the mixing length or eddy size l in that it represents the average scale of the smaller eddies which control the dissipation process; its trend is indicated in diagram (*d*) by a broken line.) Comparison of the dissipation curve 10(*h*) with the spending curve 6(*f*) will now show that the two differ essentially by the local magnitude of curve 9(*h*), which is positive near the walls and negative near the center. In other words, if the comparatively small rate of dissipation by viscous action in the mean motion (not plotted herein) is ignored, the spending curve 6(*f*) will be seen to represent the algebraic sum of the turbulence-dissipation curve 10(*h*) and the generation-minus-decay curve 9(*h*), in accordance with previous statements. Thus, the ultimate difference between the laminar and the turbulent mixing processes lies in the fact that turbulence generated near the walls is continuously being transferred toward the center, so that the dissipation rate in this region actually exceeds the rate of spending.[44]

Despite the qualitative clarity which such an analysis should yield, the fact must be stressed that existing experimental data permit exact evaluation of only part of the functions shown schematically in the several diagrams. The laminar curves, of course, are accurately known. Completely lacking, however, are systematic measurements of $\overline{(u')^2_t}$, l, λ, and ϵ, for various boundary and flow conditions. Even the curve of velocity distribution in turbulent flow becomes indeterminate in the neighborhood of rough walls, as a result of which all curves for turbulent flow in Fig. 31 have advisedly been broken in the wall vicinity. Just what happens in the neighborhood of the wall, and at the wall itself, must therefore remain for the present a matter of complete conjecture. It is possible, however, to perform the following bulk evaluation of the relative parts played by the wall and the central regions, which may shed further light upon the dissipation problem.

---

[43] "Statistical Theory of Turbulence," by Theodor von Kármán, *Journal of the Aeronautical Sciences*, Vol. 4, No. 4, 1937, p. 135.

[44] "Statistical Theory of Turbulence," by G. I. Taylor, *Proceedings*, Royal Soc. of London, Series A, Vol. CLI, 1935, pp. 462–464.

In the case of smooth pipes, of course, the method of analysis discussed in the foregoing pages can be carried to the wall itself, for reasonably precise information as to the velocity distribution from boundary to center line is at hand. If one were to assume, arbitrarily, that the nominal thickness of the laminar sublayer $\delta = \frac{11.6\,\nu}{\sqrt{\tau_o/\rho}}$ represents[45] the border between the central and the wall regions, it becomes possible at once to evaluate independently W_c, W_w, and W_o, the rates of energy spending per unit length of pipe in the central region, the wall region, and over the entire cross section, respectively. For example, since the velocity gradient in the sublayer is very nearly constant, as a close approximation (except at very low Reynolds numbers) the rate of dissipation in this wall zone will be $2\,\pi\,r\,\delta\,\mu\,(du/dy)^2$, which reduces to

$$W_w = 11.6\,\pi\,D\,\tau_o\,u_f \quad \text{(101a)}$$

while the total rate of energy expenditure for the pipe becomes, in similar units,

$$W_o = \pi\,D\,\tau_o\,u_f/\sqrt{f/8} \quad \text{(101b)}$$

The following ratio then results:

$$\frac{W_w}{W_o} = 11.6\sqrt{\frac{f}{8}} \quad \text{(102)}$$

Since the resistance coefficient f is a known function of the Reynolds number, a plot of W_w/W_o versus R may be made directly.

A diagram of a somewhat similar nature[46] is reproduced in Fig. 32. The over-all ordinate AD of this diagram represents the total rate of energy expenditure as given by Eq. 101*b*, and the ordinate AB the rate of dissipation within the laminar sublayer approximately in accordance with Eq. 101*a*. The spending rate in the central region, shown by the ordinate remainder BD, has been further subdivided into part BC, the rate of dissipation due to the mean motion, and part CD, the rate of dissipation within the superposed turbulence.

---

[45] "Modern Conceptions of the Mechanics of Fluid Turbulence," by Hunter Rouse, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 498.

[46] "Sur la répartition entre le mouvement moyen et le mouvement d'agitation de l'énergie dissipée dans l'écoulement turbulent d'un fluide incompressible," by J. Kampé de Feriet and A. Martinot-Lagarde, *Comptes rendus des seances de l'Académie des Sciences*, December 13, 1937.

Immediately evident is the fact that the wall region plays a relatively large part in the total dissipation process, although the turbulence mechanism becomes more and more effective with increasing Reynolds number (that is, decreasing thickness of the laminar sublayer). Equally apparent is the very small rate of dissipation attributable to the mean motion in the central region, which likewise diminishes with increasing **R**.

Comparable representation of the relative dissipation rates for rough pipes would require a separate diagram for each successive degree of roughness. It would appear, moreover, that preparation of such diagrams must entail equally explicit information as to flow conditions near the boundary, which information is notably lacking in the case of boundary roughness. However, it will be recalled that the ratio W_w/W_o is equal to $1 - W_c/W_o$, which can be evaluated independently for all conditions. The authors, for instance, utilize this fact in interpreting the similar gradients of the velocity curves for different roughnesses in Fig. 16. That is, by assuming the same hydraulic slope for flow through pipes of the same diameter but different relative roughness, they show that the energy expenditure in the central region will be identical, whereas the total expenditure—and hence that in the wall region—will decrease with increasing roughness. The writers believe, however, that a far more general and significant interpretation may be made.

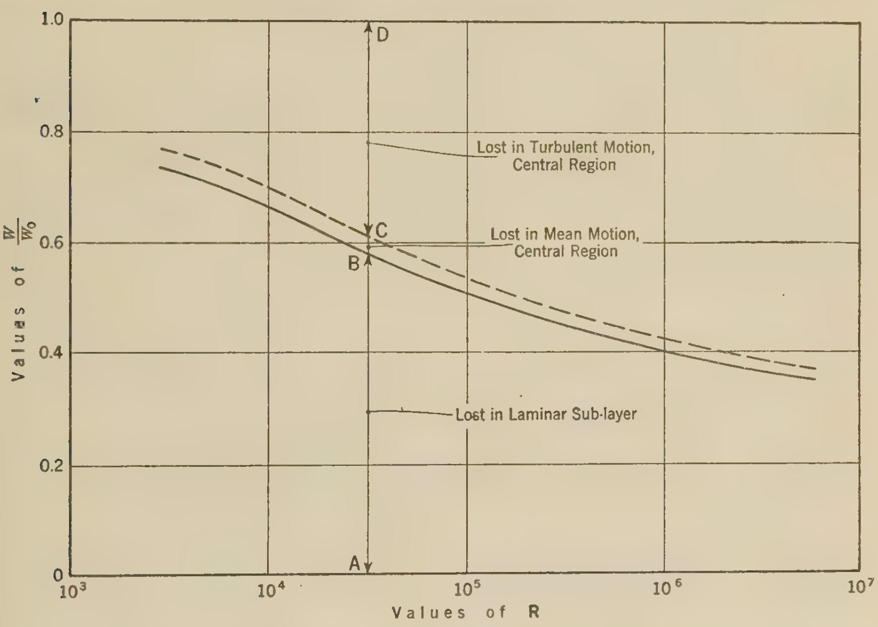

FIG. 32.—RELATIVE RATES OF ENERGY LOSS IN DIFFERENT ZONES OF FLOW FOR SMOOTH PIPES, AFTER KAMPÉ DE FERIET AND MARTINOT-LAGARDE

As must be concluded from Fig. 16, the dimensionless gradient $\frac{d(\bar{u}/u_f)}{d(r/r_o)}$ is the same for all velocity-distribution curves at any particular value of r/r_o in the central zone, regardless of the magnitude of the Reynolds number or the relative roughness. Therefore, the rate of energy expenditure in this central zone, up to that value of r/r_o at which the type of boundary begins to influence the given dimensionless gradient, may be expressed in completely general terms. In other words, letting $x = \bar{u}/u_f$ and $z = r/r_o$, it may be shown that

$$W_e = \pi\, D\, \tau_o\, u_f \int_0^{z'} z^2 \left(-\frac{dx}{dz}\right) dz \ldots\ldots\ldots\ldots\ldots (103)$$

in which z' is the limiting value of r/r_o for the central zone under discussion. The integral may readily be evaluated from the logarithmic velocity equation, for which $dx/dz = -\frac{1}{\kappa(1-z)}$, its magnitude evidently depending solely on the value of the limit z'. Upon division of Eq. 103 by Eq. 101*b*, and subtraction from unity, the desired ratio of the rates of wall and total energy expenditure is seen to become simply a function of z' and f:

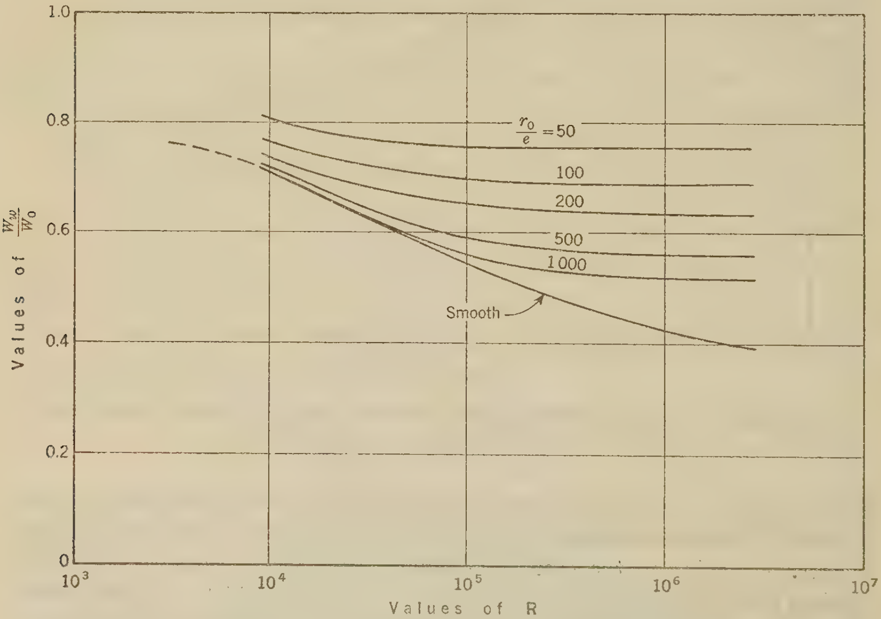

FIG. 33.—RELATIVE RATES OF ENERGY LOSS IN WALL REGION FOR SMOOTH AND ROUGH PIPES

$$\frac{W_w}{W_o} = 1 - \frac{W_c}{W_o} = 1 - \sqrt{\frac{f}{8}} \int_0^{z'} z^2 \left(-\frac{dx}{dz}\right) dz \ldots\ldots\ldots (104)$$

The question still must be answered as to what magnitude of z' to specify in determining values of W_w/W_o to plot against **R** and e/r_o. In the case of smooth pipes, of course, use of $z' = 1 - \frac{\delta}{r_o}$ will reduce the result to that of Eq. 102. In the case of rough pipes, it would then appear reasonable to seek a function of the roughness e which would involve a comparable portion of the pipe section; it would be desirable, moreover, to incorporate in this function the effect of viscosity in the practically important transition range from the smooth to the rough phase of the resistance phenomenon. Comparison of the intercepts on the smooth-pipe and the rough-pipe velocity-distribution curves indicates that a value of $3\,e$ is approximately the counterpart of the value δ used in Eq. 101a; and further consideration indicates that the relationship $1 - z' = \frac{\delta + 3\,e}{r_o}$ is the only simple function approaching the assumed limits of $\frac{\delta}{r_o}$ and $\frac{3\,e}{r_o}$.

Based upon this function, the writers have prepared from Eq. 104, together with a diagram of f versus **R** for smooth and rough commercial pipes,[47] the system of curves of W_w/W_o versus **R** shown in Fig. 33. Despite the admittedly arbitrary nature of the assumed relationship for z', it is believed that this diagram gives a particularly clear picture of the part played by the wall region in the process of energy expenditure, and of its variation with the relative roughness and the Reynolds number. In fact, only through a plot of this nature is it truly possible to judge the effect of roughness under comparable flow conditions. The similarity of Fig. 33 to the f : **R** diagram is simply an indication of the close relationship which exists between f and the ratio W_w/W_o in the several equations given.

If the writers' premise that Eq. 103 reduces the mechanism of energy transfer and expenditure in the central region to a truly common denominator is justified, it must be concluded from Fig. 33 that the rôle played by the wall zone increases markedly with the relative roughness under comparable flow conditions (that is, constant Reynolds number rather than constant hydraulic slope). It must be realized, of course, that the relative thickness of the wall zone considered by the writers is by no means fixed, since $1 - z'$ has been assumed proportional to both δ/r_o and e/r_o, which vary considerably in magnitude. On the other hand, since the velocity curve in the central region depends upon these same two variables, and hence is just as flexible a function, the writers' assumption appears in close accord with the probability that the zone of marked turbulence generation must also vary in radial extent as the Reynolds number and the relative roughness change.

Since, in the case of fully developed roughness action, there is no longer a laminar film at the wall in which direct dissipation of energy can occur, one is also led to conclude that the increase in the proportional rate of energy expenditure in the wall region must be due to the relative violence of the turbulence generated by the wall irregularities. It must not be assumed, however, that this large rate of expenditure represents an equally large rate of conversion into energy of turbulence which is subject to transfer toward the central region. On the contrary, as shown by the authors, a considerable portion of the actual energy dissipation probably occurs locally during the generation process. This is due to the extremely high instantaneous stresses produced within the eddies as they are formed. The energy required to maintain equilibrium of the turbulence structure, in other words, while eventually dissipated in its entirety, does not all pass through the intermediate stage of transferable energy of turbulence.

---

[47] "Evaluation of Boundary Roughness," by Hunter Rouse, *Proceedings*, 2d Hydr. Conference, June 1–4, 1942, State Univ. of Iowa, Iowa City, *Bulletin No. 27*, Studies in Eng., 1943.

In this discussion the writers have consistently sought to add to, rather than detract from, the value of the authors' detailed presentation. As a new approach to a problem of vital importance is invariably subject to modification and improvement, the writers are hopeful that the interpretation presented herewith may likewise be altered and extended by the authors in their closure, and by those who later use the paper as a reference. Indeed, quite aside from the fundamental material which the paper has provided, it is probable that it will have lasting worth as a stimulus to creative thought on a very stubborn problem.

Boris A. Bakhmeteff,[48] Hon. M. Am. Soc. C. E., and William Allan,[49] Assoc. M. Am. Soc. C. E.—A step forward in treatment of "a very stubborn problem," as the reviewers express it, and a "stimulus to creative thought" is all that the writers could aspire to in summarizing the results of years of cogitation and study. The encouraging comment of a practical engineer like Mr. Stevens is especially appreciated. Mr. Rich has at once seized upon the possibilities by extending the new approach toward energy balance in "free discontinuity" or "separation" zones. This field is of special importance, as separation forms the basis of all resistances of the "local" or "form" type. For the laminar case, Mr. Rich's solutions are indisputable. Unfortunately in practice, most separation zones are in highly turbulent condition, and here the difficulties begin as the physics become very complex[50] and the factual knowledge most defective. The writers hope to return to the subject in some not too distant future.

Messrs. Rouse and Kalinske have generously added to the original paper. The remarks which follow, and which deal largely with their discussion, are offered in the same cooperative spirit of contributing toward a better understanding of a complex case. The writers realize only too well, how difficult it is for reviewers, especially if a subject lies in the field of their own interest, to adjust their viewpoint to that of the writers and to disengage themselves from the particular problems which preoccupy their own thoughts. Indeed, the statement that—

> "* * * the application of these concepts [the different phases in the energy exchange mechanism] to laminar and turbulent flow alike served to conceal rather than to emphasize the fundamental difference between the two types of motion."

—indicates that Messrs. Rouse and Kalinske have misinterpreted the purpose of the paper.

---

[48] Prof., Civ. Eng., Columbia Univ., New York, N. Y.

[49] Associate Prof., Civ. Eng., School of Technology, College of the City of New York, New York, N. Y.

[50] *Transactions*, Am. Soc. C. E., Vol. III, 1946, p. 382.

The major objectives of the paper were to reveal what Mr. Rich so aptly describes as the "spatial implications of the energy balance," and to show that these implications, which embody the interrelations between the different phases of the process, are wholly determined (1) by the shape of the velocity profile, and (2) by the stress distribution. In fact, the same mathematical expressions describe the quantitative features of the process irrespective of the nature or the physical agencies that happen to shape the flow pattern. Therefore, it is the unity and not the difference of the fundamental premises which the writers tried to emphasize.

In approaching any natural phenomenon two questions arise, the "how" and the "why." The "how" relates to the functioning as observed, and it implies a comprehensive interpretation of factual data derived from experiment, without recourse to ambiguous or conjectural assumptions. Thus, the graphs of Figs. 2, 11, and 17 portray "how" the energy balance mechanism unfolds in the laminar and in the turbulent case, with the graphs typifying observed unquestionable facts. The human mind, on the other hand, is never satisfied with knowing only the "how." It naturally strives to penetrate into the mysteries of the universe and to unveil the internal working of things, in an endeavor to answer the "why." This realm is fascinating even if usually closely guarded; necessarily, it is a realm of hypothesis, conjecture, and guesswork.

The writers have nothing but commendation for the effort of the discussers to penetrate deeper into the "why" of the internal turbulence mechanism, but a word of warning might be inserted against the danger of placing too much emphasis on the alleged similar traits in the internal workings of "eddy kinematic viscosity" ϵ with the customary ν. The elegance of a single mathematical form for expressing stress in both instances, should not shield the essential differences in physical phenomenology. The important point, however, is that the comparative analysis presented by Messrs. Rouse and Kalinske relates principally to the stress-producing process, and bears only indirectly on the energy exchange as such. The pivotal point in the case is the concept of what the writers term the "transmittance function." Messrs. Rouse and Kalinske seem to visualize the latter as a bodily transfer of kinetic energy, inasmuch as they state:

> "In order to be rigorously acceptable in the mechanics sense, the authors' concept of energy borrowing and transmission must involve an actual mass exchange between neighboring zones of flow."

The writers brought out the new concept of the internal energy transmittance process as a physical fact, based upon direct observational data. Whatever the internal workings, the function is a dynamic reality because there is an extant velocity and stress distribution. The ostensible "how" is indisputable, independent of whatever hypothesis is used to disclose the secrets of the internal "why." In any event the internal process does not imply bodily transfer of kinetic energy. The concentration of borrowed energy near the wall zone is a cumulative process; and, if such accumulation were affected by a bodily transfer of kinetic energy from one layer to another, the transfer would necessarily require compensation by an appropriate reduction of the kinetic energy in the axial direction. Kinetic energy in uniform motion remains unchanged. In fact, all the borrowing and transmittance unfolds at the expense of the potential energy, the withdrawal of which is manifested in the axial pressure drop.

Work or energy is not a physical entity such as salinity, sediment, or heat, which are transferred in the course of diffusion. Work is a composite quantity involving force and displacement. A belt, or a sequence of gears, in a mechanical system conveys the force, whereas the kinematics of a mechanism conditions the displacements. In a moving fluid the extant velocities and stresses supply the constituents; they combine in shaping the transmittance process and the resulting spatial accumulation of borrowed energy. The writers feel that concentration on the idea of bodily energy transfer, instead of acceptance of the extant mechanical implications of the process prompted the rather severe attitude of Messrs. Rouse and Kalinske toward the mechanical analogy used by the writers. Perhaps it should be explained that, long before the paper took final shape, the writers on different occasions discussed the subject matter with members of the profession. There never was any difficulty about the borrowing and spending phase, but it was not always easy to "put across" the implications of the transmittance function; and just for this reason the writers took recourse in a mechanical analogy, with repeated and distinct success. Of course, analogies may be objected to on general principles. Indeed, the question has preoccupied the science of logic since the ancient days of Aristotle's "Organon" down to the present-day scientific epistemologists. Obviously an analogy is only a simile and therefore is not a proof; but, in the words of Raymond Poincaré ("Science and Hypothesis"), "a semblance of a proof" may be "so luminous."

The graphs of Fig. 31 deserve every possible commendation. There is only one reservation and that is in regard to curve 6(*f*) in Fig. 31 (*f*), which is termed a spending curve, with the concomitant curves 9(*h*) and 10(*h*) in Fig. 31(*h*). In the paper the writers systematically insisted on distinguishing between the process effecting loss of the main flow energy, and the events in the superimposed turbulent structure. In fact, the term "spending" was used exclusively to signify the disappearance of the main flow energy, whether caused by direct local dissipation or by conversion into eddying vortical form. The sequence of the different phases and their spatial distribution were presented schematically in Fig. 14. The concepts underlying this diagram constitute, in the view of the writers, the very essence of the over-all turbulent pattern.

The first question which arises in connection with the interpretation of curves 6(*f*) to 10(*h*) in Fig. 31 is whether or not local spending of the main flow energy in the central zone is accompanied by any appreciable local generation of turbulence. In this connection it should be noted that, in the light of recent knowledge, turbulence may properly be defined as a product of disintegration of "eddying patterns." Furthermore, it should be remembered that the formation of eddying patterns, exemplified by the rolling up of flow filaments under the influence of excessive strain, is accompanied by a highly concentrated absorption of main flow energy. The larger part of such absorbed main flow energy is dissipated in place through viscous attrition, and only a comparatively small part of the absorbed energy may survive in the form of disintegrated eddies, which vitalize and manifest turbulence. No single investigator has contributed more toward a proper quantitative understanding of these facts than has Professor Kalinske.[38]

Whether or not turbulence is produced in the course of local spending in the central zone depends on the intensity of the local viscous strains, engendered in the course of the swarming motion of the large turbulent eddies. At the present state of knowledge, scholars cannot answer this question conclusively in either one sense or another. They can state definitely, however, that, even if local turbulence happened to be generated, the added turbulent energy would be only a small fraction of the locally spent main flow energy and that, in turn, the local rate at which energy is spent in the central region is only a minor part of the total energy. Thus, under all circumstances the locally generated turbulence is insignificant in comparison with the bulk turbulence, that appears and diffuses from a region near the wall in the conversion zone. That is the reason why, when visualizing the over-all turbulent pattern as in Fig. 14, for all practical purposes, the turbulent energy added in the central zone may be neglected, and turbulence may simply be considered as a superimposed pattern, arising from the conversion of the main flow energy accumulated by transmittance in the near-wall zone, and spreading from the latter. Under all circumstances, to maintain the proper perspective in the succession of events, the process of local spending of the main flow energy and the dissipation of turbulent energy diffusing from the wall region should be kept separate. Embracing the two under a single spending concept, as done by the discussers, inevitably obscures the broad spatial implications of the turbulent flow mechanism.

The questions may be raised, of course, as to where the "central" zone ends and what delimits the inner region in which the eventual local generation of turbulence is held negligible. It stands to reason, furthermore, that one zone passes into the other gradually, and that the rate of turbulence generation increases continuously, so that the distinction between the central and wall conversion zone is at best a question of relative "quantity." The answer is that there are so many instances (as, for example, in interpreting Eq. 45) in which the predominance of one factor or the other lends ostensibly distinct over-all characteristics to a phenomenon, substantiating once more the dictum of Hegelian dialectics that at a certain degree "quantity changes into quality." A glance at Figs. 11 and 17 indicates a distinct and rather abrupt change in physical circumstances after the reversal point M is passed, especially in regard to the transmittance W_t-curve, which starts to decline rapidly, evidencing a greatly intensified absorption of energy. For this reason the writers broadly associated the wall "conversion" zone with the reach between the reversal surface M and the solid boundary. The writers would not be surprised if future research were to show that, actually, the region of active turbulence generation is much narrower (see last paragraph of Section 11, in the paper).

The discussers refer to G. I. Taylor's classical "Statistical Theory of Turbulence."[44] When that paper was written, the existence and the rôle of the transmittance phase were not realized, and it was only natural to present facts without taking this basic function into consideration. Hence, in Fig. 34, which appeared in Mr. Taylor's paper and was reproduced by subsequent commentators,[51,52] the local spending of main flow energy (curve 1) was set face to face with curve 2, portraying local dissipation of turbulent energy. Curve 1 corresponds to the accrual of the ordinate measuring the difference between OD and OC, Fig. 14, whereas curve 2, Fig. 34, exemplifies the rate of decay of the curve B'O, Fig. 14. Physically, the Taylor curves refer to phases, which are not interrelated in any direct fashion and therefore are not comparable.

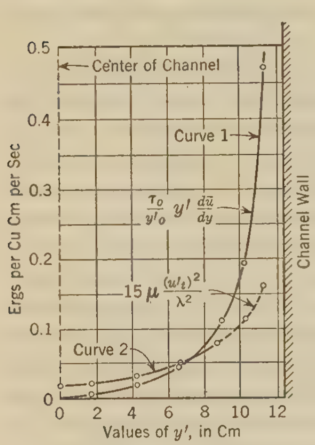

FIG. 34

A very interesting part of the Rouse and Kalinske discussion is related to Fig. 33, and attendant Eqs. 103 and 104. It is not clear whether Eq. 103, which, represents the cumulative spent energy W_s, was established by the discussers independently. However that may be, Eq. 103 follows directly from substituting Eqs. 43*a* and 43*b*, with the discussers' symbols, into Eq. 44, making

$$\left|W_s\right|_0^z = \pi D \tau_o u_f \left[\int_0^z 2\,z\,x\,dz - z^2 x\right] = -\pi D \tau_o u_f \int_0^z z^2 \frac{dx}{dz}\,dz \quad (105)$$

which, for the logarithmic velocity curve, leads to:

$$\frac{W_s}{W_o} = \frac{1}{\kappa}\sqrt{\frac{f}{8}}\int_0^z z^2 \frac{dz}{1-z} = -\frac{1}{\kappa}\sqrt{\frac{f}{8}}\left[\frac{z^2}{2} + z + \log_e (1-z)\right]_0^z \quad ..(106$$

In seeking what they claim to be a more general and significant interpretation than the writers' analysis (based initially on the premise of an identical hydraulic slope), the discussers merely demonstrate what is already presented by the curves in Fig. 17(*b*), which serve to account for smooth and rough boundaries of the entire cumulative exchange process for the range of high Reynolds' numbers, where fully developed rough patterns have been attained and where the shape of the velocity curve in terms of u/u_f remains practically unchanged. The aforementioned outlines are based on observed data, and the conclusions cannot be questioned. Inasmuch as the curves of Fig. 33 are intended to represent essentially the same facts as Fig. 17, both sets should point toward identical conclusions. The implications to be drawn from Fig. 33, however, are diametrically opposite. The fundamental idea revealed by Fig. 17 is that the spending curve for rough boundaries lies above the smooth outline—thus,

---

[51] "Modern Developments in Fluid Dynamics," edited by S. Goldstein, Clarendon Press, Oxford, England, Vol. II, 1938, p. 396.

[52] "Turbulence and Energy Dissipation," by A. Kalinske, *Transactions*, A.S.M.E., Vol. 63, 1941, p. 41.

with an increase in roughness, a relatively larger part of the over-all energy is spent in the central region and therefore a smaller part is left for concentration through transfer and for ultimate conversion into eddies in the near-wall region. Contrary to the foregoing interpretation, in Fig. 33, the part of energy alleged to be spent in the wall zone is shown to increase with the boundary roughness. At first this might seem to be a fundamental discrepancy; but a glance at Eq. 106 (which was used by the discussers in preparing Fig. 33) indicates that, for the same relative distance $z = r/r_o$, the proportionate part of the spent energy increases with the friction coefficient f and that therefore within the reaches where the logarithmic velocity equation does apply, the general properties indicated by the curves of Fig. 17 are substantiated.

The reason for this inconsistency is to be found in the method used for calculating Fig. 33 and primarily in the manner of selecting the integration limits. As the discussers state, the present knowledge of flow circumstances in the proximity of rough boundaries is very meager, and guesses of "just what happens" remain "a matter of complete conjecture." The discussers proceeded by way of certain assumptions (which in all fairness were just as good as any other premises based on preconceived theoretical notions) without a solid foundation in actually known facts. On the other hand, as seen from Fig. 17, the W_s-curves near the wall rise very abruptly so that a slight difference in assumed transverse distances may lead to widely diverging results. The writers feel, sincerely, that the revealed discrepancy offers a pertinent example of the type of questions the further study of which is usefully stimulated by the discussion.

In general, space will not permit a thorough analysis of the question of what constitutes the limits of the "boundary zone." Moreover, as stated, for rough boundaries, additional factual knowledge is needed urgently. For smooth surfaces the question can be approached with some measure of certainty. Thus, it is known[53] that the numerical value of the so-called distance friction parameter $u_f = 11.6$, in Eqs. 101 and 102, actually refers to the intersection of the extended straight laminar sublayer line with the prolonged turbulent curve, and that therefore in reality the value 11.6 represents a distance from the wall, which is larger than the thickness of the purely laminar sublayer and considerably smaller than the total transverse dimension of the over-all boundary region beyond which a fully turbulent regimen is established. Usually the thickness of the latter is associated with $y_f \sim 30$. In this light the appraisal for the wall-zone spending, appearing in Eq. 102 and reflected in Fig. 33, are much too small and lead to an erroneous perspective. Equally misleading are the presentations of the French scientists (Fig. 32), who used the wholly unjustifiable parametric value of $y_f = 15$. Actually the energy lost in the laminar sublayer is only about one half of the indicated amount. Also the main flow energy spent in the turbulent central region is considerably smaller than suggested by Figs. 32 and 33. Indeed, in the case of smooth pipes the energy concentrated and used for conversion in the entire boundary region is of the order of 80% of the total; and, in so far as approximate appraisals are concerned, Eqs. 47 to 50 seem to represent events in truer fashion. Messrs. Rouse and Kalinske, as well as the French scientists, seem to disregard, entirely, the rôle and function of the transitory region between the laminar sublayer and the fully developed turbulent zone, clearly indicated by the Nikuradse experiments. The writers feel, that this "in-between" zone is the main seat of the turbulence generation process.

[53] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 1936, pp. 78 and 82.

The writers could not close this paper without referring to the very vital questions raised by Mr. Stevens in regard to watercourses, in which the maximum velocity filament is below the surface. In the stream gaging manual of the U. S. Geological Survey,[54] a set of typical velocity curves shows the maximum velocity, in all instances, to occur at the surface of the stream; this is in contrast to earlier assumptions, by which the fastest filament was invariably placed below the surface. The reason for the "drowning" of the maximum velocity, which always occurs in comparatively narrow channels, has been a subject of lively discussion for many years. Generally, the phenomenon may be traced to secondary currents, always present in nonsymmetrical profiles;[55] perhaps the most plausible explanation was the one given by Ludwig Prandtl.[56] The writers dealt only with two-dimensional flow, in which case the maximum filament would be at the surface. For the present, available knowledge of the more complicated three-dimensional patterns is much too meager to permit any comprehensive energy-exchange analysis, except by way of broad qualitative generalizations.

EFFECTS OF RADIANT HEAT ON REINFORCED-CONCRETE RIGID FRAMES

By Milan A. Johnston,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. I. Oesterblom, N. M. Newmark, L. C. Hollister, A. A. Eremin, and Milan A. Johnston

Synopsis

The reinforced-concrete rigid frame is subjected to two types of temperature stresses: (1) Those resulting from long-range, or seasonal, temperature changes, and (2) those resulting from the radiant heat of the sun.

The method of determining stresses caused by seasonal temperature changes has been well established, although designers differ in opinion as to the importance of these changes. The purpose of this paper is to present an analytical method of finding the moments at the knee and crown of a reinforced-concrete rigid frame subjected to the second type of temperature change—namely, that caused by radiant heat from the sun. In order to present numerical computations for a structure of known cross section, a two-span rigid frame highway bridge, previously designed for H-20 loading, was used. A rigid frame was selected because of the increasing popularity of this type of structure for railroad and highway grade-separation projects.

Analysis shows that the radiant-heat moment at the crown of the specific frame used is equal to 35.5% of the maximum design moment. This moment is reduced somewhat because the deck is probably elongating due to the rise in seasonal temperature on the days when radiant heat causes the greatest effect. Main longitudinal steel in the crown for the purpose of resisting the effects of a seasonal temperature drop is also available for the radiant-heat stresses.

Introduction

In the future there should be a marked increase in the number of long-span rigid frames built as a feature of superhighway grade separation. Consequently, the secondary effects of temperature will become more important in

---

Note.—Published in June, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Instr., Univ. of Minnesota, Eng. Experimental Station, Minneapolis, Minn.

their design, especially as the spans become longer. Many designers now include in their design of reinforced-concrete rigid frames the secondary effects of temperature change, shrinkage, and settlement of footings.

The present temperature specifications, whenever used in the design of indeterminate structures, refer to the axial strains caused by long-range or seasonal temperature variation. These unit strains, although not necessarily uniformly distributed over a cross section, will be symmetrical about the neutral axis as long as the difference in air temperature causes the strains. Hence, maximum axial deformations will occur roughly in half-year cycles.

Methods of analyzing the stresses due to seasonal temperature changes are well established, but the authorities responsible for design specifications among the various states differ in opinion as to the importance of these changes. (Questionnaire data collected by D. H. Pletta, and loaned to the writer, show this to be true among state highway departments.[2]) This difference of opinion is not surprising in view of the many variables present in temperature design.

For example, some designers rely on low allowable unit stress for the primary loads to provide additional safety from secondary effects. They also realize that any strains due to extreme temperature changes during the early period of the structure are modified by plastic flow. The data collected by Captain Pletta[2] showed that most of the states having mild climates, with a small mean temperature difference between January and July, either disregarded temperature changes or provided very little plus and minus temperature change from some mean value. As an exception to this, some of the states with mild climates provided nearly twice the plus and minus temperature change of states having much greater mean temperature difference between January and July.

Closely allied with seasonal temperature changes is the effect of radiant heat on rigid frames. This paper will be limited to the analysis of stresses caused by radiant heat not only to illustrate a method of analyzing a more complex type of temperature change, but to emphasize the need for more uniform seasonal temperature specifications in the milder states where radiant heat has its greatest effect.

Some work already has been done in Europe on variable temperature change in rigid frames,[3,4] but, as far as the writer knows, this is the first time such a method has been offered for publication in the United States. According to tests made by the Swiss Government on fifty reinforced-concrete rigid frames built between 1924 and 1927, variable temperature change has no damaging effects on frames properly designed and built, even though variable temperature change was neglected in the design.

THE EFFECT OF RADIANT HEAT

Differential temperature strain, most frequently caused by radiant heat from the sun, occurs because the temperature of the top surface of the deck is relatively higher than that of the bottom surface. An experiment conducted in 1941 and 1942 by the Minnesota State Highway Department[5] showed that the surface temperature of a concrete slab is sometimes raised 30° F above the air temperature because of radiant heat. Investigations conducted in states with warmer year-round climates would probably show even higher relative surface temperatures. This difference in temperature tends to elongate the upper fibers and to cause the deck to bulge upward. In the basic, or simply supported, beam this bowing effect causes angular rotations at the supports as shown in Fig. 1. In a rigid frame, where the ends are restrained, this end rotation is subdued by the resisting moments at the knees, causing fiber stresses in all the members. Furthermore, the bridge is subjected to these stresses in short cycles—once every clear, hot summer day.

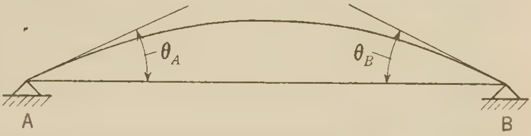

Fig. 1.—End Rotations in the Basic Beam Caused by the Heat of Radiation

Increase in the temperature of any surface above the air temperature depends on many factors—such as the intensity of the sun, the angle between the surface and the sun, the quantity of heat reflected back into the air, the wind velocity, etc. A theoretical calculation of the surface temperature rise necessarily must take into account so many assumptions and variables that it would be not only approximate but impracticable. Therefore, the surface temperatures used in the following analysis are taken from actual readings (original data) made on a comparable surface August 18 and 19, 1941, at Minneapolis, Minn.[6]

General Procedure and Tools of Analysis

Stresses due to strain in a statically indeterminate structure can be investigated only by the analysis of a specific structure. A rigid frame structure with two spans of 80 ft each, designed for an H-20 live loading, was selected. This particular selection was made because of the increasing popularity of this type of structure for grade-separation projects and because it was relatively long, since the magnitude of temperature stresses increases with length.

Details of the rigid frame are shown in Fig. 2. The deck has been divided into segments, each with a length Δs, for use in the angular rotation equation:

$$\theta = \sum \frac{M \, \Delta s}{E I} \qquad \text{(1)}$$

The general procedure for finding the moments at the knee and crown due to radiant heat is as follows:

1. Find the distribution of the differential temperature strain on a cross section of the deck (a method for doing this is presented under the heading, "Numerical Example");

[6] "Heat Transmission Through Insulation as Affected by Orientation of Wall," by Frank B. Rowley and C. E. Lund, *Technical Paper No. 44*, Univ. of Minnesota Eng. Experiment Station, Minneapolis, Minn., 1943.

2. Compute the angle change caused by temperature strain for as many sections as necessary to develop an angle-change loading equation for the entire deck;

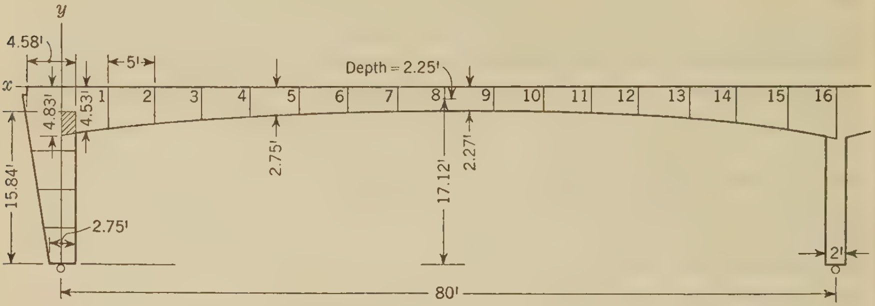

FIG. 2.—DETAILS OF THE RIGID FRAME USED IN THE NUMERICAL EXAMPLE

3. Load a 1-ft increment of deck with the angle change and compute the end rotations, assuming the deck to be simply supported;

4. Load a 1-ft increment of deck with the $\frac{M}{E\,I}$-diagram and find the end-rotation equation in terms of $M/E\,I$, assuming the deck to be simply supported;

5. Since there is no end rotation in a beam with fixed ends, equate steps 3 and 4 to find the fixed-end moment M; and

6. By the method of moment distribution, find the final or true moments in the rigid frame.

Notation.—The letter symbols used in this paper conform essentially to American Standard Letter Symbols for Heat and Thermodynamics Including Heat Flow (ASA—Z10.4—1943), American Standard Letter Symbols for Mechanics of Solid Bodies (ASA—Z10.3—1942), and American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932)—each compiled by Committees of the American Standards Association, with Society representation.

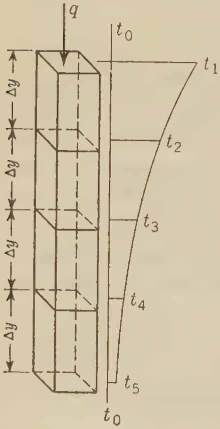

FIG. 3.—INDEPENDENT PRISM METHOD OF TRACING THE RADIANT TEMPERATURE RISE THROUGH A SLAB

NUMERICAL EXAMPLE

Step 1. Distribution of Temperature Strains on the Cross Section of the Rigid Frame Deck.—For this step, use is made of a method of tracing heat flow through a solid body presented in 1937 by R. W. Carlson,[7] Assoc. M. Am. Soc. C. E. Mr. Carlson divides the body into independent prisms of unit cross-sectional area as shown in Fig. 3. This method was modified by the writer especially to analyze the problem of tracing temperature throughout the depth of a slab if the quantity of heat q entering at the surface is known.[8] Only the general features of Mr. Carlson's method are explained in the first step, as the development of this method with subsequent numerical computations of the modified method is much too long to include in this paper.

---

[7] "A Simple Method for the Computation of Temperatures in Concrete Structures," by Roy W. Carlson, *Journal*, A.C.I., November-December, 1937, pp. 89–102.

Let t denote temperature in degrees Fahrenheit, t_0 being the initial temperature at the top surface of the slab. In Fig. 3, the subscripts 1, 2, 3, 4, and 5 denote the readings at corresponding temperature stations (spaced at depths Δy) after the first hour of radiant heat applied at the surface. Each station is considered to be the center of a volume of concrete extending halfway to each adjacent station. Since the cross-sectional area of each prism is equal to unity, the volume of the concrete (or prism) between each station is numerically equal to the distance Δy between stations.

It is assumed that the heat flow is in one direction only and that the temperatures of the deck and the air are the same at the beginning of the first hour of heat flow computations. The temperature change per hour at each station is equal to the average quantity of heat entering, and the average quantity of heat leaving, a volume during each hour. The quantity of heat entering and leaving each station depends upon the heat capacity of each volume in British Thermal Units (Btu) and the conductivity of concrete in Btu per hour per degree Fahrenheit.

The thermal diffusivity, which is the relation between heat conduction and the rate of temperature change, is equal to $\frac{k}{c\,\rho}$, in which k is the conductivity of concrete in Btu per hour per degree Fahrenheit, c is the specific heat per unit of weight, and ρ is the density of the concrete. For the numerical computations of heat flow through the slab the term $\frac{k}{c\,\rho}$ was taken as 1.00 sq ft per day.

The temperature distribution was computed for sections 1, 5, and 9 (Fig. 2), the results for sections 1 and 9 being shown in Fig. 4. The hourly surface temperatures were taken from actual readings on a concrete surface.[6] The temperature flow was computed on the basis of the method and assumptions stated previously.

Step 2. Angle Change Caused by Temperature Strain Distribution.—The strain on each fiber of the cross section is taken as equal to

$$\epsilon = \alpha\, \Delta t_f \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which α is the coefficient of thermal expansion of concrete, and Δt_f is the temperature change of each fiber in degrees Fahrenheit. The temperature distribution shown in Fig. 4 will also represent the strain distribution multiplied by $1/\alpha$. It can be seen from these curves that the temperature or strain distribution does not vary as a straight line. Furthermore, the strains are present only in the first foot or so of the slab depth. Angle-change computations are simplified with slight error by approximating a straight-line strain distribution as shown by the heavy dashed line in Fig. 4.

---

[8] "The Effect of Temperature Stresses in a Reinforced Rigid Concrete Frame," by Milan A. Johnston, thesis submitted to Univ. of Minnesota, in Minneapolis, in 1942 in partial fulfilment of the requirements for the degree of Master of Science, pp. 20–27.

Fig. 5(*a*) shows a single unrestrained section with temperature strains drawn in solid lines. The adjoining section is shown as a dashed line, having been rotated to touch the top and the bottom of the unrestrained section.

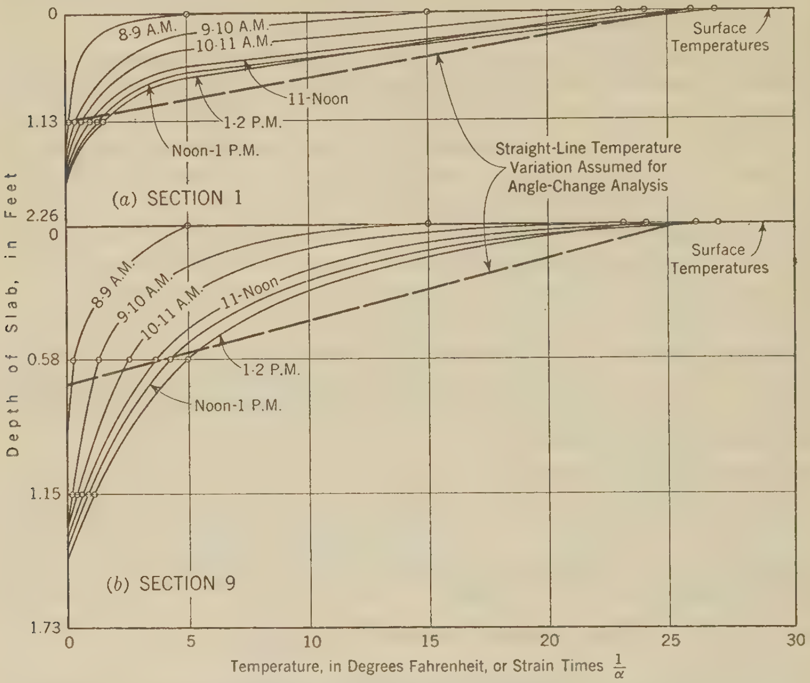

FIG. 4.—HOURLY TEMPERATURE RISE THROUGH GIVEN SECTIONS OF THE DECK, DUE TO THE HEAT OF RADIATION

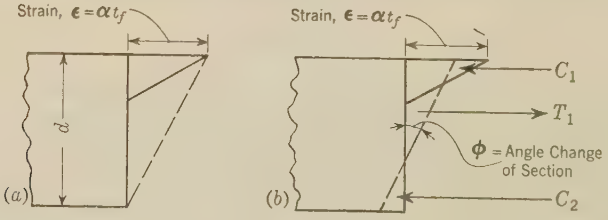
Since the surfaces or adjoining sections must actually be in continuous contact, and assuming that "a plane before bending remains plane after bending," it is necessary to continue the movement of both surfaces until all the boundaries meet between top and bottom of the section. This has been done in Fig. 5(*b*).



Strain, $\epsilon = \alpha t_f$
d
(*a*)
Strain, $\epsilon = \alpha t_f$
C_1
T_1
ϕ = Angle Change of Section
C_2
(*b*)

FIG. 5

The final position of the dashed line in Fig. 5(*b*) must be such that the summation of the horizontal forces and moments on the section is zero (ΣH and $\Sigma M = 0$; and also assuming that stress is proportional to strain). The movement of the surfaces to their final position (dashed line in Fig. 5(*b*)) will produce compressive forces C_1 and C_2 and a tensile force T_1. Since an algebraic solution for the final position of the section yields cumbersome equations, a semigraphic trial solution is used. This method is shown in Table 1, numerical computation being by slide rule.

TABLE 1.—SEMIGRAPHICAL TRIAL SOLUTION FOR ANGLE CHANGES AT A GIVEN SECTION OF DECK

[a] Unsatisfactory in the first trials but satisfactory in the second trials.

Assuming the coefficient of thermal expansion of concrete $\alpha = 0.0000065$, the angle change at the center line of section 1 of the rigid frame (see Fig. 2) is $\phi_1 = \dfrac{0.0000065 \times 11.6^\circ}{3.17 \text{ ft} \times 12 \text{ in.}} = 0.000002$ radian; and the angle change at section 9 is $\phi_9 = \dfrac{0.0000065 \times 13^\circ}{1.65 \text{ ft} \times 12 \text{ in.}} = 0.0000042$ radian. Similarly, the angle change at section 5 is found to be $\phi_5 = 0.0000035$ radian.

Inspection of these three sections shows that the angle change varies inversely as the depth of the section. For example, section 9 has an angle change approximately twice that of section 1 and its depth is one half of section 1. Similarly, section 5 has an angle change equal to 1.67 that of section 1, and its depth is equal to 0.606 times the depth of section 1.

Since the thickness of the deck (see Fig. 2) conforms with the parabolic equation,

$$y = \frac{(x - 40)^2}{2\,a} + 2.25 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

(in which a is a constant found from known boundary conditions = 310), it follows that the angle-change loading in this case is also parabolic. The angle-change loading for the deck is shown in Fig. 6.

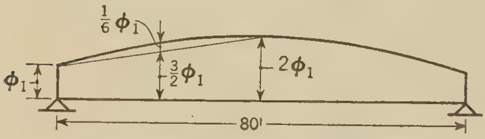

FIG. 6.—ANGLE-CHANGE LOADING OF DECK

Step 3. Computation of End Rotation in Basic Beam.—From Fig. 6, using the method of elastic weights,

$$R_e = \theta_A = \theta_B = \frac{\phi_1 + 2\,\phi_1}{2} \times \frac{L}{2} + \frac{2}{3} \times \frac{1}{6}\,\phi_1 \times \frac{L}{2}$$

$$= 40 \times 12 \left(\frac{3\,\phi_1}{2} + \frac{1}{9}\,\phi_1 \right) = 773\,\phi_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which R_e is the elastic reaction of the angle-change loading.

Step 4. Computation of End Rotation of Basic Beam Loaded with $\frac{M}{E\,I}$-Diagram.—Since in beams with fixed ends there can be no end rotation, it is necessary to apply moments at each end of the beam large enough to rotate the tangents back through the angles θ_A and θ_B. Since θ_A is equal to θ_B, the applied moments are equal. In this step, $\theta_A = \theta_B$ equals the elastic reactions of a beam loaded with the $\frac{M}{E\,I}$-diagram, or

$$\theta_A = \theta_B = \frac{M}{E} \sum_{0}^{40} \frac{\Delta s}{I_s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which Δs = the length of each deck division for use in the summation = 60 in. The summation equation (Eq. 5) is necessary since the moment of inertia of the deck is not constant. The moment of inertia of each segment I_s is equal to

$$I_s = \frac{1}{12}\,b\,(d')^3 + A_s\,(n - 1)\,\frac{d_s^2}{4} \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which b is assumed to be a transverse 12-in. strip of the deck; d' is the total depth of the section; A_s is the cross-section area of the steel reinforcement; $n = \frac{E_s}{E_c}$ = the ratio of the moduli of elasticity; and d_s is the distance between compression and tension steel, assuming neutral axis of section halfway between steel bars. Values of the ratio $\Delta s/I_s$, for use in Eq. 5, are:

Segment No.	$\frac{\Delta s}{I} \times 1{,}000$
1	0.325
2	0.480
3	0.712
4	1.063
5	1.450
6	1.900
7	2.280
8	2.295
$\sum \frac{\Delta s}{I} \times 1{,}000$	10.505

Step 5. Equating Steps 3 and 4 to Find Fixed-End Moment.—Combining Eqs. 4 and 5, $\frac{M}{E} \times \frac{10.505}{1{,}000} = 773\ \phi_1$; and

$$M = \frac{773\ \phi_1 E}{0.0105} \qquad (7)$$

If $\phi_1 = 0.000002 = 2 \times 10^{-6}$ radians and $E = 3 \times 10^6$, the fixed moment for the deck is $M = \frac{773 \times 2 \times 10^{-6} \times 3 \times 10^6}{0.0105} = 450{,}000$ in-lb.

Step 6. Distribution of Fixed-End Moments.—In this step the Hardy Cross method of moment distribution is used to find the final moments at the ends of the deck of each span, the stiffness and carry-over factors for the beams of varying moments of inertia being as shown in Fig. 7.[9] Accordingly, the final resisting moments in span BC, Fig. 7 (symmetrical about the center line) are:

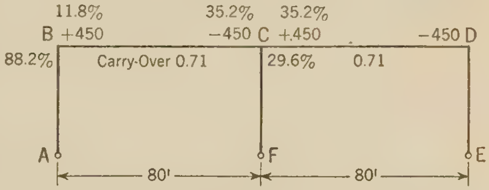

FIG. 7.—FIXED-END MOMENTS READY FOR DISTRIBUTION, SHOWING STIFFNESS FACTORS AND CARRY-OVER FACTORS

Description	End A	End B
Inch-kips	397.0	488.0
Foot-kips	33.1	40.6
Direction	Clockwise	Counterclockwise

The moment at the crown of span BC is the average of the end moments, or knee moments, plus the thrust at end B, multiplied by its arm to the center line of the deck at the crown: $\frac{33{,}100 + 40{,}600}{2} + \frac{33{,}100}{15.83} \times 1.28 = 36{,}850 + 2{,}670 = 39{,}520$ ft-lb.

---

[9] "Analysis of Rigid Frame Concrete Bridges," Portland Cement Assn., 11th Ed., 1936.

INTERPRETATION OF RESULTS

The moments M_{BC} and M_{CB} at the ends of the deck, caused by radiant heat, act in a direction opposite to the primary dead-load moments and live-load moments. Therefore, radiant heat causes no serious effects at these points. At the crown, however, the radiant-heat moment of 39,520 ft-lb acts in the same direction as the primary moments. The design moment at the crown for this particular frame included the following moments:

Description	Foot-pounds
Dead load	37,120
Live load	25,340
Impact	6,200
Shrinkage and movement of footings	25,500
Temperature change (−45° F) from a mean value	17,160
Total design moment	111,320

For this frame the radiant-heat moment at the crown equals $\frac{39{,}520}{68{,}660} \times 100$ or 57.5% of the primary moments, and $\frac{39{,}520}{111{,}320} \times 100$ or 35.5% of the total design moment. This represents a moment of considerable magnitude, and one which would necessitate the provision of additional steel were it not for the compensating seasonal temperature changes. The following relationships exist between these seasonal changes and the theoretical radiant-heat moment: (*a*) The maximum design moment at the crown includes the effect of a 45° F drop in temperature; and (*b*) the remaining 56% of the radiant-heat moment and its corresponding fiber stress effect are further reduced by a seasonal temperature rise.

(*a*) *Effect of a 45° F Drop in Temperature.*—The maximum design moment at the crown includes the effect of a 45° F drop in temperature. Accordingly, in this design there is steel and compressive area to resist 17,160 ft-lb of moment which would not occur on the days when the effect of radiant heat is greatest. This material would be available for $\frac{17{,}160}{39{,}520} \times 100$ or 44% of the radiant-heat moment at the crown.

(*b*) *Effect of a Seasonal Temperature Rise.*—The remaining 56% of the radiant-heat moment and its corresponding fiber stress effect are further reduced by a seasonal temperature rise. On the days when the radiant heat causes the greatest strains, the deck is probably elongating due to the rise in seasonal temperature. In addition, the axial strains in the deck, due to the radiant heat itself, increase the length of the deck somewhat. The effects of radiant heat and axial elongation counteract each other. Exactly how much the remaining 56% or 22,000 ft-lb is reduced is difficult to evaluate since radiant-heat stresses occur in short cycles whereas seasonal temperature elongation is a long-range process. It is possible that the reduction could be from a small amount on certain days to an amount corresponding to the maximum seasonal temperature rise. In this particular design, if one of the radiant-heat cycles occurred on the same day that the full seasonal elongation was effective, the reduction would be 17,120 ft-lb. The axial elongation accompanying the radiant-heat strain distribution is also difficult to compute because there is both elongation and contraction of the cross section as shown in Fig. 5(*b*).

CONCLUSIONS

The most definite design procedure to provide for the effects of radiant heat in a rigid frame is to include in the maximum design moment at the crown the moment due to a sizable seasonal temperature drop (−45° F or more for frames comparable in length to the one just analyzed). This should be done in states with warm climates, where radiant heat is likely to be high, even though the actual temperature drop is moderate.

The assumptions made in computing the heat flow through the slab due to radiant heat, in this paper, are on the conservative side. For example, the heat was assumed to flow in one direction only—downward into the slab. The effect that the main longitudinal steel may have on the temperature distribution was not taken into account. Temperature and shrinkage steel at right angles to the main longitudinal steel would also probably absorb some of lateral heat strain which surely exists. Practical measures, such as expansion joints in the slab itself, would relieve some of the strain. However, the magnitude of the moments that were found with the assumptions made should indicate a need for further study and discussion of this type of temperature stress. Possibly more uniform seasonal temperature change specifications will result.

Six conclusions seem reasonable on the basis of this paper:

1. The radiant-heat moments at the knee sections of the rigid frame would not affect the maximum combination of design moments as they act in a direction opposite to the dead-load and live-load moments.

2. The radiant-heat moment at the crown of the particular frame analyzed in this paper is equal to 35.5% of the maximum design moment and acts in the same direction as the dead-load and live-load moments.

3. If the maximum design moment at the crown includes the moment caused by a substantial seasonal temperature drop (45° F or more from a mean value), steel will be available for the radiant-heat stresses, as this temperature drop will not coincide with maximum radiant heat. Material was present in this design to account for 44% of the radiant-heat moment, corresponding to a 45° F drop in seasonal temperature.

4. Axial strains due to seasonal temperature rise and radiant heat itself reduce the effect of the radiant-heat moment, although it is difficult to ascertain exactly how much on any given day or radiant-heat cycle.

5. The magnitude of radiant-heat moment at the crown should warrant serious consideration of seasonal temperature specifications, particularly temperature drop, in the design of long-span reinforced-concrete rigid frames.

ACKNOWLEDGMENT

Material from which this paper was prepared was taken from a thesis by the writer, entitled "The Effect of Temperature Stresses in a Reinforced Rigid Concrete Frame," presented in 1942 to the University of Minnesota, at Minneapolis, in partial fulfilment of the requirements for the degree of Master of Science. Constructive criticism and guidance in the preparation of the thesis were given by Prof. C. A. Hughes, formerly of the structural department at the University of Minnesota.

DISCUSSION

I. OESTERBLOM,[10] M. AM. SOC. C. E.—Had the author used a more restrictive title his paper would have had mathematical interest, limited, however, to the extent that it is based on the conventionally assumed (but approximate) relations between stress and strain. The paper does not seem to cover the subject of radiant heat as applied to frames.

Assuming that radiant heat comes from the sun, the investigator must begin with the basic radiation formula:

$$H = \sigma\, \epsilon_1\, \epsilon_2\, dA_1\, dA_2 \frac{\cos O_1 \cos O_2}{\pi L^2} (T^4_1 - T^4_2) \ldots\ldots\ldots\ldots (8)$$

Eq. 8 defines the quantity H that is radiated from dA_1 to dA_2 with radiating temperatures T_1 and T_2 (absolute), respectively. The symbols ϵ_1 and ϵ_2 represent the emissivities and σ represents the Stefan-Boltzmann constant. The angles of incidence (the symbols O_1 and O_2) may be set equal to zero for solar radiation, if a perpendicular plane is assumed at the earth.

With what is known about dimensions, distances, and temperatures, Eq. 8 gives a theoretical maximum value of the heat radiation on earth of about 400 Btu per sq ft per hr for any perpendicularly exposed area of black body emissivity—when no atmospheric interception occurs before the rays of the sun reach this area. Usually only 300 Btu is taken as the reduced maximum.

Some of this heat is absorbed, some is re-radiated into cosmic space to $-50°$ F, and some is re-radiated into the atmosphere. When the atmosphere is heavy only a part of the 300 Btu can reach the earth. Much of that which arrives is re-radiated to the heavily absorbent atmospheric moisture.

Then there is also the angle of incidence which, for construction planes, generally is not perpendicular to the rays of the sun. Here again the effect is very much reduced through the low value of O_2. In the middle of the day only roofs are heavily affected; and walls are very lightly affected. During the forenoons and afternoons even the walls are spared because the atmospheric penetration distance is so much extended. The over-all, all-day, picture thus is not a bad one.

The temperature of the air adjacent to any exposed area is now a function of the residual heat which is not re-radiated. It is not a function of that alone, however. The heat that has penetrated the atmosphere on its way from the sun must equal that which has been re-radiated into space, plus another portion which the construction is able to absorb and store or pass through to the interior. The second part must pass through the all-important surface film, a concentration of air molecules with definite thickness and temperature gradient which depends on the thermal balance and the convection velocity for its magnitude.

Even assuming that the residual heat is known, the establishment of a balance between the film and the interior is very difficult. Mass, and the shape of the construction, affect both heat storage and conduction, according to the Fourier laws, and the film is governed by the radiation and convection laws. Thus one must resort to guesses about film temperatures; but this can be done only if, afterward, one proves that the guesses were reasonably correct and that they actually apply to both film and construction.

---

[10] Engr., Carbide & Carbon Chemicals Corp., South Charleston, W. Va.

The author has assumed surface temperatures as reported by Frank B. Rowley and C. E. Lund of the University of Minnesota,[6] Minneapolis, Minn. One would like to know how high those temperatures were, how they varied during the day, how the surface was located, and what mass and form were below the exposed surface. This information would be useful not only to follow the author's reasoning, but also to enable an engineer to repeat the method for other cases, if it seems good enough. It is quite possible that, in the light of the foregoing argument, the "comparable surface" (see heading, "The Effect of Radiant Heat") computed in the "Numerical Example" is far different from the one that the author asks his readers to accept on faith. The proposed "comparable surface" is quite insufficient to establish reasonable similarity.

In setting up his numerical example, the reason for selecting a slab is not clear. In a thermal sense a frame element is not a slab, and in Fig. 2 it is not shown as such. Reference to the work of Roy W. Carlson,[7] Assoc. M. Am. Soc. C. E., and his (no doubt) very specialized and seemingly graphical solution is also questionable. It would be almost impossible to extend any graphical solution to a two-way, or a three-way, flow of heat, and that is the type of problem encountered in a frame element protected by walls. For an exposed frame, involving a four-way flow of heat, the possibility of extending a graphical solution is even more remote.

Ever since J. B. Fourier[11] first raised the question of flow and absorption of heat this problem has been treated extensively by various authorities, generally physicists and mathematicians (Laplace, Poisson, Green, Lamé, Heine, Liouville, Thompson (Lord Kelvin), and Riemann) and more recently also by engineers (Gurney, Heilman, King, McAdams, McMillan, Newman, Preston, Schack, Schmidt, and others). However, Fourier's theory does not take into account heat used for evaporation of water—free, adsorbed, or crystallic—which is present in most construction materials. There is a very definite and well-established procedure, therefore, by which to compute the thermal changes in bodies of various shapes.

A homogeneous section must be assumed (the problem is exceedingly difficult even so) and, therefore, reinforcement cannot be included in the setup. However, this fact is not important. The conductivity of steel is so high in relation to the heat-storage capacity that the disturbing influence through a very high diffusivity acting on the small area of reinforcement is insignificant.

The Fourier equation for heat flow through a prism—with the use of conventional symbols and the coordinate axes at one of the corners—reads as follows:

$$\alpha \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) = \frac{\partial u}{\partial \tau} \qquad (9)$$

---

[11] "Théorie du mouvement de la chaleur dans les corps solides," by J. B. Fourier, l'Académie Française, 1812.

in which the thermal diffusivity is given by α, the same as in the paper. Symbol τ denotes time, and

$$u = \frac{t_1 - t}{t_1 - t_o} \qquad (10)$$

is the temperature function, which expresses how far, in temperature increase, the point x,y has gone as compared to the ultimate possible change, when the uniform mass at temperature t_o has reached the surface temperature t_1 at that point.

The Fourier equation (Eq. 9) is for a two-way (or a four-way) flow of heat along the x-axis and the y-axis—in other words it applies to a rectangular prism only. By dropping one of the axes and making the equation apply to a slab, the solution becomes greatly simplified.

One can thus write, in trigonometric form:

$$S_x(\theta_x) = \frac{4}{\pi}\left[e^{-(0.5x)^2\theta} \sin\frac{\pi x}{2\,b_x} + \frac{1}{3}\,e^{-9(0.5x)^2\theta} \sin\frac{3\,\pi x}{2\,b_x} + \frac{1}{5}\,e^{-25(0.5x)^2\theta} \sin\frac{5\,\pi x}{2\,b_x} + \frac{1}{7}\,e^{-49(0.5x)^2\theta} \sin\frac{7\,\pi x}{2\,b_x} + \cdots\right] \qquad (11)$$

Values of $S_x(\theta_x)$ from Eq. 11 may be tabulated and charted so as to obtain a quick solution of specific problems. The symbol θ_x is defined as:

$$\theta_x = \frac{\alpha\,\tau}{b^2_x} \qquad (12)$$

in which b_x is the distance from the outer surface to the thermal center of the slab; and, as in Eq. 10:

$$S_x(\theta_x) = \frac{t_1 - t}{t_1 - t_o} \qquad (13)$$

The solution has been presented by many authorities following parallel methods. An outline derivation of Eq. 11 is offered by T. K. Sherwood and C. E. Reed[12] who in turn refer to H. S. Carslaw[13] for further details. The derivation of Eq. 11 has been presented by F. C. W. Olson and O. T. Schultz. All writers make a general acknowledgment to other helpful authorities.

For reintroducing the y-axis and finding the following simple solution for a two-way heat flow—

$$S_x(\theta_x)\,S_y(\theta_y) = u \qquad (14)$$

—credit is due especially to Albert B. Newman[14] who presented a proof that Eq. 14 is true. Thus, by taking two infinite slabs perpendicular to one another and finding $S(\theta)$ for each at a common point (x,y), the investigator is able to establish first the temperature function u (which is common to the two) and then the temperature for the point; and by solving Eq. 10 for the temperature t:

---

[13] "Mathematical Theory of the Conduction of Heat," by H. S. Carslaw, The Macmillan Co., London, 1921.

[14] "Heating and Cooling Rectangular and Cylindrical Solids," by Albert B. Newman, *Industrial and Engineering Chemistry*, May, 1936, p. 546.

$$t = t_1 - u\,(t_1 - t_o) \qquad (15)$$

Various graphs for the determination of $S(\theta)$ have been produced by H. P. Gurney and J. Lurey[15] although the logic supporting them has never been published. By the use of such special graphs the problem of a rectangular prism thus becomes quite simple: (1) Establish the relative location of the point x,y in terms of b_x and b_y; (2) indicate the diffusivity by $\alpha = \frac{k}{c\,\rho}$; (3) find the two values of θ by Eq. 12; (4) find the values of $S(\theta)$ by the charts; (5) combine the two values of $S(\theta)$ as shown by Eq. 14; and (6) find the temperature of the point by Eq. 15.

The complication introduced by variable surface temperatures now enters, and a problem already difficult (to find a rational solution such as Eq. 11) becomes almost impossible. The variable boundary conditions would make it impossible, and even if that were not so the variability cannot be expressed directly and rationally.

However, it is possible to assume that the average surface temperature is constant for the duration, and to compute the interior temperatures on the basis of this approximation. One would then be ready for the structural problem of stress, as soon as enough critical points had been computed. The effect of the thermal stress would be equivalent to a supplementary axial eccentric load.

For a section away from the walls one would have the top exposed and subject to high temperature. For a section next to a wall the top and one side would have higher temperatures than the inside faces. In all cases there would be set up an extra stress covering the entire area and not (as shown in Fig. 5) applied above the neutral axis only.

Fig. 5 is based on conventional approximations regarding stress and strain, and that is scarcely permissible when one ventures into a new field. The true answer must be ascertained first, and only then may one be allowed to look for reasonable simplifications. Serious consequences have followed opposite procedure. Did the London Bridge fail in 1832 because of the overextension of a method? Most likely it did not, because, when it was built, one did not know even the basic method; but the second Quebec Bridge fell—due to a fateful extrapolation of a limited formula—in 1916. Because of his misapplication of the basic thermal theory, as well as the original stress diagram due to load, the author should recompute his example so that comparable figures would be available as an illustration. Only the author can do this, on the basis of the assumed surface temperatures used in the example, but not stated in the paper. The stresses thus computed certainly would be substantially less than those reported in the paper. Indeed, if it were not for this probability there would have been many failures of many famous structures due to thermal stress.

---

[15] *Industrial and Engineering Chemistry*, 1923, p. 1170.

The integration of stress into deflections and moments is elementary, and many methods might be used for this purpose. The revision proposed in these notes will cause a surprise, however. A frame next to an outer wall would show lateral deflection and, as a result of that deflection, torsional shears would occur next to the supports. A point that is often overlooked should be given thought in this connection: One cannot assume an average temperature, arbitrarily, as a basis for computing temperature stresses. The basic temperature of the frame (the atmospheric temperature plus something added for chemical heat) is the one at which concrete takes its initial set when poured. The chemical heat is a relatively small item on ordinary frames but a heavy item on heavy construction. Cold weather construction thus gets a heavy, extra load during the summer and hot weather construction is subject to a considerable reduction.

The writer would like to summarize his criticism as follows: "David" went out to slay a "Goliath," but he did not search first for a slingshot, and thus this "Goliath" is still very much alive. Nevertheless, the entire profession should be highly grateful for the paper, because the author has ventured into highly dangerous and difficult territory which should have been explored extensively but which all research engineers have feared to enter. He may indeed have stirred into action many thoughtful but hesitant engineers who have constructive ideas to present.

It is not solar radiation alone that should be considered; neither is the concrete frame the most important structure. There are other sources of heat; and there is also fire, accidental fire. When one gives thought to this vast field it comes to mind at once that so little has been done to produce a safe design. Why? Because so little is known, or expressed in rational form.

This is true even in the important field of fireproofing. Suppose that a 3-in. fireproofing cover is safe for a given steel column. The same covering may be applied to another section where similar heat intensity is expected; and the column fails nevertheless because of a fanciful curiosity of shape and texture. Why? Simply because the diffusivities of compounded materials in relation to the areas they cover, and the flow paths they present, offer unlimited combinations of time and temperature, for which no one has ever found a rational formula.

N. M. NEWMARK,[16] ASSOC. M. AM. SOC. C. E.—So much essential information has been omitted from this paper that it is difficult to follow the author's reasoning, particularly in those places where mistakes seem obvious.

The curves shown in Fig. 4 for the temperatures at various times in two different sections of the deck have the correct general shape, but the numerical values are grossly inconsistent. Since the temperature rise does not extend very far into the slab in either case, it seems unreasonable that the variation of temperature with depth should be different for the two sections. One should expect to have the same temperatures at equal depths, and, moreover, these temperatures should be the same as in an infinitely deep slab at the same depth from the surface. One suspects from the figure that the author used increments of depth of different lengths for the two sections, and obtained different curves by reason of inaccuracies in his numerical procedure. If this is the case, the lower set of curves should be more dependable, and should apply to all sections of the bridge.

---

[16] Research Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

The explanation of the computation of angle change in step 2 is not easy to follow. The writer does not understand why the relatively tedious computation of Table 1 is necessary when the angle changes can be written directly if one knows the area of the depth-temperature strain curve and the position of its centroid. Let the area of the depth-temperature strain curve be denoted by Q, and let the distance from the top of the slab to the centroid of the area be denoted by y_0. Then the angle change ϕ is given by the equation

$$\phi = \frac{Q\,(c - y_0)}{I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which c is the distance from the top surface to the neutral axis of the section.

In addition, the direct strain at the neutral axis, ϵ_c, from which the axial elongations may be determined, is given by the relation

$$\epsilon_c = \frac{Q}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which A is the area of the cross section. Values of Q and y_0 were estimated from the lower curve in Fig. 4(*b*) with some difficulty since the scale of the drawing is small. The results were: $Q = 8.9\ \alpha$ ft-degrees and $y_0 = 0.24$ ft. The straight-line distribution given in the figure as an equivalent strain distribution leads to slightly different results—namely, $Q = 8.0\ \alpha$ ft-degrees and $y_0 = 0.21$ ft.

The latter set of values is used in the further calculations below, where it is assumed that these quantities are the same for all sections, in contradistinction to the author's assumptions. Angle changes for sections 1, 5, and 9 are computed in Table 2. With $\alpha = 0.0000065$ ft per ft per degree, the value of Q becomes 0.000052 ft. It will be noted that only the angle change at section 9 checks the author's value, since the author used different strain-distribution curves for the other sections. Incidentally, the units for angle change as given in the paper should be radians per inch. The author's diagram for angle-change loading is changed somewhat. The final values for fixed-end moments at B and C, estimated from the physical constants tabulated, are approximately +32.5 ft-

TABLE 2.—ANGLE CHANGES FOR SECTIONS 1, 5, AND 9

Description	Section 9	Section 5	Section 1
Depth d, in ft	2.27	2.75	4.53
Moment of inertia I, in ft⁴ per ft, $= \frac{d^3}{12}$	0.98	1.74	7.8
Distance to neutral axis $c = \frac{d}{2}$	1.14	1.38	2.27
$c - y_0$	0.93	1.17	2.06
Angle change ϕ, in radians per ft (Eq. 16)	0.000049	0.000035	0.000014
Angle change ϕ, in radians per in.	0.0000041	0.0000029	0.0000011
Strain ϵ_c at the neutral axis, in ft per ft (Eq. 17)	0.000023	0.000019	0.000011

kips instead of +37.5 ft-kips as given by the author (using the designer's convention where positive moment indicates compression in the top fibers).

The effect of the elongations at the neutral axis may be estimated as follows: The average strain is approximately 0.000018. This corresponds to an elongation of the neutral axis of 0.0014 ft. In order to bring the footings back to their proper position, rotations of joints B and D (Fig. 7) are required, of magnitude $\frac{0.0014}{15.84} = 0.00009$ radian. These correspond to fixed-end moments at B and C of magnitudes −7.4 ft-kips and +5.3 ft-kips, respectively, using the designer's convention.

With the author's numerical constants, the final moments in span BC are computed, as shown in Table 3. The final values are considerably less than those given by the author.

In interpreting these results, one factor completely neglected by the author must be taken into account. This factor is the stress due to the internal distortions caused by the nonuniform temperature. For example, if the deck were completely unrestrained at the ends, there would still be a statically balanced stress distribution at every cross section, corresponding to the conditions shown in Fig. 5(*b*). At section 9 the compressive strain at the top fiber, even if no moment acted at the section, is determined from the quantities in Table 2, as follows: $\epsilon = 27\,\alpha - 0.000023 - 0.000049 \times 1.14 = 0.000176 - 0.000023 - 0.000056 = 0.000097$. The neglected compressive stress is, therefore, 291 lb per sq in. There is also a compressive strain at the bottom of the section, of magnitude 0.000079 in. per in., and tensile strains near the middle of the section. These stresses or strains are to be added to the others computed, and are of the same order of magnitude.

TABLE 3.—FINAL TEMPERATURE MOMENTS, IN FOOT-KIPS (PLUS INDICATES COMPRESSION AT TOP FIBER)

Description	Point B of BC	Crown of BC	Point C of BC
Neglecting axial elongation	+28.7	+34.3	+35.2
Due to axial elongation	−8.5	−2.6	+4.7
Total moments	+20.2	+31.7	+39.9

The net effect in this structure is almost, but not quite, the same as if the only stresses introduced by the radiant heat were the compressive stresses near the top of the deck required to eliminate the temperature strains near the top. This is not unreasonable because of the great restraint given the deck by the short stiff columns.

The foregoing comments are made in order to clarify the method of calculation which may perhaps find utility for other problems. However, the writer would like to emphasize that the stresses due to temperature should not be considered in the same light as stresses due to loads. Temperature strains are fixed by the temperature conditions, but the stresses produced thereby are reduced when the load stresses are high since the effective modulus of elasticity of the material is reduced for high stresses. In a structure made of concrete or of structural steel, temperature stresses are generally secondary stresses, and do not ordinarily greatly impair the capacity of the structure to carry overloads, although at working loads the stresses may be fairly high. The question raised by Mr. Johnston—whether the temperature effects can always be neglected—is an important one. Certainly in the structure he has considered, the radiant-heat effects do not appear to be serious.

L. C. Hollister,[17] Assoc. M. Am. Soc. C. E.—The effects of radiant heat on reinforced-concrete rigid frames, as outlined in the paper, are very interesting. Most engineers have been aware that, in some climates, the differential temperatures within a member of a concrete frame could be rather large. However, they have not bothered to attempt an analysis of such stresses; the paper, therefore, should be a valuable contribution.

Mr. Johnston finds, for the example used, that stresses due to radiant heat amount to 35.5% of the total design moment. This is astonishingly high, and indicates that designers should not completely ignore the possibility that such a condition exists.

The California State Highway Bridge Department has built many so-called rigid frame structures. It is the practice of this department to design for 35° temperature rise and 45° temperature drop in the colder parts of the state, and 30° rise and 40° drop in the more moderate areas. Stresses due to shrinkage, equivalent to about 30° drop in temperature, are also considered. Spans for the reinforced-concrete rigid frames built in California vary from moderate lengths to 130 ft. Some have quite wide roadways, and others have rather sharp skews, all of which tend to add to the intensity of temperature stresses. Some of these structures could be subjected to relatively severe radiant-heat stresses. For instance, the Sacramento and San Joaquin valleys of California have large daily temperature ranges throughout the summer months. The daily change in temperature is from 30° to 50° and a change as high as 62° has been noted in some parts of the state. With an accumulation of heat on the surface of the slab, to 25° or 30° above air temperature, it would not be unreasonable to expect the differential temperature from top of slab to bottom of girder to be around 60°. This is approximately twice that used in the "Numerical Example" of the paper. These structures are inspected frequently and no signs of distress that might be attributed to temperature have been noted.

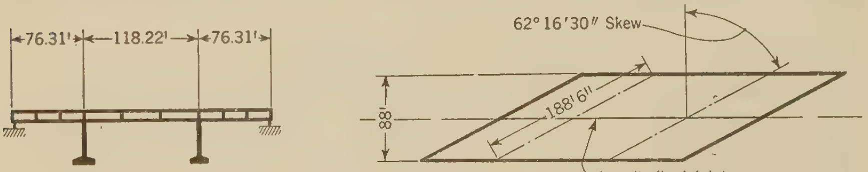

Fig. 8.—Bridge Across the Arroyo Seco Channel Near Hough Street, South Pasadena, Calif.

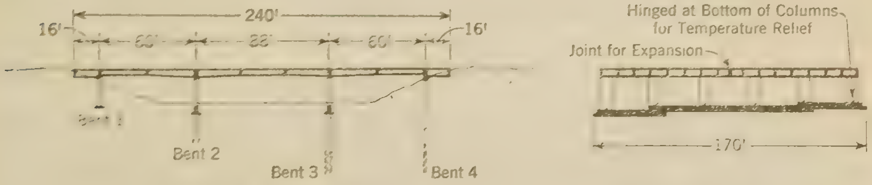
---

[17] Engr. of Design, State Bridge Dept., Sacramento, Calif.

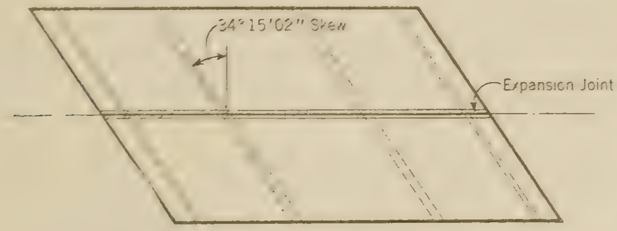
Some modern framed highway structures are becoming so wide and so severely skewed that stresses due to temperature are becoming increasingly important. For instance, several years ago the state constructed a reinforced-concrete frame structure with the dimensions shown in Fig. 8. The superstructure was provided with a longitudinal joint down the center; but the two main piers were one solid mass of concrete 4 ft 9 in. wide by 188 ft 6 in. long. Inspection reveals no distress in the superstructure that could be blamed on temperature or radiant heat. The piers, however, have cracks which are probably due to shrinkage. Other than this there appear to be no harmful effects of any kind.

Another example is afforded by Fig. 9. To relieve temperature stresses it was necessary to provide a longitudinal joint down the center of the superstructure, and also a joint in the cap of the pier at the center line. The bottoms of the columns are hinged to relieve temperature stresses.

It is regrettable that California does not have more specific data on the relative temperatures between top of slab and the interior parts of the girders, especially regarding some of the larger structures located in regions subject to high radiant heat.



(*a*) ELEVATION OF STRUCTURE (*b*) ELEVATION; BENTS 2 AND 3



(*c*) PLAN

Fig. 9.—Design of Undercrossing on Glendale Boulevard, Los Angeles, Calif.

The author has presented the paper in a clear, understandable manner, and outlines six well-defined steps necessary for the computation of radiant-heat stresses. The work of finding the angle changes at a given section would be somewhat more complicated for a T-beam or a box girder than for the example used; however, the same principle would apply.

Probably it will be a long time before designers are willing to go to the trouble of computing radiant-heat stresses as a regular practice. Nevertheless, it is well to have on record a method by which such stresses can be computed.

A. A. EREMIN,[18] ASSOC. M. AM. SOC. C. E.—That radiant heat has an important effect on the stresses in bridge frames, as stated by Mr. Johnston, is undeniable. However, the writer does not agree with conclusion 3, namely, that the radiant-heat effect on the maximum moment at the crown may be obtained by considering "a substantial seasonal temperature drop (45° F or more from a mean value)." The action of radiant heat is not the same as that of seasonal temperature variation. The primary effect of radiant heat is to rotate plane sections whereas the effect of seasonal temperature variation is to displace joints. Furthermore, the author's computation of the stresses resulting from radiant heat may be simplified so as to make unnecessary the substitution proposed by the author.

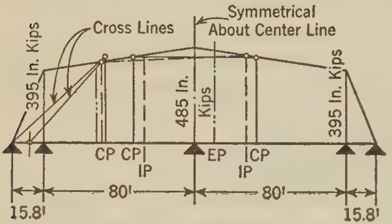


FIG. 10.—*M*-DIAGRAM

Radiant heat may be assumed to decrease uniformly along the slab section as shown in Fig. 5(*a*). Then, in the author's numerical example, the identical angular rotation of slab ($\phi = 2 \times 10^{-6}$ radians) may be obtained from Figs. 4 and 5(*a*) by assuming $t_f = 16.5°$. The end rotations of a beam may be expressed as

$$\theta_A = \theta_B = (e + e_0)\frac{L}{I} \dots\dots\dots\dots\dots\dots\dots (18)$$

in which the constants e and e_0 vary with the shape of member and are read from prepared diagrams.[19] For the slab in Fig. 2, $e = 0.168$ and $e_0 = 0.112$. Substituting the values of constants in Eq. 18, $\theta_A = \theta_B = 10{,}300$, which is very close to the value computed by the author.

Fixed-end moments induced by radiant heat may be distributed graphically by the use of "cross lines," as shown in Fig. 10. From the foregoing it is evident that the effect of radiant heat can be computed very quickly without the analogy proposed by the author. The best result is always obtained by a direct estimate of the cause.

MILAN A. JOHNSTON,[20] JUN. AM. SOC. C. E.—As Mr. Oesterblom states, the problem of flow and absorption of heat through solid bodies has been treated extensively by many authorities. Because of this fact and for the sake of brevity, the writer purposely omitted a detailed analysis of the equations for obtaining the heat flow of curves of Figs. 4(*a*) and 4(*b*) in the paper.

However, since Mr. Oesterblom is under the misapprehension that the temperature curves of Figs. 4(*a*) and 4(*b*) are the result of a graphical solution; and, since both he and Professor Newmark raise other pertinent questions regarding the assumptions made in determining the radiant-heat temperature flow, the writer welcomes this opportunity to discuss the subject more completely.

---

[18] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[19] "Analysis of Continuous Frames by Graphical Distribution of Moments," by A. A. Eremin, Sacramento, Calif., 1943.

[20] Asst. Prof., Mech. Eng. Dept., Univ. of Minnesota, Minneapolis, Minn.

First of all, it did not occur to the writer that any reader would assume the paper was attempting to cover any other subject than radiant heat as applied to reinforced-concrete rigid frame highway bridges. The particular case illustrated in the paper was the "barrel type" concrete deck poured monolithically so as to act as an integral unit with the supporting legs. The width of the deck of the so-called rigid frame structure is so large in comparison with the thickness that it certainly can be regarded as a slab with the exception of the elements close to the edges and the ends. There will, of course, be heat loss through the outside vertical edge of the slab, but this local effect can be neglected for all practical purposes because of the aforementioned ratio of horizontal surface exposed to slab thickness. Mr. Oesterblom's objection to the use of a slab instead of the entire area of the rigid frame for the temperature load is pertinent to a treatise attempting to cover the subject of radiant heat as applied to a series of isolated or single rigid frames used for industrial structures, but seems to be irrelevant for the particular structure used in the numerical example of the paper.

Although Mr. Oesterblom's discussion of the variables and guesswork confronting the investigator attempting a theoretical computation of film and surface temperature rise due to radiant heat was interesting, it should be made clear that the writer was already aware of this fact. This was evidenced by the writer's statement that "A theoretical calculation of the surface temperature rise [of the deck] necessarily must take into account so many assumptions and variables that it would be not only approximate but impracticable."

In view of the aforementioned assumptions, experimental or actual readings of the hourly variations of surface temperature rise (above the air temperature) due to radiant heat were used as a known quantity in the heat transfer equations for tracing the flow of heat to the interior of the slab.

The surface readings were taken on a horizontal 6-in.-thick concrete slab, with top dimensions of approximately 4 ft by 6 ft. The slab was blocked up to waist height to allow free passage of air under it. Readings were taken by thermocouples embedded at the surface of the slab. The hourly rise of the surface temperature above the air temperature can be seen by inspection of Fig. 4 of the paper. Thus, at 9 a.m., the temperature of the concrete surface had risen 5° F above air temperature; at 10 a.m., 15° F; at 11 a.m., 23° F; etc. At 1 p.m., a maximum of 27° F above air temperature was recorded. These readings were the average of readings taken on two consecutive hot days.

Although it is not claimed that these readings are the same as would occur on actual rigid frame decks in the field, it does seem reasonable to assume that the readings are an indication of the magnitude of surface temperature variation which can occur. Hence, the statement of "comparable surface," to which Mr. Oesterblom voiced an objection.

The equations for tracing the heat flow into the interior of the slab, using the aforementioned experimental hourly surface values as known variables, apply to one-way heat flow through a slab. Their solution is an algebraic, not a graphical, one.

Professor Newmark is correct in assuming that the temperatures in Fig. 4 should be the same at equal depths for the several sections of the deck. A projection of the computed points (shown as small circles) at depth 1.13 ft, section 1, Fig. 4(*a*), down to the curves interposed between the computed points at depths 1.15 ft and 0.58 ft section 9, Fig. 4(*b*), shows the temperatures to be the same opposite depth 1.13 ft, section 9. Similarly, computed points at depth 0.58 ft, section 9, will intercept approximately the same temperatures on the curves of section 1 at 0.58 ft. Unfortunately, the ordinates or depths of the two sections were drawn to different scales in Fig. 4, causing other points on the interposed curves between the computed points to be somewhat in error.

The equations used to compute the temperatures at each station will give equal temperatures at the same depth for each section. The only limitation is that the same number of temperature stations must be used for comparison between sections of different depths.

The writer is also indebted to Professor Newmark for the method of finding the angle change ϕ by Eq. 16. This method eliminates the necessity of approximating a straight-line temperature-depth strain relation, and will simplify the writer's angle-change computations, providing a planimeter is used to find the area Q under the maximum temperature-depth strain curve. Integrating to find the area Q under the curve becomes involved because of the complexity of the equation for the maximum curve.

Mr. Eremin's objection to conclusion 3 would be valid if the conclusion read as he restates it: "* * * that the radiant-heat effect on the maximum moment at the crown may be obtained by considering 'a substantial seasonal temperature drop' * * *." However, Mr. Eremin has evidently misinterpreted the meaning of conclusion 3 which actually reads, "If the maximum design moment at the crown includes the moment caused by a substantial seasonal temperature drop * * * steel will be available for the radiant-heat stresses, as this temperature drop will not coincide with the maximum radiant heat."

Conclusion 3 states, in effect, that both radiant heat and seasonal temperature drop create moments, and subsequently fiber stresses, at the crown which necessitate the addition of steel (or extra cross section). It does not imply that the analysis for obtaining radiant-heat moments is the same as the analysis for obtaining seasonal temperature moments.

Mr. Eremin's use of prepared diagrams to compare the end rotations of the basic beam is interesting. Most design offices do make use of prepared diagrams as labor and time-saving devices.

The author was pleased to learn from Mr. Hollister that the California State Highway Bridge Department designs for a temperature drop of from 40° F to 45° F. As was stated previously, the resulting steel from this design temperature is available to resist about 50% of the radiant-heat moment. Safety factors on the primary dead and live load stresses and other practical measures, such as expansion joints, will also help to eliminate temperature cracks.

CORRELATING FLOOD CONTROL AND WATER SUPPLY, LOS ANGELES COASTAL PLAIN

By Finley B. Laverty,[1] M. Am. Soc. C. E.

With Discussion by Messrs. A. L. Sonderegger, Warren N. Thayer, George B. Gleason, and Finley B. Laverty

Synopsis

Depletion of ground-water supplies by the heavy draft of new war industries has reemphasized the importance of water conservation in Los Angeles County, California, and other arid sections of western United States. The scope of this paper is limited to a description of the use of flood control reservoirs to supplement normal surface water supplies as well as underground storage; a description of development of, and a presentation of data obtained from, extensive off-stream flood water spreading grounds used to replenish ground water by percolation; and data gathered on the quality of flood waters.

Flood control works in Los Angeles County consist of three principal types—dams, channels, and water spreading grounds. Each of these takes a part in the water supply of the Los Angeles Coastal Plain. Since its inception as a State District in 1916, Los Angeles County Flood Control District has carried on a program of development of flood control and water conservation works. At present this system includes 18 dams and 18 debris basins, controlling 447 sq miles of mountain watershed; 226 miles of permanently or temporarily improved flood channels; about 2,500 check dams; and 7 water spreading grounds located adjacent to some of these channels.

It is unusual to operate reservoirs for both flood control and water conservation. Yet this dual function is necessary—first, to cope with the intense storms which frequently occur in the Los Angeles area making flood control of prime importance during the storm season; and second, to meet the demands of a high degree of agricultural development in a naturally arid region by conserving water which would otherwise waste to the ocean. Consequently, the reservoirs are operated primarily for flood regulation during the period of the greatest likelihood of severe storms, which is from December into March.

Note.—Published in June, 1945, *Proceedings*. Positions and titles are those in effect when the paper or discussion was received for publication.

FIG. 1.—DAMS, GROUND-WATER BASINS, AND SPREADING GROUNDS, LOS ANGELES COUNTY FLOOD CONTROL DISTRICT, CALIFORNIA

During this period regulated releases often increase contributions to ground water from stream-bed percolation; and off-stream spreading grounds are operated whenever the quantity of water stored and the probable period between storms warrant constructing temporary diversion dams in natural river beds, or operating permanent diversion works in improved channels. After the middle of March, flood control regulating capacity is gradually encroached on until the middle of April when all available surplus stream flow is stored. This accumulated storage is used for direct domestic and agricultural supply. Any additional reservoir water is put into underground storage by percolation in channels and spreading grounds. In this manner the cycle is completed and the reservoirs are ready for flood regulation prior to the next storm season.

Pertinent data relative to the principal mountain reservoirs (Fig. 1), listed from west to east, are presented in Table 1. These data show that for years of plentiful water supply the storage capacity of the reservoirs is relatively small. This emphasizes the importance of utilizing the large underground reservoirs in the alluvial filled valleys below. The tabulation also shows that very little of the peak flows of severe storms can be detained for spreading.

[a] Except in Col. 2, all units are in acre-feet. [b] Averages are for the number of years shown in parentheses.
[c] Does not include the Pasadena Water Department diversion to direct use above the reservoir.

This paper will set forth: (1) Examples of direct use of flood waters conserved in the reservoirs; (2) water spreading practices in this area, and some of the problems encountered, together with percolation rates under various conditions; and (3) water analysis data based on samples taken from flood waters.

DIRECT USE OF STORED FLOOD WATERS

Practically all the reservoirs listed in Table 1 serve to increase the supply of water furnished by these streams for direct domestic or agricultural use. A few of these uses will be described (see also Fig. 1).

Pacoima reservoir, controlling a drainage area of 27.8 sq miles in the western portion of the Sierra Madre, lies above valuable agricultural and residential areas in the San Fernando Valley. Annually, 1,000 to 2,000 acre-ft of the stored flood waters are released to the stream and picked up by downstream diversions for irrigation of several hundred acres of citrus groves. Since the stream above the reservoir is dry in the late summer and fall months, this supply is of large value to the ranches which would otherwise have as their only local supply a very limited ground-water basin. Additional stored flood waters are percolated in the spreading areas downstream.

Devils Gate Dam controls a mountain drainage area of 31.9 sq miles including principally the Arroyo Seco northwest of Pasadena. Here the reservoir area is owned by the City of Pasadena which has constructed galleries under, and wells adjacent to, the reservoir bed for the purpose of extracting an urban water supply. The storage in the reservoir is the primary means of supplying the galleries. These galleries had functioned well for several decades prior to the forest fire and subsequent mud flows in the fall and winter of 1933–1934, but the organic matter carried by these mud flows so increased the carbon dioxide content that the reduced amount of water percolating to the galleries has since been useless. Recently the District has conducted sluicing operations, using stream flow to scour the overburden from the reservoir bed. Results indicate that further sluicing, particularly with the aid of improved facilities, will succeed in regaining this source of water supply.

San Dimas Dam, Puddingstone Diversion Dam, and Puddingstone reservoir offer the most complete conservation system so far constructed for direct water supply. Flood flows originating in the 19 sq miles of San Dimas Canyon are regulated by San Dimas reservoir and Puddingstone Diversion reservoir and diverted through a 2.7 mile concrete channel (capacity 3,500 cu ft per sec) into Puddingstone reservoir. This entire storage may be utilized for irrigating 2,700 acres which constitute one of the most productive citrus areas in Los Angeles County. This system made it possible to conserve the entire runoff of the heavy storm of March, 1938, amounting to 9,365 acre-ft, and also that of the storm of January, 1943, amounting to 6,835 acre-ft. This salvage created an asset worth at least $15 an acre-ft for irrigation use. Puddingstone reservoir has a capacity to spillway of 17,900 acre-ft. Subsequent use of this stored water in lieu of pumping has aided ground-water basins Nos. 7 and 8 (Fig. 1) to regain sufficient storage to cope with withdrawals during dry years. The rise in water table underlying this agricultural area, since 1938, has ranged from 65 to 175 ft.

San Gabriel Canyon flows are regulated by the Flood Control District's Dams No. 1 and No. 2, and by Morris Dam which creates a 36,000 acre-ft water conservation reservoir (owned by the Metropolitan Water District of Southern California). The flows from this and near-by tributary areas will eventually be controlled by the Santa Fe and Whittier Narrows reservoirs as part of the flood control program of the United States Engineer Department. The reservoir system in the San Gabriel Canyon mountain drainage area of 210 sq miles also furnishes the means of conserving the most important local source of water supply in Los Angeles County. The first 135 cu ft per sec of normal flow is allocated to direct diversion for irrigation of citrus lands. Of this flow 90 cu ft per sec also forms a steady winter-time source of power generation which seldom falls below 30 cu ft per sec during the summer months.

The remainder of the flows which can be salvaged (Table 1) are available (*a*) for storage as direct water supply, or (*b*) through the medium of pumping from underground basins after storing in these basins by means of channel and off-stream spreading ground percolation. Subsequent discussion will deal specifically with spreading on the San Gabriel River.

WATER CONSERVATION BY SPREADING

Extensive spreading ground development was first undertaken in Los Angeles County in 1906 at the mouth of San Antonio Canyon. Since then, the District has developed 1,300 acres, and other agencies 765 acres, of percolating area utilizing one or more methods.

General methods of water spreading practiced in Southern California are (1) the ditch and furrow method, (2) the basin method, and (3) percolation of regulated flows in natural stream beds. All three have modifications or variations, and often are used in conjunction with each other.

(*1*) *The Ditch and Furrow Method.*—This is generally used in areas of very rough or sloping terrain, where the water at times may have a heavy silt content. Canals and ditches are laid out roughly on contours with sufficient slope to prevent deposit of the suspended material, yet flat enough to prevent scour of the waterways. Due to variation of soils across the spreading area, the proper slope is often quite difficult to determine, yet may be corrected after construction by installation of check gates.

A modification of this method is to install main canals, as broad as possible and with shallow depth, from which smaller ditches at regular intervals lead the water out and spread it over the ground, much in the same manner as flood irrigation. Water not absorbed by the flooded area flows to the next lower main distribution canal by which it is again distributed to a series of smaller ditches and their flooding area.

Advantages of the ditch method and its variations are the low costs of maintenance and operation when the works are once correctly installed. When so constructed that the main channels may be flushed, this method will handle a greater silt content than any other type. An objection to this system is that the percentage of the total spreading grounds in direct contact with the water is very low, usually not more than 10% or 12% as compared with 75% or 80% for basins.

(*2*) *The Basin Method.*—In its simplest form this involves the construction of dikes or small dams at regular intervals across the abandoned natural channels on a debris cone or former river-bed areas outside of controlled channels. The water is led into the upper basin by means of a canal and from succeeding basins, as each fills, it spills to the next; or the canal may extend past and feed basins on each side. From the last basin the waste water is returned to the flood channel. The upper basins may serve as desilting ponds and prevent excessive silt from being deposited in the lower ponds. During recent years the basin method has been used predominantly due to its economic use of land.

(*3*) *Stream Channel Spreading.*—In some form this method is practiced on most major streams in Southern California. All these streams are subject

FIG. 2.—INITIAL TEMPORARY DEVELOPMENT OF RIO HONDO COASTAL BASIN SPREADING GROUNDS UTILIZING BASIN AND CANAL SYSTEM

to flash flows of short duration, but of comparatively high rate. On the lower valley areas this condition results in a broad, flat, sandy bed which is dry during the summer months and during most winter months normally has a surface flow covering but a small portion of its area.

For several years conservation associations and county agencies have diverted the streams in these areas and spread them by various systems. Where the stream channels are composed of materials that tend to consolidate and seal off, the stream bed is broken up by tractors dragging cultivators or plows. In flat sandy stretches, the stream is diverted into plowed furrows. Temporary basins are also constructed by furrowing machines on these flood plains. In these ways water from a narrow meandering channel may be made to cover a considerable portion of a wide wash.

In Practice.—The general procedure followed in selecting spreading areas involves an initial study of ground-water use and supply. From these data and measurements of stream-flow percolation under existing conditions, the quantity of water which it would be desirable to handle in off-stream spreading grounds is determined. The possible locations of the spreading areas relative to geologic features of the ground-water basin concerned, ground-water level range, and general soil characteristics which would indicate the precolating capacity are studied. Promising areas are checked to depths of 30 ft or more by test holes to reveal the presence of clay lenses and other soil conditions which would have an important effect on the long-time spreading rate.

Following study of these data, if a local water supply of a few cubic feet per second is available, a small sample basin is often tested for a period of several weeks to obtain further data on percolation rates. When the most suitable set of conditions has been ascertained, the ground is purchased and developed on a temporary basis—that is, with wooden intake, canal and basin structures, and a temporary sand dam for diversion from the stream. This development is operated full scale until the data derived warrant revision or replacement of the structures.

An initial 40-acre temporary development at the Rio Hondo Coastal Basin spreading grounds, constructed in 1938, is illustrated in Figs. 2 and 3. The canal is controlled by a 25 ft wide 5-bay flashboard intake faced with a 20 ft wide 4-bay flashboard sluiceway which governs the head available for the canal and enables discharge for river percolation as well as sluicing of sand from the forebay. At all drops or outlets, flow gages or recording gages are installed. The canal can handle a flow of 200 cu ft per sec (to care for additional development). The cost of developing this area was approximately $10,000; the water conserved is worth at least $10 an acre-ft in the ground.

It is estimated that the cost of spreading, including the wooden structures (retired on a 10-yr basis), interest, maintenance, and operation, amounts to less than $5 per acre-ft of water spread. With several hundred acres of coastal basin spreading grounds completely developed, the cost might be as little as $3 per acre-ft for conservation of the long-time average available flow which would otherwise waste to the ocean. (Cost of retirement of land was not included in these unit charges as the value is not impaired.) This average flow is calculated to amount to a minimum of 10,000 acre-ft annually.

Adjacent to these spreading grounds the Rio Hondo channel has been intensively developed (Fig. 4). This is a typical example of the coverage which may be obtained by the use of a large plow and occasional checks to redistribute the flow. Of course, it is only practical to set up this type of intensive river spreading for regulated flows to be released after the storm season. The work performed is also instrumental in spreading the next

season's storm flows until low water channels have been created again. The equipment used was a specially constructed plow capable of making a furrow from 2½ to 3 ft deep and was drawn by a 70- or 80-hp tractor. The check levees were constructed by bulldozer. One hundred ten acres developed in this manner percolated approximately 150 cu ft per sec, with rather high ground water.

Fig. 4.—Rio Hondo Channel Adjacent to Spreading Grounds

Some Spreading Problems.—Intensive study has been given to both useful and economic means of conserving San Gabriel Canyon flows for use in the two principal ground-water basins over which the river and its distributary, the Rio Hondo, flow (see Fig. 1, basins 3 and 24). The upper, known as the Main Basin, including the area from the mouth of the canyon near Azusa on the north to the vicinity of Whittier and Montebello on the south, and from Alhambra on the west to Covina on the east, has a capacity between experienced ground-water levels of 615,000 acre-ft. It is overlain by 61,000 acres of irrigated land.

The lower basin, known as the Central Coastal Basin, is also largely agricultural, having an area of 99,000 irrigated acres. Its useful capacity is approximately 275,000 acre-ft. While the upper basin is of consistently porous material typical of upper portions of a detrital cone, the lower basin contains porous material in only the upper five miles along the courses of the rivers. The balance is overlain by clay strata which controls an intermittently artesian pressure supply.

Replenishment of the Main Basin is accomplished readily by percolation in the stream channels and the normal spreading which will automatically occur in Santa Fe reservoir. Percolation of flows in the Main Basin has supplied interesting data relative to the distribution of ground water dependent on the location of percolation.

Fig. 5 shows the course of the San Gabriel River and its distributary, the Rio Hondo, through the Main Basin. Prior to the construction of the Santa Fe Dam and reservoir, the 200% of normal rainfall during the season of 1940–1941 provided a large volume of canyon flow which traversed the channels. These channels split near the upper portion of the reservoir site, and the contribution of percolation from the channels to the ground-water body was very significant. The dashed ground-water contours indicate the distribution occurring principally from this stream-bed percolation. In comparison, the full line contours show conditions following the 160% normal rainfall season of 1942–1943 when the Rio Hondo was cut off from percolation and the principal source of contribution to ground water was from percolation in Santa Fe reservoir and flows released down the San Gabriel River. It is evident that the latter condition spread the ground water over the broad front of the cone making full use of available storage instead of concentrating ground-water ridges under the channels. Knowledge of such characteristics is particularly helpful in handling spreading works in relation to developed areas which are subject to high ground-water difficulties.

In contrast to the easily replenished Main Basin, the Coastal Basin has been depleted to such an extent that, in certain areas, sea-water intrusion threatens the quality of its supply. Hence, it is in this basin that the Flood Control District has developed its primary off-stream spreading works. The works now developed in the upper portion of this basin (Fig. 1, spreading areas 8, 9, and 10) consist of 240 acres adjacent to the San Gabriel River and Rio Hondo, a portion of which has been operated since 1938. Operations have included test runs to determine the characteristics of the spreading grounds as well as routine use between winter storms and percolation of flows stored in reservoirs during spring months.

Valuable data have been gained relative to percolation of water under varying ground-water conditions. The principal factors determined have been percolation rates, relation of shape of spreading grounds to outlying areas, effect of depth of water in basins, and effect of ground-water mound. Rates obtained have varied from initial values of 9 cu ft per sec per wetted acre to final values under high ground-water conditions of 0.9 cu ft per sec per wetted acre, the latter having held constant for many weeks of continuous spreading.

FIG. 5.—COMPARISON OF GROUND-WATER LEVELS AT SANTA FE DAM AND VICINITY

When the normal water table is less than 25 ft from the surface it has been found that spreading quickly builds a water mound up to the surface of the spreading basins. Consequently the water percolated in these basins, which would normally descend vertically to a low water table, can only move away from the spreading area at its periphery. This indicates the value of elongated spreading grounds. Fortunately, the best natural sites are the natural stream benches of these rivers. Consequently, the most inexpensive land is often the best shaped and situated area for spreading.

Tests for effect of various depths of impounded water in basins, relative to percolation rates, indicate that, when the percolating water has a free escape, surface depth has little effect. However, when ground water is in contact with the water in the basin, an increase in the depth from an average of 1 ft to an average of 2 ft may increase the percolation rate as much as 20%.

Ground-water mound—that is, the tendency of the underground water surface to build up to a higher elevation immediately under the stream bed or spreading area—is probably the most important factor governing percolation rate in porous soil. Tests along the San Gabriel River have indicated that, when the normal water table is less than 20 ft from the ground surface, continuous percolation will result in the mound reaching the stream surface within a period of a few days and thereafter will reduce the percolation rate. Hence, the economy of creating water supply in underground storage at any location may be affected largely by the normal depth to ground water.

Data on Percolation Rates.—Obviously, each spreading ground location offers benefits and problems which can be ascertained only from trial operation. Hence, a concise summary of percolation rates obtained at the several spreading grounds which the District has operated, together with pertinent comparative material at each location, should be useful. In Table 2, these are given for seven spreading grounds and three additional locations at which temporary tests were conducted. A further description of the areas in Fig. 1 and Table 2 is as follows:

Area 14.—This area is on both sides of San Antonio Wash below the mouth of the canyon. The soil (Col. 8) is a coarse sand containing a large proportion of gravel and stones. Subsurface exploration revealed gravel, and gravel containing boulders, as far as the water table.

Area 11.—This area is at the mouth of the Big Dalton Canyon. The soil (Col. 8) is a porous, gravelly, sandy loam containing a variable proportion of large and small stones.

Area 12.—This area is at the mouth of the Little Dalton Canyon. The acres (Col. 3) are only partly developed. The soil (Col. 8) is the same as in area 11.

Area 6.—This area is on the east side of the San Gabriel River channel below the mouth of the canyon. The soil (Col. 8) is a coarse micaceous sand, such as that found west and southwest of Azusa, containing large quantities of stones. Subsurface exploration revealed gravel and gravel mixed with boulders to a depth of 255 ft.

Area 9.—This area is on the west side of the San Gabriel River channel. In the gross area of 94 acres (Col. 3) only 73 acres have been developed. The soil (Col. 8) is a medium textured, friable, micaceous sand containing a proportion of fine sand and silt in the subsoil. Subsurface exploration in the upper area revealed: Sand from the surface to 10 ft, sand and gravel to 70 ft, clay to 80 ft, and sand and gravel to 120 ft; and in the lower area: Soil and sand from the surface to 7 ft, sand and gravel to 8.5 ft, fine silty sand to 12.5 ft, and silty sand to 14 ft.

Area 8.—This area is on the east side of the Rio Hondo channel. Of the 309 acres gross area (Col. 3), only 160 acres are developed. The maximum initial percolation rate at the apex of the ground-water mound (Col. 5) was 2.0 whereas the maximum initial rate for the area was 9.0. The soil (Col. 8) is a light-textured, micaceous, friable, fine, sandy soil containing stratified

[a] B = basin type, D = ditch type, and O = shallow overflow type. [b] Maximum initial rates (Col. 5) and minimum rates after an extended run (Col. 6) are given in cubic feet per second per wetted acre (Col. 4). [c] Mean percolation rate for the area. [d] Apex of ground-water mound at the level of the basin beds. [e] Temporary testing grounds. [f] 1.5 in Col. 5 is the mean value for a month with clear-water flow and 0.7 in Col. 6 is the mean value for a month following silty storm flows.

deposits of sand, silt, and gravel in the subsoil. Subsurface exploration revealed alternate strata of sand and gravel with 2-ft layers of clay at depths of 58 ft and 115 ft.

Area 1.—This area is on both sides of Pacoima Wash. The percolation rates (Col. 6) and the capacities (Col. 7) are averages of 26 days of silty flows and 16 days of clear-water flows, the latter on cultivated basins. The soil (Col. 8) is the same as area 8 except in the south half of the east side. This part is Hanford gravelly sandy loam, a coarse, sandy loam with a large percentage of granitic gravel. Subsurface exploration revealed that underlying the recent alluvium, at depths of 10 ft to 20 ft, is a less permeable surface of weathered old alluvium. Beneath this material there is sand and gravel with a 20-ft layer of clay at a depth of 220 ft.

Area 19.—In the upstream part of the San Gabriel Cone, Area 19, the river wash (Col. 8) was composed of undifferentiated alluvial deposits. It was generally very coarse and stony soil, the finer material having been washed away. Subsurface explorations revealed sand, gravel, and boulders to a depth of 260 ft. To blast the overflow channel, thirty holes were driven 10 ft apart and 3 ft deep. Each hole was charged with six $\frac{7}{8}$-in. sticks of 40% dynamite which formed craters 3 ft deep. The off-channel contour basins were interconnected to permit the circulation of water. A shutdown of two hours resulted in a 15% reduction (to 85% of 5.0) in the percolation rate for these off-channel basins. The rate of 3.8 is the average for 72 days.

In the downstream part of the San Gabriel Cone, Area 19, the soil (Col. 8) differs from the upstream part in that there is a scarcity of gravel and stones on the surface. Subsurface exploration revealed a medium gravel to a depth of 200 ft.

In the farthest downstream area on the south side of Rio Hondo (Area 19), the soil (Col. 8) is a brown, friable, micaceous, sandy loam, open and porous. There is a 6-ft layer of such soil, underlain with sand and gravel.

The area data emphasize the economic use of land by the basin method. Spreading areas 6, 11, and 14 (Fig. 1) were set aside as spreading grounds when land was relatively cheap. Equipment for development was scarce and hence "ditch" spreading solved the problem of conserving the flows available at that time.

San Antonio spreading grounds (Fig. 1, spreading area 14) is an unusual layout. It lies at the apex of the cone immediately below the canyon of the same name. The tributary uncontrolled watershed of some 30 sq miles rises to an elevation of 10,000 ft. A large portion of the runoff results from melting snow and is therefore often prolonged into the late spring—a condition which makes spreading without reservoir control and storage quite practicable.

In order to cope with storm conditions, basins have been constructed on the east side of the stream, into which flows up to 400 cu ft per sec of sand and silt-laden water can be diverted, stored, partially desilted, and circulated for percolation. These are used but a short period for flash flows, after which the water characteristically clears rapidly. When the solid content has reduced to 0.5% or less, the water is turned into the ditch and basin system on the west side of the stream. These spreading grounds have absorbed practically all the dry season flows and a maximum of 26,630 acre-ft, which was 93% of the total runoff during the 200% of normal rainfall season of 1940–1941. They are practically the sole source of supply, other than direct rainfall, for ground-water basins 11, 12, and 14 (Fig. 1) which are covered by citrus ranches.

Table 2 shows that percolation rates in terms of cubic feet per second per wetted acre vary widely with location. Maximum initial rates under low ground-water conditions are quite high for all locations because these locations are on recent alluvial cones or in river beds.

Areas 8 and 9, already discussed in some detail, were recently developed where land available for spreading is limited and land costs are high. During 1933 Area 1 was developed as a model canal and ditch system. Later experience gained from test basins indicated the probability of better economic use of the area. Hence, half of the grounds have been completed recently as a canal-basin layout. The rates shown in Table 2 were obtained during the transition and despite the old alluvium noted at shallow depths, it appears that the average rate will be increased to 2 cu ft per sec per wetted acre for even slightly silty flows. The ditch system wetted area was 12% of the acreage while the basin system covers 80%.

Extended periods of spreading bring into play factors such as clay lenses, control of finer sands, spreading of silty flows, and rising ground water. A study of the surface soil type, log of subsurface materials, and depth to water table emphasizes these characteristics.

Under Area 19 data are tabulated for temporary test spreading grounds (1) on coarse porous stony soil; (2) on brush land containing considerable gravel; and (3) on an area in which sand predominates.

(1) On the stony soil the initial test was in a well-sealed overflow channel in the San Gabriel River. Sealing had been by deposit of silt between the rocks and by calciferous cementation. The blasting experiment was undertaken primarily to break up this sealing. Its effect was pronounced.

Later tests on the same type of stony soil were conducted on an off-channel area of approximately 15 acres. Many years previous, this area had been a portion of the river bed during major floods, but was not sealed by either silt or calciferous deposits. Clear water was diverted to contour basins which spilled from one to the next, thereby providing slow circulation through the basins. As long as the test continued uninterrupted, the water sank at the rate of 10 ft a day. This unusually high rate continued for several weeks until the shutdown of the regulating dam upstream dried up the basins temporarily, although the soil did not have a chance to dry out. When the basins were filled a few hours later, the percolation rate had reduced approximately 15%. A similar sequence has been noted on several other spreading areas having considerably finer soil.

(2) Tests on brush land were undertaken to compare with percolation rates on barren areas which have been scoured by stream flow. Water was sunk by sheet overflow and from still ponds as compared with the basins described under (1). Although the base soil was somewhat finer, it is believed that the

lack of circulation as well as the fines introduced by growth of vegetation were the principal factors in giving a reduced percolation rate. Experience on several soil types and with water almost clear or slightly silty has indicated a definite benefit from pond velocities as low as 0.05 ft per sec. In addition to carrying fine particles through the basins, even this slow movement discourages the concentration of algae and the scum it leaves on basin beds.

(3) Tests on a quite sandy soil in the flood area of a natural river bed gave an opportunity to check the relation of percolation through the natural crust formed by a small amount of silt and calciferous action, and that through the same ground after cultivation. Although the differential found was more pronounced than has been experienced in larger scale operation, nevertheless the trend was the same.

Comparative Water Analyses

It is pertinent to compare the qualities of the supply available from local mountain and valley storm waters with other sources of water supply available to the Los Angeles Basin. Table 3 presents such a comparison through the medium of samples from storm and after-storm flows, which were taken during the storm seasons from 1932 to 1934. The data were gathered as a cooperative project of the Sanitary Group of the Los Angeles Section of the American Society of Civil Engineers and the Flood Control District. Laboratory facilities arranged by R. F. Goudey, M. Am. Soc. C. E., were an important contribution in analyzing the flood waters.

Despite the fact that it has been several years since the data were obtained, it is believed that the values on other supplies are representative with the exception of the water which the Metropolitan Water District is furnishing the Coastal Plain from its Colorado River source. Although study of the data reveals many interesting comparisons, those that are perhaps the most significant will be mentioned.

The pH-value of the local mountain and valley flood water averages about 7.6, which is comparable to other supplies. Chlorides are all within the drinking water range and generally average the same as other available supplies. The total hardness is less or not greater than the average local supply.

Nitrites and nitrates are generally lower than free ammonia, showing that there is nitrogen that needs to be oxidized in order to have stable water. However, most samples show sufficient dissolved oxygen to accomplish this oxidation. Organic nitrogen was generally equal to or less than that in aqueduct water. The higher values were from the upper Los Angeles River—that is, valley water having its source in farming lands.

The comparison of dissolved oxygen and oxygen demand as shown by B.O.D. from 21 mountain water samples shows only 5 with excess B.O.D., and only 1 of the 5 was from an after-storm flow, indicating further evidence of the stability of the water. The majority of mountain water samples compare well with those from the High Sierras brought in by the Owens River aqueduct.

Color and turbidity, and suspended solids furnish the prime difference between storm waters and other supplies. The after-storm flows are generally better in respect to these factors and reservoir storage readily corrects the excess derived from storm flows.

The greater part of the total solids is comprised of suspended solids. The analysis divided suspended solids into the subdivisions of quickly falling solids and those remaining in suspension. The division was found to be at a size of approximately 25 microns. The data from this division indicate that more than 50% of the suspended solids might be classed as quickly falling—that is, those which would drop immediately upon contacting relatively still water.

TABLE 3.—COMPARISON OF LOCAL STORM WATERS WITH OTHER SOURCES OF WATER SUPPLY AVAILABLE TO THE LOS ANGELES BASIN

Although the copious rainfall since 1936 has filled many of the ground-water basins in the Los Angeles area nearly to capacity, the importance of maintaining these supplies through artificial replenishment is emphasized by recent war-industry draft and the fact that approximately 75% of the water supply of the area is derived from this source and direct mountain stream flow.

It is hoped that this paper will stimulate interest in the presentation of further data on many phases of this work.

ACKNOWLEDGMENTS

The writer is indebted to L. W. Jordan, Assoc. M. Am. Soc. C. E., for assistance in assembling and checking data, and to Paul Baumann, M. Am. Soc. C. E., for review of material presented herein. Lt.-Col. H. E. Hedger, M. Am. Soc. C. E., is Chief Engineer of the Flood Control District (on leave with the Armed Forces). M. E. Salsbury, M. Am. Soc. C. E., is Acting Chief Engineer, and Mr. Baumann is Assistant Chief Engineer in charge of the work described in this paper; the writer directs the operation of reservoirs and the layout, testing, and operation of conservation works, and Mr. Jordan supervises office and field work on ground-water and spreading studies, and conservation operations.

DISCUSSION

A. L. **Sonderegger**,[2] M. Am. Soc. C. E.—Clear statements of the principal methods applied in the utilization of flood waste by spreading and of the correlation of flood control and water conservation, as practiced by the Los Angeles County Flood Control District, are presented in this paper. Conservation by spreading is supplementary to, and an improvement on, the natural process of seepage from stream beds on the debris cone and also supplementary to the natural cyclic regulation of water supplies by underground storage which is peculiar to Southern California. It is this natural regulation which has made possible the development of this area and which has carried its population with immunity through a period of predominantly dry years which extended from 1922 to the latter part of the 1930's.

Referring first to the quality of conservation water, Table 3 shows what was to be expected—namely, that the storm runoff from the granitic watersheds of the Sierra Madre is stable, organically pure, and potable from the standpoint of total dissolved solids. The total hardness of 80 of Southern California storm water appears to be high, but compares favorably with the total hardness of 25 of the Mono Basin snow water and of aqueduct water of 96, which in part is fed from snow fields.

Cols. 2 and 3, Table 3, indicate that the comparatively short-time contact of the "after storm runoff" with the disintegrated soil cover of the watershed materially increases the percentage of dissolved solids and the hardness. This tends to prove that disintegration and decomposition of the granitic formation make some of the constituent components available for solution. This conclusion is further borne out by the fact that storage in ground-water basins and the long-period contact with alluvial deposits materially increase the dissolved solids. This is apparent from a comparison of the analysis of mountain water "during storm" (Col. 2, Table 3) and valley water "after storm" (Col. 5, Table 3), the latter being a mixture of "after storm" mountain runoff and rising ground water. The proportion of sulfur hydroxide increased from 28 ppm to 93 ppm, chloride from 24 ppm to 36 ppm, and total hardness from 80 ppm to 177 ppm. The relatively harmless increase in dissolved solids by underground storage is compensated by the preservation of the purity and potability of the water for indefinite periods.

Conditions, more severe, result from reservoir storage in the mountain watershed. Under natural conditions, the periodic scour of canyons by floods, small and great, removes decayed vegetable matter, ashes, and other impurities. With the interception of all debris, fine and coarse, in storage reservoirs, or behind debris barriers, this flushing process remains incomplete, with the result that silt and ashes accumulate above dams, decaying debris is piled up in stagnant pools, and a growth of a multiplicity of organic life may be induced, including Crenothrix. Nevertheless, the more important fact remains that water supplies are conserved by impounding, and if they are of inferior quality modern methods of purification are able to cope with them.

---

[2] Cons. Engr., Los Angeles, Calif.

The volume of water that can be salvaged in wet years by spreading is substantial and is directly dependent upon available storage and the methods of operating flood-control reservoirs. The most complete plans for flood control and conservation are those for the San Gabriel River prepared jointly by the Los Angeles County Flood Control District, and the U. S. Engineer Department. Available storage as of 1945 is as follows:

Dam	Storage in acre-ft
San Gabriel No. 2	12,000
San Gabriel No. 1	47,000
Morris	36,000
Santa Fe	30,000
Whittier Narrows	....

Assuming the proportion of the total storage at Morris Dam available for flood control as 18,000 acre-ft, and the proportion of the combined total storage at Santa Fe Dam and Whittier Narrows Dam as 10,000 acre-ft, the total storage available for purposes of conservation will be 85,000 acre-ft. Under these conditions the Flood Control District estimates the net seasonal salvage available for the valley above the Narrows at 3,000 acre-ft and for the coastal plain at 12,700 acre-ft. The total is 15,700 acre-ft, which is 11.5% of the mean seasonal runoff of 136,000 acre-ft at the mouth of the canyon and 18½% of the conservation storage.

In 1924 an estimate of possible salvage of flood waste was made for a report on the water supply of the metropolitan area of Los Angeles by a board of engineers composed of the late J. B. Lippincott, Hon. M. Am. Soc. C. E., Louis C. Hill, Past-President, Am. Soc. C. E., and the writer. Under the assumption of an available storage of 200,000 acre-ft then planned at San Gabriel site No. 1, the estimated salvage for San Gabriel River watershed was 34,000 acre-ft per acre or 17% of the conservation storage, and this quantity was credited in the report to the ultimate local water supply available for the Los Angeles metropolitan area.

Mr. Laverty refers to the first spreading development in Los Angeles County, on San Antonio Creek cone above Pomona in 1906. An interesting story is connected with the initiation of spreading in that area. In the 1890's, there was a beeman by the name of Arenz, of whom it was said that he truly had "a bee in his bonnet." Arenz noticed that along the wet washes in the upper San Antonio Creek cone there was a more vigorous growth of brush and a more luxurious bloom than along the dry channels. More bloom meant more food for the bees, and more food for the bees meant more honey in the hives; so in order to promote the growth of brush over wider areas he conceived the ingenious idea of diverting and spreading the stream artificially. This practice continued over some years and as a matter of fact ripened into a right of appropriation. After the turn of the century, a great development of citrus began on the cones in that vicinity, after it had been proved that the debris deposits were an excellent medium for the propagation of citrus, particularly lemons. The ranchers, in need of more water supplies, realized the advantage of recharging the underflow by spreading the flood waters and a general movement for the appropriation of flood waste began. Some bright men realized that the beeman had acquired a priority to a substantial portion of the creek flow of the early spring months and they promptly bought him out. They continued the diversions, not for the propagation of brush however, but for ground-water recharge and in a subsequent action in the courts in 1912 successfully maintained their position and priority by proving that the spread water percolated to their wells and fed their ciénagas. The late F. E. Trask, M. Am. Soc. C. E., was the first engineer to practice water spreading in Southern California in the nineties.[3]

The question naturally arises as to the legal status of the spread water. A water right is established generally by diversion for beneficial use. The Los Angeles County Flood Control District is charged by Legislative Act with the conservation of flood water; but the District is not a water user and hence not an appropriator. After the water is diverted and spread, it changes its status from that of surface flow to that of percolating ground water and is then available for appropriation to overlying lands or for export. In most instances where conservation is practiced in this area, the diversions are made by incorporated conservation and protective associations who are not water users, but operate for their volunteer membership. Spread water mingling with natural seepage loses its identity, although not necessarily its status as appropriated water, provided the appropriator can trace his spread water to the point of abstraction. In the case of these associations, the member water users are not the original appropriators. Moreover, their wells may be many miles from the spreading grounds and widely distributed over the ground-water field. In closed basins, it is believed that the appropriator and impounder of floodwater may legally defend his right.

In the case of Pasadena vs. Alhambra,[4] relative to the adjudication of rights to the water supply of the Raymond ground-water basin in the Pasadena area, rights were established on the basis of pumping abstractions for beneficial use; no credit being awarded for the spreading of local supplies. As to possible rights to imported water, if spread in the basin, the situation is left open as indicated by the following quotation[5] from said judgment:

> "That nothing in this judgment contained shall be considered as a determination of the right of any party to water hereafter imported by it into the Raymond Basin Area and spread therein, with the intent to recapture the same."

After the destructive floods of 1914 and 1916, Los Angeles County undertook a program of flood control by the construction of reservoirs with the dual intent of regulating peak flow and conserving floodwaters. As a matter of fact, bond elections were carried on the issue of water conservation. A majority of the population had moved in after 1916 and were not familiar with local flood conditions; hence they did not grasp the necessity for flood control. However, they did realize the effects of dry years and the need for conserving flood waste.

[3] "Water Conservation in Southern California," by F. E. Trask, *The Rural Californian*, 1903.

[4] No. Pasadena C-1323 in the Superior Court of Los Angeles County, California, decided December 23, 1944.

[5] *Ibid.*, paragraph XVIII, p. 23.

During the recent protracted period of drought, public opinion and pressure were sufficiently strong to give conservation precedence over flood control and reservoirs were operated accordingly. Since the flood of 1938 a more cautious attitude in operating detention reservoirs has been adopted.

It is concluded, in the disposal of flood waste, that preference be given to: (1) Flood control, (2) conservation, and (3) quality of water—in the order of their economic importance.

The writer's opinion as to the relative importance of flood control and conservation may be expressed by paraphrasing one of the famous sayings of the late William Mulholland, M. Am. Soc. C. E., who, when campaigning in 1906 for a bond issue of $23,000,000 to finance the Los Angeles (Owens Valley) Aqueduct, told his audience: "If you don't get the water, you won't need it." If Southern California does not get flood control, it will not need conservation.

Warren N. Thayer,[6] Esq.—Flood control and water conservation methods as practiced in Los Angeles County are described adequately and concisely in this paper. In recent months some additional data have been obtained on the growth and dissipation of the ground-water mounds which need to be recorded.

Mounds and ridges on a water table (also cones of depression and troughs) are well-known ground-water phenomena in alluvial aquifers. They do not, and cannot, occur in aquifers that do not have potentially direct hydraulic continuity with the surface upon which the water is absorbed.

The principles governing the growth and dissipation of a ground-water mound are described in most textbooks on hydrology, and they are simple. When a drop of water enters the surface soil (after field capacity has been satisfied), it descends along a path as nearly vertical as possible until it reaches the water table. Then, the physical laws governing influent seepage stop functioning; the laws governing percolation begin to apply; and the rate of lateral movement of that drop of water in any direction depends on the $\frac{h}{l}$-ratio of the water table, modified by an appropriate coefficient of permeability, k. This rate is generally so much slower than the rate of vertical descent that a mound starts to build up; and, depending on the depth of the water table and the permeability of the aquifer, it may eventually reach the surface.

In January and February, 1946, it was possible to make some careful observations on the growth and dissipation of a large ground-water mound at the spreading grounds of the Rio Hondo Coastal Basin. Conditions were ideal.

---

[6] Geologist, Los Angeles County Flood Control Dist., Los Angeles, Calif.

The preceding year had been one of below normal rainfall, and the water table was falling. Spreading began on January 3 and ceased on January 23, after a continuous run. There was no rainfall during the period.

To determine what actually occurred beneath the surface, measurements of water-table elevations were made daily at about forty wells within a radius of about a mile, measured from the midpoint of the spreading grounds. Eight of the wells are on a practically straight line passing through the spreading grounds parallel to the channel (see Fig. 1); and four of them are on a practically straight line normal to the channel and passing through basin No. 4 (see Fig. 2).

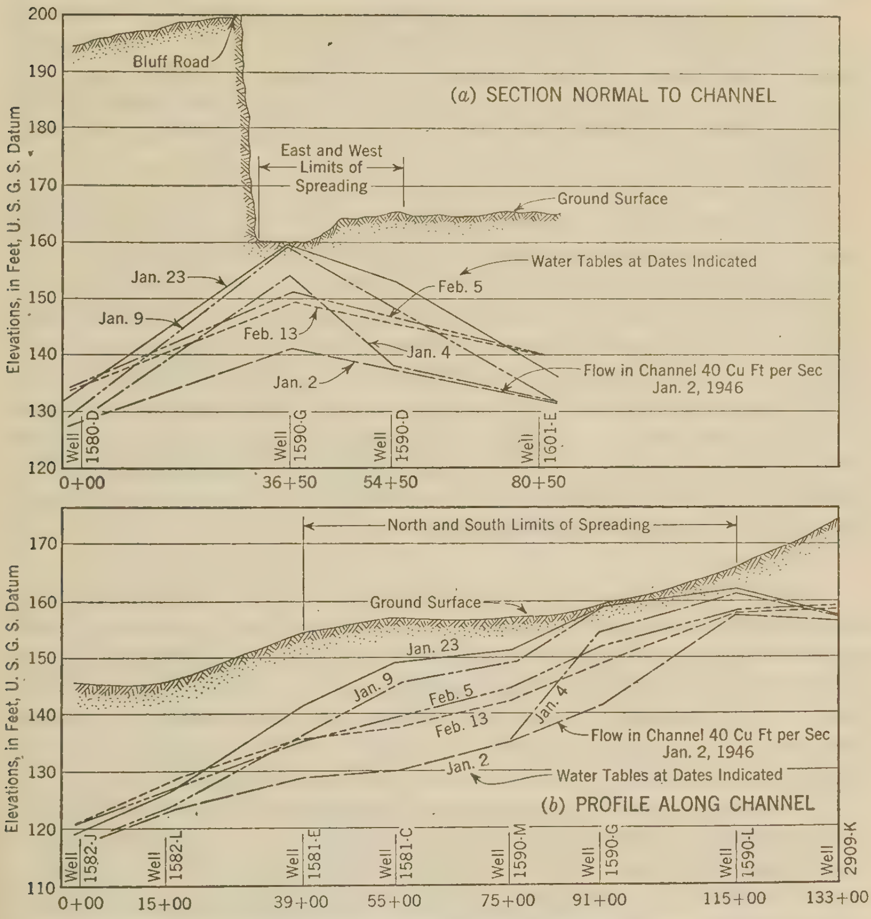

Fig. 6.—Study of Water-Table Elevations During a Spreading Period in January, 1946; Spreading Grounds, Rio Hondo Coastal Basin

Fig. 6 shows the water-table elevations along the two lines of wells on the day before spreading started (spreading started January 3, 1946), on three days during the spreading period, and on two days after spreading ceased (spreading ceased January 23, 1946). (Note the exaggeration of the vertical scales.) The day before spreading started the depth to water varied from 8 ft at the upstream end of the spreading grounds to more than 25 ft at the downstream end; and there was a low ground-water ridge under the spreading grounds (see Fig. 6(*a*), the section normal to the channel) because of a continuous flow of from 30 to 40 cu ft per sec in the channel for several months.

The day after spreading started (January 4), the water table had risen 4 ft at the upstream end of the grounds and 13 ft under basin No. 4. The spreading water had not yet reached the lower basins. Six days after spreading started (January 9) the ground water contacted the spreading water in basin No. 4; and the mound reached maximum height at that place, after rising 18 ft above the initial elevation.

About 3,500 ft downstream from basin No. 4 the mound also reached maximum height after rising 18 ft above the initial elevation, but the ground water did not meet the water in the spreading basins because the initial elevation had been farther below the ground surface. These facts verify the statements made in the paper that the normal depth to ground water is an important criterion in selecting spreading sites, and that the minimum depth for economic spreading in the coastal plain of Los Angeles County is from 20 ft to 25 ft.

After spreading ceased, the water table under the basins gradually dropped, but around the periphery of the mound it continued to rise for about three weeks as the water body sought its natural level. During the spreading period 4,800 acre-ft of water was absorbed in a wetted area of about 140 acres of spreading ground and adjacent channel.

GEORGE B. GLEASON,[7] ASSOC. M. AM. SOC. C. E.—Three beneficial purposes that may be served by spreading are indicated by the author: (1) The conservation of water which would otherwise waste; (2) the lessening of damage in areas of high water table through changing the location at which percolation occurs; and (3) the prevention of landward movement of sea water by increasing the elevation of the ground water near the coast. A fourth benefit might have been mentioned, namely, a possible reduction in the pumping lift.

In evaluating spreading, many factors are involved. Mr. Laverty has ably discussed those which fall within the scope of his paper. In the course of investigations conducted for many years by the California State Division of Water Resources in, and adjacent to, the area covered in the paper, others have been considered. When this is done it may in a particular instance be found among other things that: (1) Only a part of the spread water is actually conserved; (2) the intended purpose might be accomplished more effectively by other means; (3) the purpose might be accomplished equally well by other means at less cost; or (4) factors other than physical characteristics or economic considerations control. Within the area covered by the map (Fig. 1) are several basins that differ sufficiently in their significant characteristics to provide illustrative examples.

---

[7] Senior Hydr. Engr., California State Div. of Water Resources, Los Angeles, Calif.

The author states that Main San Gabriel Basin is readily replenished by percolation in the stream channels and from the Santa Fe Reservoir. He also shows the effect of changing the place of percolation as related to the area of high water table in the lower portion of the basin.

Reference to Fig. 5 shows that the general water table and ground surface are almost coincident between El Monte and the southwest corner of the area there mapped. This condition is the result of a pronounced constriction of the cross-section area through which the oceanward moving ground water in Main San Gabriel Basin must pass in leaving that basin and entering the Central Coastal Plain. Along the incised channels of San Gabriel River and Rio Hondo the general water table is above the ground surface so a portion of the outflow is on the surface in these streams.

Since the cross section at the constriction (Whittier Narrows) is about full at all times and the water-table slope must closely approximate that of the ground surface, the underflow is virtually constant. The so-called rising water (that which originates in the ground water of the basin but flows out on the surface) varies, however, with the general elevation of the water table in the basin. Since 1923, the relationship between water-table elevation at a long record well near Baldwin Park and the measured quantity of rising water at the Narrows during each year has been quite well defined.

One characteristic of Southern California weather, quite significant from a water supply standpoint, is that periods of several years averaging materially wetter than the long-time average, alternate with periods about equally long which are correspondingly dry. Water-table elevations at the long record well reflect this "cyclic" variation as well as the variations in supply and extractions during each year. In January, 1905, the water table stood at 282 ft above sea level. By May, 1916, it had risen to 329 ft above, had dropped again to elevation 257 ft by November, 1931, and in June, 1944, it again stood at 325 ft above sea level. In 1931–1932, rising water totaled about 31,000 acre-ft and in 1942–1943 about 86,000 acre-ft. Based on the relationship between water-table elevation and rising water mentioned in the preceding paragraph, rising water outflow in 1915–1916 is estimated to have been about 119,000 acre-ft.

Despite this wide range in rising water outflow—from 31,000 acre-ft to 119,000 acre-ft—considerable regulation of the still more widely varying supply to Main San Gabriel Basin is afforded by the changes in storage in the basin. It is estimated that each foot of rise or fall of the water table at the key well represents a change in storage of about 4,000 acre-ft in the area affected by San Gabriel River. Thus, between May, 1916, and November, 1931, a total of 288,000 acre-ft of water came out of storage in this portion of the basin. Only a little less has gone back in during the subsequent wet period.

By far the greater part of the rising water is diverted and used directly on the Central Coastal Plain, or percolates in the channels below the Narrows, or is available for spreading in areas numbered 8 and 9 in Fig. 1. Thus Main San Gabriel Basin not only stores water for use on overlying lands, but serves as a partial regulator of the supply to the Central Coastal Plain (basin 24). If the interests of the latter area alone were considered, the utilization of all possible regulatory storage capacity in the main basin, through spreading or otherwise adding to the ground water a greater part of the flood flows, would be beneficial. Any material increase in the water so salvaged would result, however, in raising both the average and peak elevations of the water table throughout the basin and so increasing the area near the Narrows which is already adversely affected by a high water table. Under the circumstances, the practice followed by the Los Angeles County Flood Control District, in limiting so far as may be, the percolation in Main San Gabriel Basin and spreading as much as possible in the grounds below the Narrows, cannot be justly criticized.

In evaluating spreading, it is worthy of note that in a basin like Main San Gabriel Basin, where the outflow of rising water is large, and where it responds quickly to changes in water-table elevation, the greatest benefit so far as conservation is concerned accrues to the basin below and requires that a part of the water be spread again there. Until the water table is so drawn down as to virtually eliminate the rising water, there is always ample water for use on lands overlying the upper basin, so benefit there is limited to that resulting from change in location of percolation, mentioned before, and from reduction in pumping lift.

The Central Coastal Plain Basin (No. 24, Fig. 1) is characterized by a relatively small forebay area into which water percolates and within which storage changes occur, and a larger pressure area into which percolation from the surface to pumping aquifers is negligible because of virtually impervious intervening strata, and changes in storage are very small because the aquifers are confined and are substantially full of water at all times.

In the forebay, the water table dropped some 50 ft during the dry period preceding 1934; it has refilled during the subsequent wet period, with a considerable flow across the basin onto the pressure area and thence to the ocean at times when the forebay was full. At a well not far from the lower boundary of the pressure area near Long Beach, the pressure level decreased a little more than 80 ft between 1922 and 1937 and has not again increased since that time. In October, 1945, it there stood 36 ft below sea level.

Although other wells in the vicinity have recovered a few feet, the rise has in no case approached that in the forebay area, and if the intended purpose is to protect against the intrusion of sea water some procedure other than spreading alone seems to be indicated. Since it appears that the deficiency is due to the resistance to movement of water through the restricted cross section of the confined aquifers, rather than to a lack of sufficient water at the source in the forebay area, reduction of the heavy extractions near the lower boundary of the pressure area would provide a solution. This would require that a substitute supply be provided, either by importation, by the use of water from some other source such as reclaimed sewage, or by transferring the pumping to a point nearer the forebay area.

The regulation of the cyclically varying supply to the Coastal Plain requires that large storage capacity be available there. The fact that some water wasted recently because there was not room for it in the basin shows that extractions during the dry period prior to 1934 were insufficient to draw down the water table far enough to provide the capacity necessary to hold the excess which was available during the wet period. Had the supply for the lower portion of the pressure area been pumped in the forebay area throughout the cycle more storage capacity would have been available near the end of the cycle and there would have been less waste.

The measure of the water conserved by spreading or by any other means is the amount by which the waste is reduced thereby. In this case the spread water caused the basin to fill sooner than it otherwise would have with the result that some water which would have percolated naturally, was wasted. Thus, only that part of the spread water which was required in addition to natural percolation to just fill the basin was actually conserved.

This leads to the conclusion, that, in a basin that fills periodically, the amount that can be conserved is limited by the amount of the extractions until such time as average extractions exceed average supply, in which case the basin will no longer fill. In a basin of this type any water spread during a particular cycle in excess of requirements during that cycle is not conserved. However, in those cases where storage capacity will ultimately be available to conserve the percolation from larger spreading grounds, the difference between present and probable future costs of acquisition and construction is a factor to be considered. In the interim at least a portion of the area will benefit from decreased pumping costs during periods when the basin is nearly full. In such a case economy dictates when the works should be constructed.

Pasadena area of Raymond Basin (basin 2, Fig. 1) differs from Main San Gabriel Basin in that outflow changes very little with water-table elevation, and from the Central Coastal Plain in that demand is as great as total supply and the basin does not fill. For many years prior to July, 1944, at which time, in accordance with the terms of a court decree, extractions were limited to the safe yield, the basin was overdrawn and the water table was lowered far below the surface over a large part of the area. Compliance with the terms of the decree requires a large auxiliary supply if the demand is to be satisfied. Any water conserved, therefore, decreases the amount that must be imported or otherwise provided. Any water that is spread is virtually all conserved.

In a basin of this type, spreading or otherwise adding to the ground water an amount considerably in excess of present needs, solely for the purpose of decreasing pumping costs, might prove feasible. For purposes of discussion it may be assumed that a 25-ft increase in average elevation of the water table throughout a long period of time would produce a negligible change in outflow. To produce this increase in elevation a total of about 40,000 acre-ft in excess of demand is required. The safe yield of the basin is about 12,000 acre-ft per yr.

Assuming this to be the amount pumped and that the 25-ft reduction in lift reduces the cost of pumping 1 acre-ft by 50¢, a total importation of 40,000 acre-ft produces an annual saving of $6,000, or 15¢ per acre-ft. This justifies an expenditure of a little less than $3.00 per acre-ft of water spread, imported or otherwise supplied. In this basin, so long as the assumption that increased water-table elevation does not result in increased outflow holds true, it makes no difference whether the importation is all in one year or spread over a period of time. The total determines the benefit. In the case of Main San Gabriel Basin, where outflow responds quickly to changes in water-table elevation, this would not be true.

It is physically possible to accomplish the other beneficial purposes enumerated earlier in the discussion; namely, protection against saline intrusion and improvement of conditions in areas of too high water table through the use of imported water, of reclaimed sewage, or of water obtained by some other means. Such use, as a substitute for water now pumped in the Central Coastal Plain near Long Beach, has been mentioned as one means of raising pressure levels there. In some cases it might prove feasible to build up a protecting ridge against sea-water contamination, by forcing fresh water directly into the aquifers through wells.

In San Gabriel Basin, the area adversely affected by high water table increases and decreases cyclically with variations in the local water supply. If a greater part of the flood waters were wasted during the wet period of the cycle, with heavy extractions continued during that period but with water from some other source substituted during the dry period, it would be physically possible to reduce the fluctuation of the water table to any desired degree and thus hold the adversely affected area to a minimum at all times.

Comparative cost to the consumer is one of the factors that determines the choice as between spreading and each of the other sources that might be available. The cost of water imported from a single source may vary considerably under different conditions. That brought from the Colorado River by the Metropolitan Water District of Southern California is an interesting example. In portions of the area which, at some time, may be served by it, untreated water is available. The price, as fixed by the policy of the District, is $8.00 per acre-ft. In other portions only softened water can be obtained through present facilities. The price of this water is $15.00 per acre-ft. In neither case does this cover the total cost of the water, the remainder being covered by assessment.

The policy of the District requires (1) that except in special cases water be furnished only to member entities and (2) that all back assessments must be paid regardless of the time when the entity joins the District.

The total cost of the water per acre-foot thus depends in part upon the amount taken and the assessed valuation of property within the boundaries of the entity and, for a considerable period of time, might exceed $40.00 to certain member cities. It might eventually be less than $10.00, plus local distribution costs in portions of the agricultural area easterly of the Metropolitan Water

District treatment plant, where raw water is available and assessed valuations not so high. In the case of a basin where the only choice is between spreading or joining the District and the demand at any time in the future can be satisfied by spreading alone, this total cost of Colorado River water provides the basis for comparison. On the other hand, if membership in the District will ultimately be required, the \$8.00 or \$15.00 charge per acre-ft of water controls. It is important to note that where increase in supply is the objective the comparison is between cost per acre-foot available to the consumer rather than between cost per acre-foot delivered at some particular point in the area by the District and cost per acre-foot spread. Likewise it is the total cost of obtaining any of the stated objectives which controls rather than a comparison of cost per acre-foot.

Several factors other than cost have an important bearing on the choice of procedure. One of these is comparative quality. The author presents a comparison of local storm waters with supplies available from certain other sources. Chemical analyses of Colorado River water reaching the treatment plant and of softened water leaving the plant are now available. Averages, in parts per million, by weight, for year ending June 30, 1945, are as follows:

Chemical	Natural	Softened
HCO_3	139	110
CO_3	0	4
SO_4	365	365
Cl	96	102
Ca	92	25
Mg	32.5	10.5
Total dissolved solids	783	796
Total Hardness:	363	106
Carbonate	114	96
Noncarbonate	249	10

For many purposes both this water and the waters described by the author are entirely satisfactory. For other uses additional treatment may be required and one source or the other is preferable. The prejudice against the direct use of treated sewage for domestic purposes is difficult to overcome and must be recognized. As was stated early in the discussion, factors other than physical characteristics and economic considerations sometimes control. In an area like that tributary to San Gabriel River, where a high stage of cultural development has been attained, the interests of one part of an area might best be served by one procedure; those in another part by another. Benefits to one entity might well result in injury to another. An organization like the Los Angeles County Flood Control District, which is authorized to spread, but not to import, water, must serve these diverse interests as equitably as possible.

The Metropolitan Water District, which has provided facilities through which an ample supply can be brought in, has been mentioned as a possible source of imported water. This supply is not actually available, however, to a particular area until the voters of that area are convinced that their interests are best served by joining the District and then only if the area is one considered suitable by the District.

In Main San Gabriel Basin no entity is a member at present (1946). In the Central Coastal Plain, Long Beach and Compton are members but both are still heavy producers from the ground water in the lower portion of the area. Until such time as a greater part of the area has a flexible source of auxiliary supply available to it and means are provided by which the cost of improving the pattern of pumping on the Coastal Plain can be distributed equitably, it is improbable that the ideal procedure can be followed. Consideration of all the factors involved, in order that the best procedure possible under the existing and most probable future circumstances may be worked out, however, is justified.

In Raymond Basin the problem posed by diversity of interests was solved through court action. All large producers of water were brought into a suit; a decree finally was entered which fixed the pumping rights of each at an amount such that the total would not exceed the safe yield; a watermaster was appointed to enforce the terms of the decree. The court retained jurisdiction and provided for modification of decreed rights with changes in safe yield. Through an exchange agreement which was incorporated in the decree, each entity has available to it whatever water is required in excess of its decreed right. Under this arrangement the cost of importation and benefits derived from spread water are shared. In this basin spreading can be evaluated accurately on the basis of comparative costs for equivalent benefits.

FINLEY B. LAVERTY,[8] M. AM. SOC. C. E.—Inasmuch as the prime purpose of the paper was to present basic data for which there had been considerable demand because of the size and varying conditions of the developments outlined, the discussions have pertained primarily to further basic considerations applying to water conservation.

From his long experience in Southern California Mr. Sonderegger has enlarged on several statements in the paper. Since flood control comes first, possibly the allocations to conservation storage may be best interpreted as follows: During the winter months, 10,000 acre-ft in San Gabriel No. 1 and San Gabriel No. 2 reservoirs (consisting of the pool storage to prevent encroachment of debris on outlets); and, during the spring months, a gradually increasing storage to the totals shown for the reservoirs in Table 1, Col. 3, plus approximately 18,000 acre-ft of Morris Reservoir capacity, or a total of approximately 72,000 acre-ft. Since Santa Fe and Whittier Narrows reservoirs are being constructed by the United States Engineer Department purely for flood control, no permanent conservation allotment can be accorded to the storage available in these two reservoirs.

Mr. Gleason's discussion has provided several interesting comments on the water-right phases of the ground-water problem mentioned by Mr. Sonderegger.

---

[8] Chief Hydr. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

The reservoir operating program of the Los Angeles County Flood Control District was the same prior to the 1938 flood as it has been since this flood—that is, the prevention of damage to persons and property adjacent to improved and unimproved valley channels by delaying and reducing flood flows until valley peaks have been dissipated through the use of storage as indicated in the first part of the paper. In storms of great magnitude, some of the reservoir capacities are too small for any regulation. This condition is emphasized by the fact that the majority of the data in Table 1, Col. 7, represent occurrences during the March 2, 1938, flood, which Mr. Sonderegger mentions. During this storm 24-hr runoffs, which did not exceed the reservoir capacity by more than from two to three times, had their peaks reduced and delayed very appreciably despite the fact that the storm of February 27 and 28 which immediately preceded the record storm was the largest which the majority of the reservoirs had experienced. Few engineers realize the meager warnings given of approach or termination of severe storms on the Pacific Coast, and particularly in Southern California. Until an adequate system of reports from weather ships and planes has been achieved, the detailed planning of flood control operation in these areas will often be but a matter of hours and, in some cases, even of minutes.

The additional information on the ground-water mound provided by Mr. Thayer furnishes an interesting check on the relation of the water table to spreading operations. Such a thorough network of wells, as that from which this information was gathered, is seldom available, and it would indeed be fortunate if other classic examples of ground-water phenomena could be reported to those interested in this field.

Mr. Gleason has presented a basic discussion of the relation of capacities of ground-water basins of various types to reduction of waste and also to economic considerations pertaining to other sources of water supply. In discussing the rising water derived from the Main San Gabriel Basin, he indicates a requirement that part of this water must be spread again in the Central Coastal Plain Basin; probably he intends to convey that this is natural channel spreading, for the channel capacities in the lower basin are normally adequate to percolate the rising water and therefore require no further operation expenditures.

Mr. Gleason also states that, despite several years of spreading operations in the Central Coastal Plain Basin, water levels have continued to drop, and sea water has continued to intrude in the Long Beach area near the lower boundary of the basin. This condition is attributed primarily to resistance to movement of water through the restricted cross section of confined aquifers. It would seem just as likely that the increased supply to this part of the basin has been absorbed by the extremely high demand of new water industries. No doubt the most immediate method of improving the situation is contained in one of Mr. Gleason's suggested substitute supplies—obtained by transferring the pumping point for principal users to a point nearer the location of water spreading in the forebay area. Such a solution would prevent further encroachment of ocean water and would much more nearly utilize the ground-water basin to salvage all water available for conservation.

The writer is indebted to Mr. Gleason for furnishing further data, as well as an example of the economic relation of local water conserved in underground basins to imported water, and also for presenting information on the adjudication of ground-water basins—a procedure which seems likely to become commonplace in areas where the safe yield of a single basin or related basins has been exceeded.

In addition to parts of the West where water spreading has been practiced for a considerable period, several new developments of this nature either are contemplated or have reached the stage of field tests. The soil types, percolation rates, and other pertinent conditions in these projects would undoubtedly add useful information to that which the writer has attempted to provide in this paper.

Synopsis

Some of the more important or unusual features of structural design of the dams and other hydraulic structures constructed by the Tennessee Valley Authority (TVA) are treated in this paper. The design of power plants is discussed in the remaining two papers. The hydraulic performance of such structures is beyond the scope of the Symposium. This paper is confined to a few principles and methods governing the design of the structures themselves—and to only those which are considered to have some degree of novelty. Some evidence or argument supporting such procedures is presented. The principal hydraulic structures of the TVA, of course, are the dams. As a background for the treatment of this subject Table 1, showing the location and the more important features of these dams, is presented.

Concrete Dams

It is held to be a fundamental principle of dam design that an impervious surface should be presented to the impounded water and that provisions should be made for the escape to tailwater of any seepage or leakage that may pass the tight surface or diaphragm.

The two first dams of the TVA (Norris and Wheeler) were designed by the Bureau of Reclamation, U. S. Department of the Interior, as gravity dams and the original construction plant was assembled to be suitable for this type of structure. Efforts have been made by the TVA to transfer construction equipment from job to job. For this reason there were certain advantages in adhering to the same general types of structure from job to job. Under general conditions on these projects, form costs tended to be high, whereas the cost of materials for mass concrete tended to be low, and such comparison of costs as has been made in general showed little difference in cost between gravity dams and other types of structure. Structures of the mass type present less surface to the action of weathering agencies than do those of the reinforced type, for example. The massive TVA structures are made of excellent concrete and future maintenance expense on account of any surface deterioration of the concrete may be expected to be less for the mass structure than for the reinforced one. For these reasons the concrete dams of the TVA have been designed as gravity structures. In accordance with the principle enunciated in the preceding paragraph, the effort has been made to obtain a surface as tight as possible at the upstream face. In the larger dams the upstream face has been constructed with an enriched concrete. In the smaller structures, a richer concrete has been used throughout.

Foundation Treatment and Uplift.—Considering the foundation as an essential part of the structure, elaborate cutoff grouting systems have been specified with a view to preventing seepage and uplift beneath the structures. Holes at a spacing as close as 2 ft have been drilled for this purpose. This grouting should be effective for many years and, in the course of time, it should become reinforced by the deposition of sediments in the reservoir bottom.

On the main river dams the foundations generally have consisted of calcareous rocks with approximately horizontal bedding considered favorable to the accumulation of uplift pressures in the foundation itself. For this reason these dams, as well as those on tributaries, have been provided with a definite drainage system consisting of vertical holes 8 ft to 10 ft apart, drilled 30 ft to 40 ft into rock downstream from the grouted cutoff (see Fig. 1). The purpose of these drains is to prevent the accumulation of any considerable upward pressure in the foundation rock. In addition to the foregoing, liberal drainage has been provided under the aprons of the spillways, including the drilling of vertical holes to tap any horizontal openings that might exist in the foundation. Although these were provided primarily for the protection of the apron itself, they contribute to the maintenance of low uplift pressures under the main dam.

Having provided the drains, it was logical to capitalize upon their presence. Accordingly, in the main river dams, which are of moderate head, the uplift assumption in the foundation for design purposes was restricted to tailwater pressures downstream from the line of drains. Uplift pressures would increase uniformly from tailwater pressure at the drains to headwater pressure at the upstream face of the dam. Pressures were assumed to be applied over two thirds of the area of the base of the dam. In these cases, as elsewhere, such resistance to horizontal movement as the apron might offer was neglected.

For the higher structures such as Hiwassee, Douglas, Cherokee, and Fontana (Fig. 2), it was felt that the foregoing rule was not quite conservative enough even with the close drainage system provided. In these cases the uplift assumption was modified so as to assume one half of headwater pressure at the line of drains—the pressure varying in a straight line to headwater and tailwater, respectively. The assumed area of two thirds of the base was retained.

As to the uplift effects in the concrete itself, concerning which there is considerable uncertainty, TVA engineers have assumed that the open contraction joints, which have been used uniformly, are in themselves relief points for uplift pressures. Inspection galleries would also be relief points. However, in the higher dams where there is an excess of 100 ft of head, drainage wells were built in the dam itself, substantially on the same line as the foundation drains, to provide a more definite relief for possible uplift accumulation in the concrete than would be afforded by the joints and galleries alone. Pressure distribution is assumed the same as that for the foundation.

FIG. 2.—SECTION THROUGH SPILLWAY, HIWASSEE DAM

Measurements of Uplift.—On Hiwassee, Douglas, Fontana, and Cherokee dams, a number of devices were installed to measure uplift in the foundation in the vicinity of the foundation contact. Fig. 3 shows a typical observation of this kind on Hiwassee Dam. Similar diagrams were prepared for three other stations in this dam as well as for similar stations in the other two dams, and they all have the same general character. The uplift pressure varies more or less uniformly from headwater to the drainage line where it is a minimum; between this drainage line and the toe of the dam there is a moderate rise and subsequent fall to the toe. Inspection of the drains and frequent measurements since construction have shown that this condition is stable and well within the design assumptions for the structures. Inspection also has shown that the drain outlets from the foundation continue to flow at a moderate rate. There is continuing evidence that the foundation drainage systems are functioning as intended.

The record of certain measurements of the pressure of pore water in the concrete at Hiwassee Dam, at various distances from the surface of the concrete, is presented in Fig. 4. Pressures were detected in 1943 at a depth of 12 ft. A gradual penetration of reservoir water is indicated. Of course, these observations indicate nothing as to the effective area of application of such pressures. (It is to be noted that this water passes an enriched surface layer of concrete.) The vertical drains, however, should limit the accumulation of pressure.

Contraction Joints.—The general practice of the TVA is to provide free contraction joints in its gravity dams, relying on duplicate metal seals for watertightness. With open joints, there is general freedom for individual blocks to adjust themselves, under dead load and water load, to the peculiarities of the foundation without throwing part of their individual burdens upon their neighbors. The open joint serves as a drainage outlet and a means of relief of uplift pressures in the concrete.

If the contraction joints in high dams are keyed and grouted, certain parts of the load at the highest part of the dam may be carried by shear-twist effects into the abutment. If the abutments are steep, this effect may be quite pronounced. It may be analyzed by a trial-load method, but it seems preferable to design the structures so that the shear-twist effect will be avoided and no allowance made for it. In general, therefore, the gravity dams of the TVA are designed with completely free transverse joints.

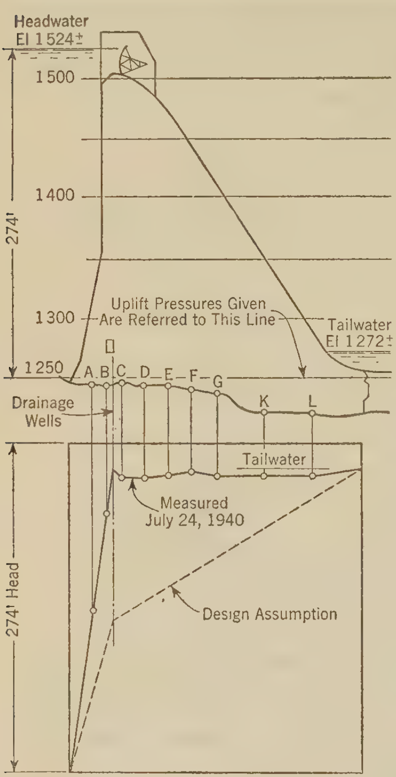

Fig. 3.—Uplift Pressure at the Base of Hiwassee Dam (Block No. 11)

In the two highest dams—Fontana and Hiwassee—this plan has been modified as follows: Keys and grouting have been provided in a limited portion of the transverse joints at the bottom of these dams. At Hiwassee Dam this amounts to about 25% of the height of the joint, and at Fontana Dam the height averages somewhat less than this proportion. This limited amount of grouting has been a concession to the belief of some members of the TVA staff in the practice of grouting. The most important justification in the writer's view is that the grouting of the joints at the bottom has a strong tendency to cure structural cracks in the concrete which tend to develop in the region of high restraint adjacent to the foundation. Although these cracks are subject to autogenous healing, if they are small, larger cracks should be penetrated by grout from the joints and be cured in this way. With limited grouting at the bottom of the joints, most of the dam section would still be free to deflect and the shear-twist effects would still be minimized.

Foundation Restraint.—Foundation restraint is taken seriously by TVA designers. Since concrete develops temperature in setting and then loses its temperature by radiation as setting is completed, volume must necessarily tend to change. At the foundation level these changes result in tensile stresses and the concrete tends to crack. It is general experience that a spacing of contraction joints of not much more than 50 ft will produce structures in which cracks transverse to the axis are not material. Nevertheless, cracks parallel to the axis tend to be frequent in the gravity dam and are considered deleterious.

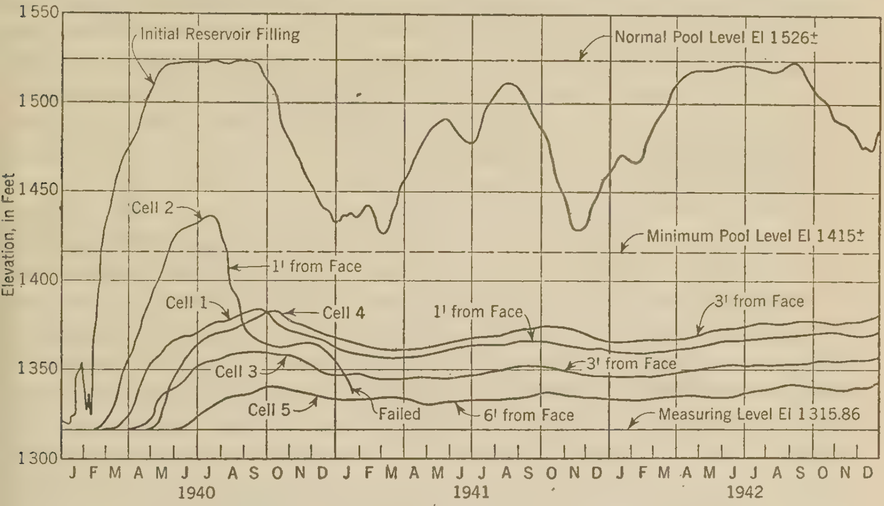

FIG. 4.—MEASURED PORE PRESSURE IN THE BODY OF HIWASSEE DAM

The most rational approach to the prevention of these cracks is to control the manufacture of concrete so as to reduce the maximum temperature of the concrete and the subsequent drop of temperature as much as practicable in the region of high restraint. Three methods to this end have been followed in the TVA organization: (1) The use of low-heat cement and a low cement content; (2) pouring concrete slowly to minimize the temperature rise in the region of restraint; and (3) circulating cold water through pipes to control the temperature rise.

(1) Lower maximum temperatures are obtained in the mass concrete when low-heat cement is used than would be realized under parallel conditions with standard or modified Portland cement. It is also the general practice of the TVA in major structures to use a maximum aggregate size of 6 in. with four grades of coarse aggregate and sometimes two grades of fine aggregate, all proportioned by weight. With such proportioning and a water-cement ratio of about 0.75 by weight, a very large amount of concrete has been made with about 0.8 bbl of cement per yard. This concrete is entirely adequate from the strength standpoint, whether low-heat cement or other grades have been used, and the low cement content causes low maximum temperatures, advantageous from the standpoint of restraint.

(2) Temperature rise in the region of restraint is minimized by slow pouring. By this is meant the placing of thin pours at a considerable time interval so as to permit the radiation of a material portion of the heat of hydration from the top of a pour before the succeeding pour is placed. This measure is of most importance in hot weather and near the foundation. It involves usually the placing of a pour, say 2.5 ft thick, with a time interval of two or three days before placing the next pour. This method is very effective in reducing the accumulated temperature rise and subsequent drop. Its necessity will vary considerably throughout the year. In the winter when the temperature of placing the concrete is likely to be below its final mean temperature, and the temperature changes are less in magnitude, this procedure is less valuable and usually can be modified materially, or eliminated.

(3) The rise of temperature can be limited by circulating cold water through pipes in the concrete to remove the setting heat and prevent the temperature from ever rising materially. This procedure was followed at Hiwassee and Douglas dams in certain local situations where the temperature conditions were particularly unfavorable, but on Fontana Dam it has been used systematically. In this case, where the dam is approximately 450 ft high and the concrete is subject to high stresses, extraordinary attention was felt to be justified in the effort to control temperature changes near the foundation and the consequent tendency to crack. In the first place, the effects of restraint were reduced by the introduction of longitudinal joints designed to be subsequently grouted. Low-heat cement could not be obtained for the Fontana Dam, but in the region of restraint adjacent to the foundation both the slow pouring method and that of artificial cooling were resorted to in the warmer weather. Concrete placed in this region in the hot months of the summer was cooled by refrigerated water at 40° F to 45° F, passing through pipes 2.5 ft, center to center. By these combined means the temperature rise was kept at about 15° F (see Fig. 5). In the region above the foundation, where restraint became unimportant, the concrete was allowed to rise in temperature and then was cooled by circulating water to approximately its final mean temperature so as to permit the effective grouting of the longitudinal joints.

All the foregoing discussion relates to mass concrete. Sometimes there are relatively thin structures, such as spillway piers, which are subject to restraint at the foundation or at the point of connection with larger structures. The tendency to crack is the same. However, in such cases it has been deemed preferable to control cracks by reinforcement rather than to endure the delay and complications caused by slow pouring and artificial cooling. Moreover, the durability requirements of such elements generally preclude a low cement content. Progressive observations on certain structures and office calculations finally led to a standard provision that, in the region adjacent to the restraint, about 0.75% of steel should be used to prevent or distribute cracks. In the thicker walls and piers, this was reduced to 0.50% of the outer 2 ft. As the height of the structure increases above the foundation, the restraint diminishes and the proportion of reinforcing steel is much reduced. Research and observation led to the conclusion that, at a height above the foundation equal to one half the length of the structural element in question, there is no longer any restraint, provided that the concrete is poured without any long interruption.

Stresses in Concrete Dams.—Some comment on stresses in gravity dams is pertinent. It has been the practice of the TVA to calculate stresses on the conventional straight-line basis. The weight of the concrete is determined as accurately as feasible and is used in calculations. Uplift assumptions have been made as outlined previously. The requirement has been made that no tension should exist at the upstream face under the conventional calculation and a somewhat variable margin over this requirement has been assumed. Some attention has been paid to the practices of other organizations as to the major dimensions so that the determination of such things as the ruling downstream slope of the dam has not been based exclusively on calculations. Fontana Dam was made somewhat heavier in section than Hiwassee Dam largely because it is higher.

FIG. 5.—THE FONTANA PROJECT (TURBINES, 91,500 HP AT 325-FT HEAD; GENERATORS, 67,000 KW)

The TVA approach has been considerably influenced by the results of research conducted on Norris and Hiwassee dams for several years. In these structures a number of Carlson measuring instruments were installed for the purpose of measuring strains, stresses, joint openings, temperatures, etc. Fig. 6 shows some results at three measuring stations as reported by Douglas McHenry.[2] This diagram covers a period of four and one-half years, including the time of filling the reservoir, and of more than three years of subsequent fluctuation. The two most striking points about this diagram are the way in which the vertical strain persists near the upstream face of the dam with increasing water load and time while the strain at the midpoint diminishes. Strains near the downstream face generally rise with the increase of load and the passage of time, as might be expected.

---

[2] "Measurements of the Structural Behavior of Norris Dam," by Douglas McHenry, *Technical Monograph No. 53*, TVA (mimeographed bulletin).

There appear to be two reasons for these marked departures from the conventional straight-line variation. During the period of observation the heat of hydration has been lost by radiation and the mean temperature of the dam has dropped to a point close to its final mean temperature. This drop has occurred mainly in the interior of the dam with consequent tendency to loss of volume. The tendency is then to throw an increasing proportion of the weight of the dam upon the concrete adjoining the faces of the structure and, therefore, to increase the vertical stress near the faces while diminishing the stress in the center of the dam. Mr. McHenry also points out that the lower part of the upstream face of Norris Dam has a considerable batter, namely 1 : 5, and that thereby a considerable vertical load is applied to the heel of the dam.[2] He believes that this water load is largely transmitted into the foundation directly, without ever being diffused in its effect over the structure as a whole. This theory seems plausible but is certainly not in accord with the conventional method of stability analysis. More recent analyses of similar conditions at Hiwassee suggest that the higher heel stress is more probably traceable to the penetration of the concrete by reservoir water, combined with the temperature load transfer.

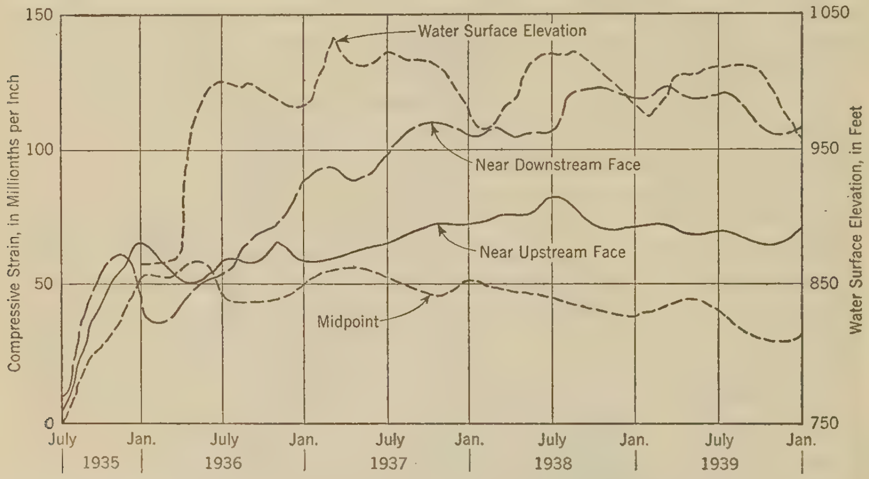

Fig. 6.—Measurements of Vertical Strain, Norris Dam

Fig. 7 records some tentative stress distributions at Hiwassee Dam, based, in this case, on data from five measuring stations. At each station strains are measured in five directions and correlated, and deformation of free cylinders under no stress is also measured. The effects of temperature change as well as load are reflected in the measurements. The phenomena are complex, as are the interpretations of them, and the diagram is tentative as to actual stress values.

The five sets were placed near the foundation in a block that was discontinued for several months, at a level a few feet above the instruments, while the river was diverted over it and cooled it. Then the pouring of the block was resumed and carried to full height. Fig. 7(*b*) shows the same high stress at the heel under water load that was found at Norris Dam. Later measurements show a drop in stress near the third points and an increase at the faces, particularly downstream as found at Norris Dam. The "hump" at the center is believed to be due partly to lack of uniformity in the foundation, and also to the manner in which temperature changes take place in the dam.

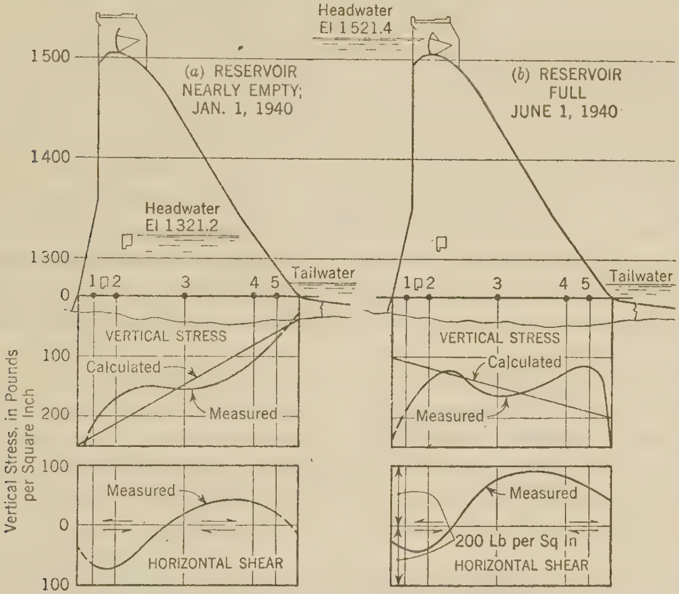

FIG. 7.—MEASURED STRESS DISTRIBUTION, HIWASSEE DAM

Attention is called to the shear diagrams. The horizontal shear diagram in Fig. 7(*a*) represents essentially temperature stresses, interpreted as being the effect of the expansion of the warm upper concrete upon the colder base. The change in the shear from that shown in Fig. 7(*a*) to that in Fig. 7(*b*) (reduced vertical scale) is roughly equivalent to the water load.

Measurements of deflection on Hiwassee and Norris dams have shown that the deflection of the top of the dam due to annual temperature variation is of the same order as that produced by water load. In certain parts of dams like Hiwassee and Norris, stresses due to temperature change are of the same order as those due to water load. When the magnitude of the temperature effects is considered, together with the indicated variation from straight-line stresses, the influence of foundation irregularity and the phenomena of plasticity and growth, one cannot rely too much on conventional calculations. Considerable skepticism is justifiable with regard to elaborate shear-twist calculations, for example.

In conclusion, there is evidence that high masonry dams actually have a greater margin of safety than is shown by the conventional calculations. So far as TVA structures are concerned, they are somewhat lighter, as a whole, than those sometimes developed by other organizations, but the evidence of the stress measurements is such as to produce confidence that the structures are entirely adequate.

Earthquake Effects on Concrete Dams.—One question confronting the TVA engineers was that of the possibility of earthquake effects on these structures. This was of particular importance in the lower valley. It is known that a very severe earthquake centering near New Madrid, Mo., on the Mississippi River had occurred in 1811, and there is some geological evidence that this quake had been preceded by another probably equal in intensity. The region near the confluence of the Ohio and Tennessee rivers appears to be seismically somewhat unstable and the underlying rocks in this locality are known to be much faulted. A special board of geologists reported that provision against earthquakes was advisable in dams on the lower river, but that it was not necessary for structures above Wheeler Dam. Consequently, no extra provision for earthquake effects was made in the storage dams on the tributaries or on the main river dams above Wheeler.

In the case of Kentucky Dam, however, much attention was given to this subject. Available literature and records were examined, geological advice was obtained, and some experimental work was done by Prof. Lydik S. Jacobsen at Stanford University, Stanford University, Calif., making use of a large shaking table. The main conclusions of this investigation (not published) were as follows:

1. When mass structures are founded upon rock at a reasonable distance from the center of seismic disturbance (at Kentucky Dam this may be 40 to 50 miles), the effects of the quake can be guarded against by applying, to the mass structure, a moderate horizontal acceleration. For Kentucky Dam an allowance of 5% of gravity was considered sufficient. To this acceleration effect is to be added the appropriate water-hammer effect as developed by the well-known theory of H. M. Westergaard, M. Am. Soc. C. E., if the structure is in contact with water.[3]

2. When slender structures founded upon rock are subjected to earthquake vibrations, a rational approach is to consider that a simple harmonic vibration is applied to the base of the structure and to trace the effects of this vibration throughout the structure. This includes determining the natural period of vibration of the structural element in question and then applying the assumed vibration. At Kentucky Dam this vibration was assumed to have a period of 1 sec and an amplitude of 0.25 in. (This corresponds to a maximum acceleration of 0.03 g.) By tracing this vibration through the structure, certain magnifications of the original impulse can be found, together with damping effects. Flexural effects on the elements will thus be determined against which suitable reinforcement must be provided.

---

[3] "Water Pressures on Dams During Earthquakes," by H. M. Westergaard, *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 418.

3. The investigation indicated that much greater effects were to be experienced in earth dams and in retaining walls supporting earth fills than would arise from the earthquake impulses in rock. This application seems to fall most logically in the subsequent discussion of earth dams.

EARTH DAMS

Earth dams constitute a considerable proportion of the hydraulic structures of the TVA. The design of these dams has depended largely upon the use of the materials available at the respective sites. In the case of the Nottely Dam (see Table 1), suitable rock was readily available and construction conditions were adverse to a full earth dam. Consequently, this dam is a rock-fill section with a rolled core. At Chatuge Dam rock was not readily available and plenty of earth could be had, so that this dam is entirely a rolled-fill section. At Cherokee Dam the earth dam had to be located on the top of a ridge and the use of a simple earth dam would have involved excessive costs by reason of flat slopes. In this case a composite of rock and earth fill was developed.

A few principles have governed the design of these fill dams. The soils laboratory determined the properties of available materials and, through field inspectors, supervised the selection and placing of the materials. The slopes of the dam sections have been generally checked by the slip circle method, using the constants determined by the soils laboratory. On the upstream face these calculations have been based on the reduced weight resulting from the sudden draw-down theory. Because this assumption is very severe, a rather moderate computed factor of safety (about 1.3) was considered sufficient. The slip circle method was applied to the downstream face also and in this case with larger factors of safety.

The primary principle enunciated in this paper applies here—namely, that the upstream face be tight and that such water as passes this diaphragm be permitted to escape readily. The minimum requirement, therefore, has included a continuous drain at the toe of the dam together with occasional wells which would drain the foundation into this toe drain. In the higher dams (Cherokee, Chatuge, and Nottely), a further drainage provision was made by actually placing a layer of porous material under a definite portion of the core or impervious element of the dam. This drainage is intended to hold down the saturation line, and to keep the downstream slope of the dam always dry, thus retaining its structural resistance. The application of these measures may be observed in the sections of Chatuge and Nottely dams (Figs. 8(*a*) and 8(*b*)).

Hydraulic fill has been used on TVA dams in only one instance—the south embankment at Pickwick Landing Dam containing about 1,000,000 cu yd. In this case materials were obtained from excavation for the lock. They consisted of clay soil gradually grading down through sand into gravel. They could have been utilized for a rolled fill, but only during the dry season. A hydraulic fill can be placed in almost any weather. For this reason, the hydraulic method was followed in this instance, with satisfactory results.

At Kentucky Dam, as indicated previously, it was necessary to design against earthquakes (see Fig. 8(*c*)). The basic design for the earth section of this dam, therefore, includes a core of rolled earth enclosed on both upstream and downstream slopes by additional fills of gravel and sand. The slopes (1 on 4) were built with high-friction material, and were decided to be sufficiently stable against the accelerations to be expected from the earthquake. If the

rolled core should be cracked or sheared by the action of the quake, it was expected that the granular material of the shoulders would immediately fill the crack to such an extent that no material amount of water would pass.

A most important feature of design on this project is the west abutment or retaining wall which separates the spillway from the west earth dam.

The experiments of Professor Jacobsen, as well as certain experiments from Japanese sources, indicated that the center of pressure of the dynamic forces produced by the earthquake was at about two thirds of the height of the wall above the base. Furthermore, researches by the TVA staff indicated that accelerations in the ground, particularly in saturated ground, would be several times the accelerations in the foundation rock in the same quake. Accordingly, the following procedure was established for the design of retaining walls.

The horizontal acceleration in the ground is assumed at 18% of gravity. This is a judgment assumption based on examination of records, certain limitations of the Kentucky project, and the report of Professor Jacobsen. This acceleration, combined with that of gravity, is applied to the Coulomb sliding wedge and the pressure on the wall is determined. The static pressure is subtracted from this quantity and the difference is designated the dynamic increment. This increment is applied when the wall has a small batter at two thirds of the height above the base and is assumed to be the resultant of a pressure varying from zero at the base to a maximum at the top of the fill. When the wall has a large batter (flatter than 12 on 4) the assumptions as to height and distribution are a little less severe.

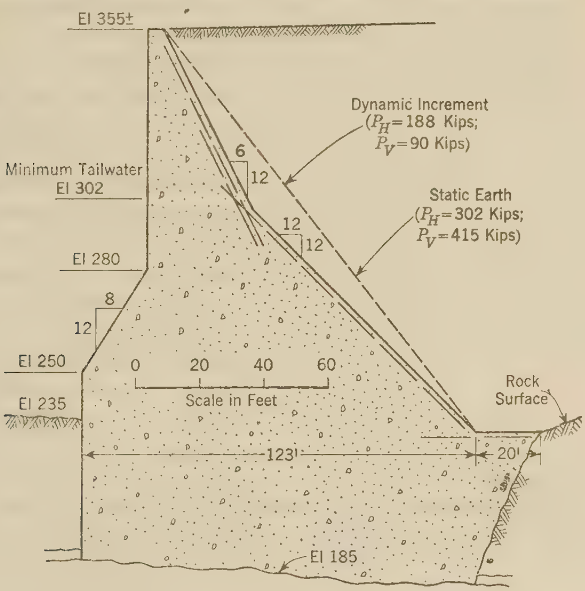

FIG. 9.—SECTION, WEST ABUTMENT OF KENTUCKY DAM

The application of this rule led to a maximum section on the west abutment as shown in Fig. 9. The base of this wall is extremely heavy whereas the top is heavily reinforced. The reinforced part is designed to withstand the dynamic increment at rather high stresses.

LOCKS

Kentucky lock is the only one on the Tennessee River designed by TVA, the others having been designed by U. S. Army Engineers. The hydraulic features of this lock have been discussed elsewhere[4] but it seems worth while to explain two unusual structural features. One is the river wall of the lock, as shown in Fig. 10. The usual drainage facilities were placed in the river wall of this lock and the wall was designed with earthquake provisions. The unusual section of the river wall is explained by the fact that the layout required that the lock be built with its river wall in the reservoir, the lower pintle being substantially on the axis of the dam. The inner face of the lock had to be a continuous vertical wall. The outer face was obliged to carry full reservoir head with the lock empty. After investigating numerous types, the design of the double wall was adopted. The chamber in the top of the wall is filled with gravel in order to secure the benefit of its weight.

---

[4] "Basic Hydraulics of Water Storage Projects," by George R. Rich, *Civil Engineering*, August, 1944, p. 351.

The other feature is a floating guide structure at the upper end of the lock, built of reinforced concrete, although at one time the plan was to build it of steel. Allowance had to be made for an unusual fluctuation in lake level; and foundation conditions, particularly in view of the earthquake risk, were very unsatisfactory for any fixed structure. Accordingly this floating guide was developed. It is 440 ft long, 24 ft wide, and is designed to be submerged about 10 ft. In its connection to the lock it is provided with a ball-and-socket traveling anchorage and its end upstream is anchored by submerged cables leading to concrete anchor blocks in the lake bottom. Aside from these provisions, the design of the lock is along conventional lines.

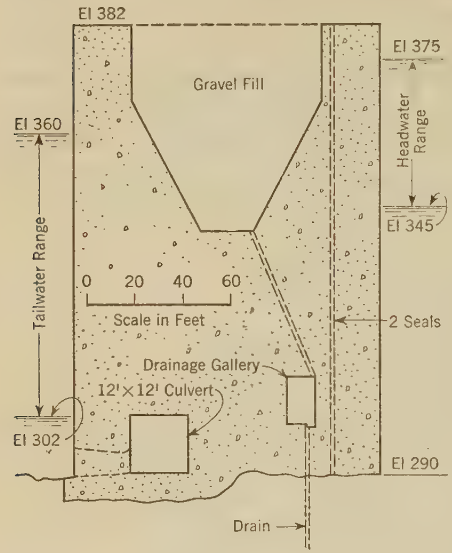

FIG. 10.—SECTION, RIVER WALL OF KENTUCKY LOCK

SUMMARY

This paper has described some of the most important features of design of TVA structures. Every project has its peculiar hydraulic and site requirements, and its design must be based upon them. However, the paper is intended to show the lines of thought governing the solution of some major problems from the structural standpoint. No mention has been made of various special designs such as the large surge tank at Apalachia Dam,[5] the several tunnels and their appurtenances, the chute spillways at Chatuge and Nottely dams,[6] and many other interesting structures that have been described adequately elsewhere.

ACKNOWLEDGMENT

The three papers of this Symposium represent activities of the design organization of the TVA. All engineering and construction work of the TVA is under the direction of C. E. Blee, M. Am. Soc. C. E., Chief Engineer. The design of structures and accessories, as well as the specification and inspection of equipment, has been the responsibility of the Design Department under the direction of George R. Rich, M. Am. Soc. C. E. until recently Chief Design Engineer.

DESIGN OF HYDROELECTRIC STATIONS

By George P. Palo,[7] and Constant R. Marks, III,[8]
Assoc. Members, Am. Soc. C. E.

Synopsis

The title of this paper, if given its broadest interpretation, describes a subject of such scope as to require a treatise for its adequate discussion. Actually, this scope is limited to certain comments on general problems connected with station layouts and substructure design for large units. In discussing the layouts, emphasis will be placed upon designing the form of the structure most efficiently for the functions it must serve and upon the effect on the design of the interdependence of many of the factors involved. Illustrations will be drawn from the projects of the Tennessee Valley Authority (TVA), which include fourteen powerhouses and additions to one, for a total of forty-two units with a capacity of about a million and a half kilowatts. Discussion will be directed particularly to low-head, propeller type installations of which TVA has built seven, six with Kaplan runners. The locations of TVA projects are shown on the map in Table 1.

The Functional Layout

Securing a satisfactory and economical layout for the powerhouse should be one of the first concerns of the designer. A study to create a properly functional layout begins from the conception of a hydroelectric power station as a mechanism for converting the potential energy of water under head into electrical energy. The various features of the powerhouse may then be arranged in a manner suited to the several component functions necessary for accomplishment of this primary function.

Fig. 11 is a partly diagrammetric drawing of the Fort Loudoun powerhouse, planned to show its six functions and their arrangement: (1) Water flow; (2) flow of electricity; (3) mechanical control; (4) electrical control; (5) auxiliary electric equipment; and (6) auxiliary mechanical equipment. The most efficient layout is that in which each function is accommodated as directly as possible and without interference with other functions. The most economical structure is secured by compact arrangement of functions so as to avoid waste space in either initial or ultimate portions of the installation and by a plan in which as much as possible of the required space can be housed in relatively inexpensive types of construction. It is very difficult to state any general rules for layout, but the results of TVA experience may offer helpful hints for similar installations.

HOUSE; FUNCTIONAL LAYOUT

Consider these functions in greater detail, as follows:

(1) The first function requires provision for the flow of the water through passages, where it imparts its energy to the turbine runner, and protection of the powerhouse against all expected conditions of headwater and tailwater. The waterways of this function, consisting of the scroll case and draft tube, are the basic factors determining the minimum outline for the powerhouse substructure. Waterway shapes have been simplified and standardized so that there is little difference between the requirements of the several turbine manufacturers. In fact, the designer may cooperate with manufacturers to obtain a single design in which any of them will install a turbine without qualifying his guarantee of its efficiency. This is particularly desirable if it is intended to complete, partly, the substructure to be used for future units. Further comment on this function will be made in the latter half of this paper, in which substructure design will be considered at some length.

(2) The second function involves provision for the flow of electric current, starting from the generator, through the conductors to the transformers, and thence to the switchyard and transmission lines. Layout for this function involves a consideration of the location of transformers on the intake deck, on the powerhouse roof, over the draft tube, or, at a greater distance from the generators, on the river bank near the powerhouse. Decision as to the best location depends on many factors, but in planning a layout the space requirement for the function should be understood clearly. In TVA practice, for example, transformers are usually on the bank, and low-tension electrical equipment is at a minimum. In the layout the engineer must plan for space for low-tension switchgear for each unit or pair of units and a clear run of the generator leads to the transformers, without interference with other features.

(3) The third function is the mechanical control of the turbine by means of the actuator, servomotors, and the gates or Kaplan mechanisms (see Fig. 11(*a*)). Layout for this function must envision the actuator cabinets and pressure tanks with piping to connect them to servomotors or Kaplan mechanisms. Economy of space and economy of direct connections are secured on many TVA layouts by placing actuator cabinets and pressure tanks on the generator-room floor, with the actuator cabinet planned, where possible, for the control of two units.

(4) Electrical control of the unit and the flowing current by means of unit controls and main control room linked with the necessary electric cables constitutes the fourth function.

(5) The fifth function concerns the auxiliary electrical equipment necessary for the operation of the main equipment and of the station itself.

(6) Finally, the sixth function constitutes the auxiliary mechanical facilities required for servicing the equipment, provision for access into and within the station, and space for use and convenience of employees and visitors.

The arrangement of the facilities serving functions (4) to (6) may vary greatly, depending on the number and size of the units, topography, type of superstructure, and other conditions. Design for economy and simplicity of layout can be aided by reclassifying these facilities, and the second and third functions as well, into unit service features and station service features. Unit service features include the mechanical control of the unit, the unit portion of the electrical control, and the provisions for physical access to the unit areas and access of leads, control cables, and pipes. Station service features include the main control area and nearly all of the auxiliary mechanical and electrical equipment as well as the employee and public space. The unit service areas are repetitive for each unit. The station service features, on the other hand, need be provided only once for the entire station. If the number of units is large and the cross section of a unit block is to be kept typical, structural economy can be secured only by limiting the space in the unit block to the minimum required for unit service features. This is particularly true if provision for future units with the same cross section is being made; for, in this case, station features must all be included in the initial construction and only additional unit features are needed when the structure for the future units is completed. Economy generally demands that station features be located in one or more service buildings separate from the unit blocks. An exception is an installation of from one to about three units where shortness of connections and operating convenience may favor location of station service features in a more central location.

The Fort Loudoun cross section is typical for several of the low-head stations of the TVA. The unit service area uses a portion of the generator-room floor for the actuator, a two-story electrical bay (one for unit control and switchgear, and the other for clear runs of generator leads and control cables), and galleries in the heavy concrete sections above and below the scroll case. Recesses from these galleries between units provide space for auxiliary mechanical unit service features which is conveniently segregated from other features. The resulting structure is a very compact, economical cross section.

The station service area is most commonly housed in a service bay at one end of the series of unit blocks. This structure usually provides an erection area at the level of the generator-room floor. As shown for Fort Loudoun, a machine shop at the same level, and space on a lower floor for station sump pumps and lubricating oil servicing, are desirable and may be planned readily in conjunction with the mechanical equipment at the same level in the galleries and recesses in the unit blocks. Other station service features should be located within the service bay so as to serve best the function of each feature and to fit them into an economical layout which coordinates with the main functions of the powerhouse. Space provided may be affected by the shape of service bay best suited to the structural problem of its design. If the structure is located in the river channel, it must be massive enough to be stable against high tailwater levels and uplift, against headwater if it forms a part of the dam, and possibly as a retaining wall if it is the transition between concrete and earth sections of the dam. If the river bank consists of suitable material for foundations and dam abutment, some of this massive structure may be saved by locating the service bay so close to the bank that a part of it may be founded at elevations well above the river bed, as was done at Fort Loudoun. Likewise, if space in the river channel is limited or if structures within it are expensive due to possibility of high tailwater, large savings may be made by a layout in which all station service facilities possible are moved to a separate structure located on the bank above maximum tailwater level. The Watts Bar project of the TVA is an example of such practice.

THE SUPERSTRUCTURE

The planning of the powerhouse layout requires early decision as to the use of indoor, outdoor, or semi-outdoor type of superstructure. A consideration of factors governing this choice will illustrate the interdependence of some of the several functions thus far discussed.

For maximum tailwater below the level of the generator-room floor, only indoor and outdoor types usually need be considered. Controlling factors are: Relative economy; operating convenience (involving alternate solutions to the problem of the mechanical service function); and appearance. There are many examples of each type of design, indicating the difficulty of evaluating these factors, and the choice of type must be considered largely a matter of organization preference and policy.

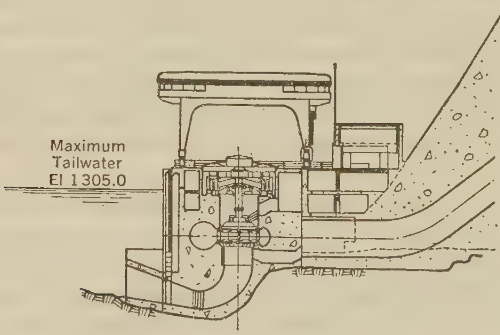

FIG. 12.—HIWASSEE POWERHOUSE

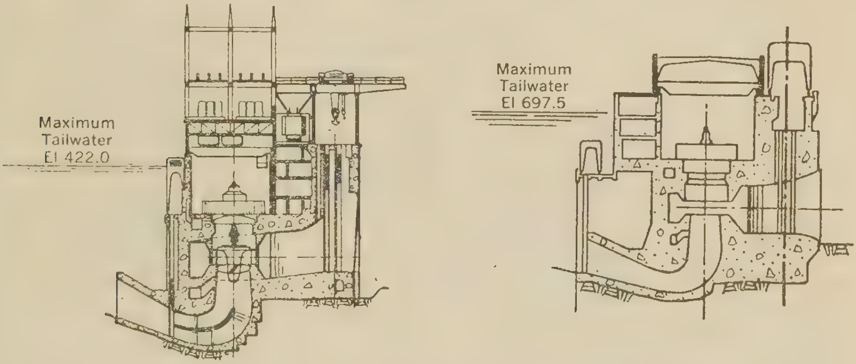
As larger streams with flatter gradients are developed and as flood studies and experience with actual developments point toward more conservative choice of maximum flood, many projects must provide for tailwater well above the generator-room floor. In this case layout requirements, particularly the one of access to the powerhouse, become of great importance in determining the proper type of superstructure.

For maximum tailwater a moderate distance above the generator-room floor level, the full outdoor type of design may be modified by building water-bearing walls to a height approximating that of the generator barrel and by roofing over the generator area. The resulting section may be like that for the Hiwassee project (Fig. 12). The space enclosed around the generator is useful, especially for electric services, and this type of outdoor station has sometimes been used for that reason alone. For high tailwater, access is at the level of the roof.

The indoor powerhouse can be adapted with minor modifications for tailwater a short distance above the generator-room floor in several ways. One solution is to locate the main entrance on a mezzanine which is above tailwater. Both size and elevation of this floor must be considered with care to minimize waste space either on or below the floor. Another solution, preferably only for small stations, may locate the entrance to the powerhouse at the generator-room floor level and reach it by a protected ramp which slopes from an entrance area above high tailwater; or, in rare circumstances, it may be considered reasonable to protect the powerhouse entrance with a temporary bulkhead set in place during floods. For conditions of tailwater more than about 15 ft above the generator floor, these solutions are rarely satisfactory. The indoor type of powerhouse can be adapted economically to very high tailwater levels only by providing access through a vertical hatch. In the Pickwick project (Fig. 13(*a*)), delivery of equipment is by barge and a crane transfers it from the barge to a hatch in the roof of the powerhouse immediately above the erection area. At the Chickamauga project (Fig. 13(*b*)), there is a railroad or truck access to the intake deck. The gantry crane used for moving intake gates can also handle incoming equipment and drop it through a hatch to the level of the generator-room floor. At this level it is moved downstream on a transfer car until within reach of the crane in the generator room. It will be noted that this layout creates waste space at the hatch opening and also prevents, for some 45 ft above the generator-room floor, any straight run of control cables or generator leads upstream from the generators through the length of the powerhouse. This is one of the factors requiring that the electrical bay for the project be on the downstream side of the generator room. At Pickwick, on the other hand, there were a number of factors pointing to an upstream electrical bay, and the need for a cable gallery necessitated the opening in the roof.



(*a*) PICKWICK LANDING (*b*) CHICKAMAUGA

FIG. 13.—INDOOR POWERHOUSES

The TVA has found the semi-outdoor type of powerhouse well adapted to many conditions. In some projects it has been the only reasonable solution. As illustrated by the powerhouse at Kentucky Dam (Fig. 14), the generator room is about 30 ft high, ample to clear the Kaplan head on the unit. The adjacent electrical bay is two floors high and the downstream and end walls provide protection against tailwater 28 ft above the generator-room floor. A gantry crane hoists equipment through hatches in the roof, and the main access road comes in at roof level. If the Kentucky section is compared to that for Hiwassee, it will be noted that the main difference is that the roof at Kentucky is at sufficient height to justify the design of a generator room, whereas at Hiwassee the lesser height leads to the adoption of a concrete barrel around the generator.

The TVA has used the semi-outdoor powerhouse at five projects and this design has proved to interfere less with other functions and to be more satisfactory than any other. At four of the projects (two Kaplan and two Francis wheel installations), tailwater may be 20 ft to 30 ft above the generator-room floor. At Watts Bar (the first project to use this design), maximum tailwater is only 13.5 ft above the generator-room floor. Here, however, the service bay is built against a precipitous abutment which precluded use of an end entrance. To have used a downstream entrance to a mezzanine would have interrupted cable runs in the downstream electrical bay which were necessary to permit use of what was considered the most economical cross section of intake and powerhouse.

FIG. 14.—SEMI-OUTDOOR POWERHOUSE

SUBSTRUCTURES FOR LARGE PROPELLER UNITS

The shape of the substructure required for large propeller units prohibits calculation of anything more than a crude approximation of the stresses involved. Even structures with identical outline and identical water loads will have different stresses, depending upon the sequence, size, and shape of the concrete pours, the conditions of temperature encountered during the construction, and the properties of the concrete used. Indeed these factors may account for the major portion of the stress in the structure. The objectives of the structural design are (*a*) to obtain an economical structure safe from actual failure, and (*b*) to make the structure watertight. The fact that actual failures are almost unknown indicates universal success in the achievement of the safety, but not necessarily the economy, of objective (*a*). That objective (*b*) is obtained less frequently is evidenced by casual inspection of many power plants. The benefits of a watertight structure are: More satisfactory operating conditions; less depreciation and maintenance; and assurance of greater over-all strength in the structure. In addition, watertightness indicates reduction of movements in the structure, so that there is more certainty that the turbine and generator equipment will be erected and remain more closely to perfect alinement. These benefits are deemed to warrant the extra care and expense in the design and construction needed to obtain them.

Safety and Economy.—The cross section of the Fort Loudoun powerhouse is an example of structural safety, with economy, obtained by designing the intake and powerhouse to function as a unit. Two units were completed initially but the success of the section shown in Fig. 11 was dependent on its adaptation to initial construction for two future units. For these units the section is complete except for most of the scroll-case roof, the lower cone, and a recess sufficient to permit the placing of the draft-tube liner. Such construction requires extensive commitments relative to waterways in these future units. Equal commitments in plants built in the 1920's were found unsatisfactory within a few years because of development of the propeller wheel and the use of the elbow draft tube. There have been no major changes in turbines and waterway design since before 1935 and those commitments may now be made more freely for future units to be installed in a reasonable time. This is a fortunate condition because, in many large propeller installations, foundation conditions require a design that will buttress the inadequacy of the intake foundation when the draft tube is excavated to a greater depth than that required for the intake. This buttressing is obtained by completing a large part of future units. In addition, partial construction of future units is almost always included to permit unwatering the area of future construction by dropping stop logs or gates into slots in the partly completed draft tube.

The Roof of the Intake.—Perhaps the most critical design feature in a cross section for a future unit, as at Fort Loudoun, is the design of the roof of the intake. Water passages of the intake are protected by trashracks set against the upstream face and controlled by service gates moved by a gantry crane on the deck. For rare occasions requiring closure upstream from the service gate, trashracks are removed by an auxiliary boom on the gantry and replaced by stop logs. This simple method of control is a factor that aids the development of a short, economical intake. For the head on this project, however, the intake is not stable by itself and omission of the scroll-case roof requires that much of the reservoir water load be transferred by the intake roof from the intermediate to the end piers, which, with the scroll-case walls and draft tube, have the length necessary for stability of the structure. The framing of the intake roof with the end piers should be such as to insure spreading of the load so that the full length of the draft tube is actually effective as a gravity section. At Fort

JOINTS, WATTS BAR POWERHOUSE

Loudoun this was accomplished by placing, initially, a part of the scroll-case roof, upstream from the cone, to function as a haunch on the intake roof beam.

Watertight Structure.—Throughout the design, the civil engineer must constantly consider the problems of volume change if he wishes to obtain a waterproof structure. Volume change as applied to a powerhouse substructure (most of which will be permanently submerged) arises largely from temperature changes in the concrete—initially as a result of the heat of hydration of the cement and later as a result of the annual temperature cycle. The magnitude of the change, and hence of its accompanying problem, will depend in part on the season of construction and the thermal coefficient of the concrete. These factors indicate the individuality of projects; yet certain general approaches to design are desirable even under most favorable conditions.

A problem encountered early in construction is the spacing of contraction joints in the powerhouse substructure. Units spaced 35 ft to 40 ft or more on centers should be built with contraction joints between units. Smaller unit spacings may be built with two units between pairs of contraction joints. For simplicity and clean design, in both substructure and superstructure, it is desirable that contraction joints be straight. The unit is always offset toward the small side of the scroll case and, if the draft tube is made symmetrical about the center line of unit, the end piers of the draft tube will not be of equal thickness. This lack of symmetry is undesirable in a structure planned for temperature changes. Best results are obtained if the draft tube is offset in the heavy elbow section so as to bring the center line of the downstream end of the draft tube on the same center line as that for the intake, and midway between the contraction joints.

With contraction joints established, consideration may turn to the individual unit. Fig. 15 affords some conception of the planning of the construction joints in the Watts Bar Hydro Station. Units are spaced 73 ft on centers, and the length from the construction joint at the intake to the downstream end of the draft tube is 100 ft. The design considers concrete outline, reinforcement, construction joints, and special concrete pouring sequence as an integrated problem with the objective of a strong, watertight substructure which can be obtained with a minimum of restriction on the construction forces.

Draft Tube.—In the draft tube the length of individual pours is held to a maximum of about 40 ft by construction joints near the center line of units and near the downstream wall of the powerhouse. These joints are made with a minimum of offsets at successive lifts so that any opening of the construction joint will not continue into monolithic concrete in another pour. Where stability requires that shears be transferred across vertical joints, joint surfaces are roughened by jackhammers before concrete is poured against them. The downstream end of the draft tube may be designed as a one-story frame. End piers for large units should be 6 ft to 8 ft thick. Intermediate piers must be 5 ft to 6 ft thick to provide for reasonable thickness at gate slots. As temperature change is considered in the frame design, the roof slab should be as light as consistent with reasonable reinforcing requirements. A thickness of 4 ft is recommended. One or two construction joints in its width also minimize temperature stress. Horizontal steel in the draft-tube piers is designed as $1\frac{1}{4}$-in. square bars, 12 in. on centers, so as to spread the cracks that will result as the concrete changes length over the restraining rock foundation.

The key to successful construction of the massive elbow of the draft tube is found in the proper concreting of the roof pours. In the entire substructure a time interval of three days between successive vertical lifts is specified; but, where effects of temperature are so critical that more complete dissipation of the heat of hydration is essential, longer intervals between successive lifts or adjacent pours are required. The elbow zone is particularly important as cracks will cause leaks into the draft-tube gallery with eventual large accumulations of laitance. The roof pour is made with one or two construction joints in the width of the unit, and a delay of seven days is specified between the placing of adjacent pours and between the first and second lifts. This gives the concrete time to dissipate a part of its heat of hydration and also to develop strength to carry the weight of succeeding pours. Roof reinforcement of $1\frac{1}{4}$-in. square bars 9 in. on center has proved satisfactory.

Additional features of interest in the design of the draft tube are the slope of the floor and the outline of the upstream nose of the intermediate piers. As the low point of the draft-tube excavation is usually well below the level of rock in the river bed, a steeply sloping draft-tube floor is usually desirable to reduce rock excavation not only in the draft tube but also in the tailrace channel. On TVA projects, floor slopes of 1 on 3 or even 1 on 2.5 have provided perfectly satisfactory tubes. Since most of the energy remaining in the flowing water is lost on emergence from the draft tube, it is necessary only to have the draft-tube outlet low enough to seal during the operation of the unit.

For hydraulic reasons manufacturers often request that the upstream end of the intermediate piers be rounded to a small radius and located as far downstream as possible. Structurally, these points are obviously subjected to considerable stress. On the Guntersville project an installation of Carlson strain and stress meters indicated stresses in the pier noses of about 400 lb per sq in. Stress analysis which considered concrete placing sequence and length change of piers under load had previously indicated this to be the probable stress although higher values had been considered possible. To allow for approximations in these data, pier noses on TVA projects are located about as shown for Watts Bar. They are rounded to a 6-in. radius, which is a good radius hydraulically, but also large enough to permit embedment of substantial, tied-column type of reinforcement.

Scroll Case.—The scroll case is usually built in two stages, the first of which permits the superstructure erection before the delivery of the parts of the turbine that are to be embedded. Such parts can then be handled by the powerhouse crane. The first stage consists of a U-shaped section formed by the downstream and side walls of the scroll-case passage. The downstream wall is carried to full height to provide support for the superstructure construction. The side walls may be carried to full height or may stop at the top of the scroll-case waterway. The design of the side walls of the scroll case requires that they be strong enough to carry the final water loads by beam action between the floor and the roof of the scroll case and that they be capable

Loudoun this was accomplished by placing, initially, a part of the scroll-case roof, upstream from the cone, to function as a haunch on the intake roof beam.

Watertight Structure.—Throughout the design, the civil engineer must constantly consider the problems of volume change if he wishes to obtain a waterproof structure. Volume change as applied to a powerhouse substructure (most of which will be permanently submerged) arises largely from temperature changes in the concrete—initially as a result of the heat of hydration of the cement and later as a result of the annual temperature cycle. The magnitude of the change, and hence of its accompanying problem, will depend in part on the season of construction and the thermal coefficient of the concrete. These factors indicate the individuality of projects; yet certain general approaches to design are desirable even under most favorable conditions.

A problem encountered early in construction is the spacing of contraction joints in the powerhouse substructure. Units spaced 35 ft to 40 ft or more on centers should be built with contraction joints between units. Smaller unit spacings may be built with two units between pairs of contraction joints. For simplicity and clean design, in both substructure and superstructure, it is desirable that contraction joints be straight. The unit is always offset toward the small side of the scroll case and, if the draft tube is made symmetrical about the center line of unit, the end piers of the draft tube will not be of equal thickness. This lack of symmetry is undesirable in a structure planned for temperature changes. Best results are obtained if the draft tube is offset in the heavy elbow section so as to bring the center line of the downstream end of the draft tube on the same center line as that for the intake, and midway between the contraction joints.

With contraction joints established, consideration may turn to the individual unit. Fig. 15 affords some conception of the planning of the construction joints in the Watts Bar Hydro Station. Units are spaced 73 ft on centers, and the length from the construction joint at the intake to the downstream end of the draft tube is 100 ft. The design considers concrete outline, reinforcement, construction joints, and special concrete pouring sequence as an integrated problem with the objective of a strong, watertight substructure which can be obtained with a minimum of restriction on the construction forces.

Draft Tube.—In the draft tube the length of individual pours is held to a maximum of about 40 ft by construction joints near the center line of units and near the downstream wall of the powerhouse. These joints are made with a minimum of offsets at successive lifts so that any opening of the construction joint will not continue into monolithic concrete in another pour. Where stability requires that shears be transferred across vertical joints, joint surfaces are roughened by jackhammers before concrete is poured against them. The downstream end of the draft tube may be designed as a one-story frame. End piers for large units should be 6 ft to 8 ft thick. Intermediate piers must be 5 ft to 6 ft thick to provide for reasonable thickness at gate slots. As temperature change is considered in the frame design, the roof slab should be as light as consistent with reasonable reinforcing requirements. A thickness of 4 ft is recommended. One or two construction joints in its width also minimize temperature stress. Horizontal steel in the draft-tube piers is designed as 1¼-in. square bars, 12 in. on centers, so as to spread the cracks that will result as the concrete changes length over the restraining rock foundation.

The key to successful construction of the massive elbow of the draft tube is found in the proper concreting of the roof pours. In the entire substructure a time interval of three days between successive vertical lifts is specified; but, where effects of temperature are so critical that more complete dissipation of the heat of hydration is essential, longer intervals between successive lifts or adjacent pours are required. The elbow zone is particularly important as cracks will cause leaks into the draft-tube gallery with eventual large accumulations of laitance. The roof pour is made with one or two construction joints in the width of the unit, and a delay of seven days is specified between the placing of adjacent pours and between the first and second lifts. This gives the concrete time to dissipate a part of its heat of hydration and also to develop strength to carry the weight of succeeding pours. Roof reinforcement of 1¼-in. square bars 9 in. on center has proved satisfactory.

Additional features of interest in the design of the draft tube are the slope of the floor and the outline of the upstream nose of the intermediate piers. As the low point of the draft-tube excavation is usually well below the level of rock in the river bed, a steeply sloping draft-tube floor is usually desirable to reduce rock excavation not only in the draft tube but also in the tailrace channel. On TVA projects, floor slopes of 1 on 3 or even 1 on 2.5 have provided perfectly satisfactory tubes. Since most of the energy remaining in the flowing water is lost on emergence from the draft tube, it is necessary only to have the draft-tube outlet low enough to seal during the operation of the unit.

For hydraulic reasons manufacturers often request that the upstream end of the intermediate piers be rounded to a small radius and located as far downstream as possible. Structurally, these points are obviously subjected to considerable stress. On the Guntersville project an installation of Carlson strain and stress meters indicated stresses in the pier noses of about 400 lb per sq in. Stress analysis which considered concrete placing sequence and length change of piers under load had previously indicated this to be the probable stress although higher values had been considered possible. To allow for approximations in these data, pier noses on TVA projects are located about as shown for Watts Bar. They are rounded to a 6-in. radius, which is a good radius hydraulically, but also large enough to permit embedment of substantial, tied-column type of reinforcement.

Scroll Case.—The scroll case is usually built in two stages, the first of which permits the superstructure erection before the delivery of the parts of the turbine that are to be embedded. Such parts can then be handled by the powerhouse crane. The first stage consists of a U-shaped section formed by the downstream and side walls of the scroll-case passage. The downstream wall is carried to full height to provide support for the superstructure construction. The side walls may be carried to full height or may stop at the top of the scroll-case waterway. The design of the side walls of the scroll case requires that they be strong enough to carry the final water loads by beam action between the floor and the roof of the scroll case and that they be capable

CIVIL ENGINEERING FEATURES OF STEAM PLANT AT WATTS BAR

By Adolf A. Meyer,[9] M. Am. Soc. C. E.

Synopsis

The civil design features of the Watts Bar Steam Station are described in this paper. The general station design and its functions within the system defined as the Tennessee Valley Authority (TVA) have been described elsewhere.[10] Only references to the general design necessary for the description of the civil engineering features are included herein.

The paper gives the reasons why the station was located on the high ground about 600 ft away from the river rather than at the river front, as is the more common solution. It outlines the characteristics of the foundation rock—a shale of very low structural strength—and the precautions used in the design of the substructure to avoid detrimental settlements of the building and to eliminate the formation of shrinkagé cracks.

The paper explains the conditions which led to the adoption of a gravity feed system for the condensing water supply, and it describes the main features and the functions of this system. It further describes the planning and design of the powerhouse structures, the yards for coal handling and coal storage, and the transportation facilities connecting these yards.

The Watts Bar Steam Station was authorized on July 31, 1940, shortly after the fall of Frânce. It was to increase the power capacity of the TVA system to insure adequate supply for the armament program then under consideration. The initial authorization was for a capacity of 120,000 kw. The ultimate station installation was to be 240,000 kw. The load center for the armament program was assumed to be in east Tennessee. As fuel costs in this area are favorable, the logical site for the new steam station was in this section at a location near a primary substation with ample transmission interconnections, good transportation facilities, and an adequate cooling water supply. These conditions were best met near the site of the Watts Bar hydroelectric development, on the Tennessee River halfway between Knoxville and Chattanooga, Tenn. At that time (1940) this project was in the course of construction. By combining the two projects, substantial advantages could be obtained from savings in construction plant and in construction supervision, in addition to the permanent operating advantages.

The paper will be limited to a treatment of the civil engineering features of the station. No sharp separation of these elements from the integrated plant can be made. However, civil engineering design predominates in the following features: Powerhouse substructure, powerhouse superstructure, condensing water supply, yards for coal storage and coal handling, railroad facilities, road facilities, and river dock facilities.

[9] Head Civ. Design Engr., TVA, Knoxville, Tenn.

[10] "The Watts Bar Steam Power Station of the TVA," by G. R. Rich and R. T. Mathews, *Mechanical Engineering*, November, 1941, p. 773.

At Watts Bar, the combined cost of these items represented approximately 20% of the total cost of the station. On first appearance it may be concluded that they did not affect the economy of the station to a marked degree. This impression, however, would be misleading. The largest items of cost are incurred in the main equipment, the purchase price of which is not very flexible for given specifications. Therefore, the cost increment involved by the civil engineering features is the most variable part when comparing different stations. For these reasons, it was considered a matter of great importance for the over-all economy of the station that a careful evaluation of the civil engineering features be the guiding rule in the selection of the site.

The Watts Bar Dam site is characterized by a steep bluff, approximately 150 ft high, on the right bank of the river. A railroad is accessible from this side only, which eliminated from consideration the wide flood plain on the left bank of the river. Sites upstream and downstream of the dam on the right bank were investigated. The costs at the upstream sites were high because an excessive amount of rock excavation was required. Approximately one-half mile downstream from the dam where the river bluff recedes, very favorable conditions for foundations and yard grading could be found. There the rock underlying the flood plain gradually rises away from the river. After a study of requirements for condensing water circulation and of the protective measures against water pressures during flood stages had established the optimum elevation of the building foundation, the specific site of the powerhouse could be chosen at a place where firm rock was at this optimum elevation. Railroad and highway facilities and a wharf area at the river front were all in immediate proximity to this area.

The generating station was built to house four units of 60,000 kw each. The plant is designed upon the unit principle; that is, all auxiliary and control equipment is arranged to allow each boiler-turbo-generator unit to operate as a self-contained plant (see Fig. 17).[11] At each such unit, coal is delivered from a bunker to four pulverizers which connect to the eight burners at the boiler. The boiler has a rated capacity of 600,000 lb of steam per hour. Steam, with a pressure of 900 lb per sq in. and a temperature of 900° F, is furnished to the 17-stage, single-cylinder turbine, which operates at a speed of 1,800 rpm. Current is generated at 13,800 v, which is stepped up to 154,000 v at an outdoor transformer yard adjacent to the turbine room. Because of the urgency of early completion of the station, all equipment was selected on the basis of established proven merit, with departures into new fields of design purposely ruled out.

The framing layout of the steel superstructure was developed hand-in-hand with the early equipment arrangements. The housing enclosure was to be kept to a minimum size and was to be built of members easily procurable, provided that these objectives did not prevent obtaining an accessible arrangement of all equipment.

---

[11] "The Watts Bar Steam Power Station of the TVA," by G. R. Rich and R. T. Mathews, *Mechanical Engineering*, November, 1941, Fig. 4, p. 776.

No contraction joints were used in the framing for the 250-ft building. Bracing was introduced close to the sources of horizontal loads. The end bays, where wind and crane bumper loads act, are braced.

For reasons of economy and dependability of service, the coal bunkers are designed to contain a supply of coal sufficient for 1.5 days. They are large structures of 1,250-ton capacity each. The plates in the lower part are of special abrasion-resistant steel. All other bin plates are of copper-bearing steel to retard corrosion.

FIG. 17.—CROSS SECTION SHOWING ARRANGEMENT OF EQUIPMENT

The heavy boiler loads are suspended from heavy girders approximately 50 ft above the generator floor. For the generator-room framing, a welded frame fabricated from 33-in. wide-flange (WF) beams was used. Because this type of construction saved approximately 7 ft of building height, its cost compared favorably with the conventional truss layout. In appearance it is superior to any type of truss. The detail of the crane bracket itself is worth mentioning. A section of the column web, 3 ft long, was removed and the inside column flange was slotted. The 3-in.-thick bracket plate was then inserted and welded on all sides.

Because early delivery of the fabricated steel was essential, built-up sections and special shapes were generally avoided. Continuity of the framing helped a good deal in accomplishing this goal. The total weight of the steel framing of the completed four-unit powerhouse amounted to 4,200 tons.

The station location could be chosen at a place where firm rock was just slightly above the elevation of the boiler foundation. For the low part of the foundation under the condenser pit, the rock was removed easily (see Fig. 18).

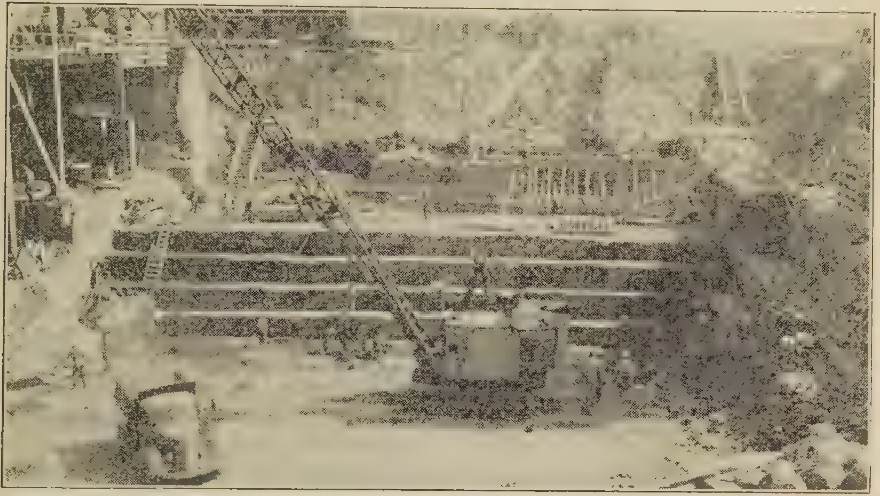

Fig. 18.—Excavation for the Powerhouse

However, this very favorable condition had one serious drawback. The structural strength of the foundation rock—a sandy fissile shale—was very low. Fortunately, considerable information on the characteristics on this rock was available because some of the structures of the hydroelectric plant already completed were built on closely related strata of shale. Many foundation test data and prototype settlement observations were on hand. Based on these data, the compressive stresses on the foundation were limited to 50 lb per sq in. In addition, careful consideration had to be given to uniform distribution of all loads in order to prevent unequal settlements of different parts. These requirements necessitated a heavy foundation slab over the full basement area, about 250 ft by 180 ft in size. Along the outside edges of the slab a continuous retaining wall supports the yard fill and building walls. The main yard level is 32 ft above the lower part of the basement. The assumed design flood reaches 19 ft above the basement floor level. Therefore, large earth pressure and uplift forces had to be taken into account. The total concrete yardage of the substructure amounts to 26,000 cu yd.

In the design of the substructure, many special conditions presented themselves. For instance, the south wall, because of space limitations, had to be designed as a gravity retaining wall. In order to prevent cracking of this wall, which was 17 ft thick, expansion joints were necessary, but no expansion provision was contemplated in the steel framing and the brick walls above. The procedure adopted was to build the retaining wall, with expansion joints at about 33-ft intervals, at a very early date. After they had cooled, a band of heavily reinforced concrete was poured as a continuous base for the brick wall above. In this bank 0.8% of reinforcement steel was used and it is free of cracks.

The foundations for the coal pulverizers consist of 6-ft slabs, 57 ft long. In order to localize vibration, these slabs are separated from the surrounding concrete at the sides and at the bottom by a 2-in. layer of a commercial cork insulating mat.

The part of the condenser pit adjacent to the boilers contains a storage tank for 40,000 gal of distilled water at each unit. To prevent any chemical reaction, the concrete surfaces are lined with carbon brick laid with a special commercially prepared mortar. To prevent any uplift under the bricks, the lining is placed over a layer of porous concrete connected by drain pipes to a special sump. Because of the high temperature to which these pits are exposed, all joints around these blocks have cork fillers to allow for expansion.

To prevent any ground water from entering the basement through these joints, two strips of copper seals were used at all contraction joints, and construction joints were sealed by a single strip.

Each of the 60,000-kw turbo-generator units is supported on a reinforced concrete frame which carries the load to a 7-ft mat for foundation load distribution. Resonant vibration and settlements are of major concern for such a machine foundation. In proportioning the foundation mat, an effort was made to obtain equal settlement under each frame column. To prevent the development of resonant vibrations, the special design recommendations of the turbine manufacturer in regard to loading assumptions, deflection limits, and unit stresses were followed closely. The structure designed on this basis is reinforced heavily. The steel amounts to 285 lb per cu yd of concrete. Because of the stipulation of the manufacturer to disregard shear strength of concrete altogether, columns and beams are crowded with stirrups. A definite sequence for placing the different groups of bars and the forms had to be established to facilitate construction of these members.

The results both as to balance of the rotating equipment and as to absence of resonant vibrations are very gratifying. From sensory inspection, vibrations are scarcely noticeable.

For the condenser water supply, special conditions led to the adoption of a somewhat unusual layout. With a site below the dam, the question arose immediately whether the system should provide circulation by pumping water from tailwater below the dam or by a gravity feed from headwater above the dam. On careful investigation, both systems proved feasible and their costs, with proper allowance for power for pumping and for the loss of generation at the hydro plant, respectively, were almost identical. Because of higher dependability, the gravity feed system was adopted.

The hydraulic conditions are illustrated in Fig. 19. A pressure conduit carries the water from the dam to the condenser. The maximum water requirement of each condenser, at full load with summer temperatures, is 156 cu ft per sec. With the station 800 ft away from the river in an area where foundation rock is substantially above normal river level, a discharge pool had to be provided at basement level. The available head above this pool, with the forebay at its lowest level, is just sufficient to provide the maximum flow. The hydraulic gradient for this condition is indicated in Fig. 19.

Fig. 19.—Condensing Water Supply Systems

Also shown is a gradient for high tailwater conditions, caused by infrequent floods. The condition shown refers to the assumed design flood, with tailwater

20 ft above the discharge pool. In case of such a flood, the conduit capacity would be reduced to 138 cu ft per sec, but because such floods do not occur during the summer season, the required condenser vacuum could still be maintained.

The intake screen house is located upstream from the shore end of the hydroelectric plant; six screen chambers, with low intakes, connect to a common conduit which leads through the service bay substructure of the hydro plant. Once past the powerhouse area, the conduit divides into two sections, each consisting of a concrete pressure pipe 6.5 ft in diameter. These pipes were fabricated by the pipe manufacturers at the project site.

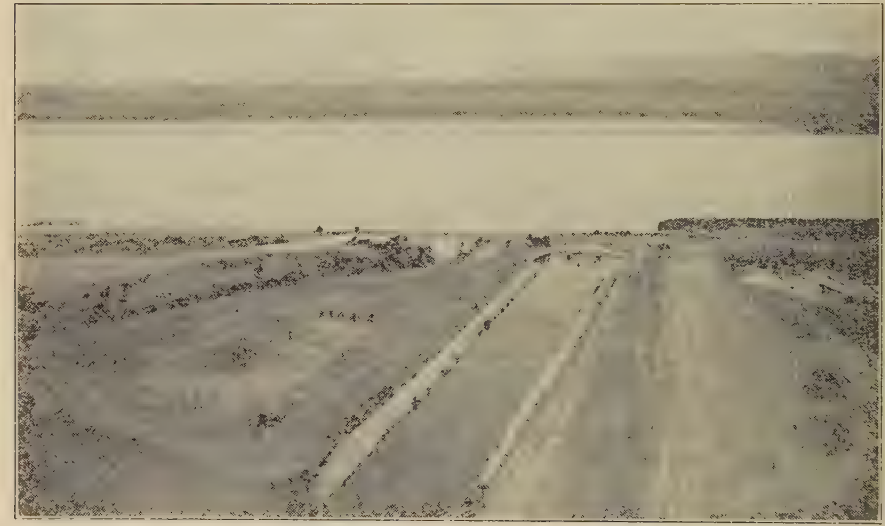

Fig. 20.—Discharge Canal and Morning-Glory Spillway

Where the conduits enter the heavy fill adjacent to the building, the pipe construction terminates and reinforced concrete boxes are used. These conduits continue as part of the substructure blocks until they reach the condenser entrance. The two entrances are each controlled by a 42-in. gate valve placed in a horizontal position and set for a slow 6-min closure, in order to minimize water hammer in the pressure line. At the outlet end of the condenser, 42-in. butterfly valves allow throttling for pressure regulation and closing against high tailwater. A branch conduit leads away from each condenser to the main discharge conduit which connects directly to the open canal in the flood plain between the station and the river.

To dissipate the energy of the drop between discharge pool and normal river level, a morning-glory spillway discharges into a box culvert built on rock under the access railroad to the hydro station. Fig. 20 is a view from the station roof overlooking the discharge canal from the outlet structure to the morning-glory spillway at the river end.

The service areas around the power station (Fig. 21) could be provided by a balanced earth grading job which involved moving approximately 400,000 cu yd of earth. Facilities for coal handling and for coal storage made the largest demand for yard grading. Coal can be delivered by rail, by truck, or by river barge. For rail delivery a large track loop is formed around the coal storage area with the tracks passing over the central unloading hopper. Ahead of the hopper, storage tracks accommodate one hundred loaded cars. At the hopper the main operating track is equipped with a rotary car dumper. Car pullers move the empty cars out of the hopper building to the head of an incline over which the cars move by gravity to storage tracks, having space for fifty cars. Trucks delivering coal enter from the access road and unload into the same main hopper.

For barge delivery a dock about 700 ft long was built along the river front adjacent to the coal handling area, using steel sheet piling salvaged from cofferdams. The dock has a face approximately 33 ft high above the river bottom. A stationary unloading crane unloads the barges, and dumps the coal into a receiving hopper which feeds a conveyer, approximately 1,250 ft long. This conveyer terminates at the hopper building. From the central hopper coal is delivered by conveyers to a crusher and from there to the bins of the power plant. Coal designated for storage is moved by conveyers and power scraper into and out of the 200,000-ton capacity storage pile.

FIG. 21.—GENERAL PLAN, WATTS BAR STEAM PLANT

Careful drainage provisions with ample storm capacity have been made for all the service areas. Care was also taken to obtain stable finished surfaces in all these areas. The slopes exposed to wave action from the river during floods are well protected by riprap. Above the normal flood lines they are protected by grass. In the building area, roads, parking areas, tracks, and grass plots are all well defined by use of concrete curbs.

Like the main building, the yard buildings are all founded on rock. Superstructures were made of light steel frames with walls of asbestos cement boards. The same type of construction was used for the conveyer bridges. Fig. 22 shows the hopper building and its relation to the track loop and the coal storage pile. The rotary car dumper and a truck are shown unloading coal.

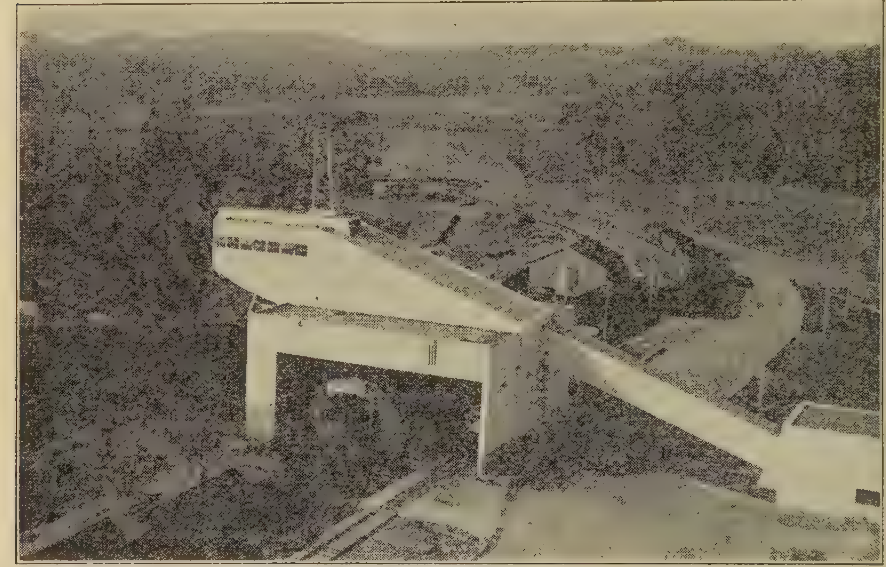

FIG. 22.—COAL STORAGE AREA

An appropriate and pleasing architectural appearance was obtained without any increase in building volume, which was established from functional requirements only and without any changes in the basic steel framing.

SUMMARY

The Watts Bar Steam Station was initiated as a war plant to furnish power for the armament program during World War II. It was ready at the time when the power was needed and until the summer of 1945 had generated more than 3.5 billion kw-hr of energy available for war production. When the war is over and normal criteria will be applied to measure its usefulness, it will stand up well to such an inquiry. Its capital expenditure is relatively low, the cost per kilowatt amounting to $76 exclusive of transformer yard, or $83 when the electrical tie-in to the switchyard is included. Its thermal efficiency is good; during average operation slightly less than 11,000 British thermal units (Btu) are required to produce one gross kilowatt hour. Coal and ash handling equipment are highly mechanized with resulting low operating cost. Dependability of service was a major endeavor in design and in equipment selection. Experience during three and one-half years of operation has shown very good results.

Now that the war task of the Watts Bar Steam Plant has ended, it can be expected with confidence that, based on the foregoing station characteristics, it will be an economical source of power in peacetime.

DISCUSSION

A. T. Larned,[12] M. Am. Soc. C. E.—Clearly and orderly, the second paper of the Symposium (by Messrs. Palo and Marks) describes the layout of a type of hydro station which has become quite standardized for large low-head, propeller type installations. The title of this paper is broad and, perhaps, should have been more explicit, as only a part of the total hydro plants is laid out with the station integral with the dam so that, for stability, advantage is taken of the mass of concrete in the dam itself. There are many other hydro developments already built and to be built in the future, with dams remote from the station and with tunnel, canal, and long penstocks utilizing water under medium or high heads, in which the design and layout of the station involve problems of a somewhat different nature than those outlined in the paper.

Functional Considerations of Design.—Quite appropriately, Messrs. Palo and Marks have emphasized the functional characteristics of power-plant layout, which enables one to visualize the over-all performance of each type of equipment and its interrelation with other types, so that each can be arranged to perform its assigned task in the most effective manner and with the minimum space requirement.

In power-plant design, the realization of directness and compactness, and the elimination of excess or waste space, assure that the lowest cost will be obtained in the construction of the plant. The designer sets the pattern and there is nothing the construction man can do later to reduce costs if the designer failed in his layout. In other words, "the money is already spent as soon as the design leaves the drafting table."

In regard to allotting space for future maintenance and repair requirements, it is of particular importance that heed should be given to the advice and counsel of the operating group who in the future must "live" with the plant, in order that all equipment be made easily accessible and the repair and tool rooms be arranged conveniently.

Simplification of Design.—The features of simplicity and economy of design have been stressed by Messrs. Palo and Marks, and it is evident that the outdoor and semi-outdoor types of station have been valuable contributing factors in the accomplishment of this objective. The writer is aware of no adverse experience resulting from this type of installation, and the elimination of expensive superstructure to house nothing more than a traveling crane has resulted in marked economy. Steam-plant designers have realized the advantages of the outdoor type of station and many of the newer steam installations utilize outdoor boilers, auxiliary equipment such as circulating fans, and, in some cases, outdoor turbine units.

Messrs. Palo and Marks make no mention of the rôle that the umbrella or overhung type of generator has played in the design of the outdoor type of hydro station. This arrangement of generating unit enables a substantial reduction in powerhouse costs through reduced head clearances. The advantages of the umbrella type of generator are that it reduces the guide bearings from three to two and materially shortens the span necessary for the bracket supporting the thrust bearing. This reduces the length of shaft necessary and also makes it possible to dismantle the generator for inspection and repairs without disturbing the thrust bearing, shaft, or turbine.

---

[12] Chf. Civ. Engr., Ebasco Services Inc., New York, N. Y.

It is advantageous to restrict the control room to the minimum space possible, with due allowance for the addition of future electric controls. In most cases, for stations with one to three main generating units, the control room has been placed on the main operating floor between the units so that full visibility of the governors and generating equipment is possible. This avoids the need for a separate building and takes up floor space that would be wasted otherwise.

The advisability of locating the governors and actuating equipment on the generator floor to save space has been noted by Messrs. Palo and Marks. There is another reason for locating this apparatus and other auxiliaries on one floor in so far as possible, the number of men on a shift can be reduced to the minimum. This is an important consideration from the point of view of reduced operating costs and increasingly difficult labor conditions.

Model tests and tests of actual installations have shown that the entrance to the penstock or upstream side of the water passage need not be increased materially in size. A moderate increase in diameter by a properly shaped bellmouth is all that is necessary to keep the entrance losses low. This type of construction is economical because the size of the intake gate can be kept to a minimum.

Design as Related to Concrete Construction.—The discussion of the need for, and the method of, locating construction joints (see Fig. 15) is especially helpful and should serve to impress both the engineer and the construction man with the need for care in placing concrete. Experience has proved that it is advantageous to have the construction joints located by the engineer rather than by the construction man. The need for an early decision as to the location of these joints is well taken as the design will depend considerably upon their placement.

Although the Palo-Marks paper mentions only construction joints in the heavy substructure, it also would be well to call attention to the need for joints in the lighter concrete sections of the structure above the generator floor. Such joints are necessary for construction purposes and also to localize the cracks that would result if large areas of concrete walls were not protected by such construction.

In some of its recent designs for steam plants the writer's company has resorted to the use of special control joints in the reinforced-concrete walls and parapets of the buildings. These consisted of wood strips tacked to the forms to leave wedge-shaped joints in both the exterior and interior faces of the walls. These have been successful in eliminating the unsightly patterns of shrinkage or expansion cracks, and they control the location of the larger cracks that usually appear. The joints are filled with a concrete-colored calking compound which preseals any cracks that may occur.

A brief general statement as to the means adopted for securing watertight joints would be appreciated. The appearance of joints, after a few years, can either make or mar an otherwise perfect job.

The generation of heat in large blocks of concrete, and the damage resulting from subsequent shrinkage when the concrete is cool are well known in connection with the design and construction of dams. However, little has been published about this subject in connection with power-station structures, since most hydro developments have not been of the magnitude of those designed and built by the Tennessee Valley Authority (TVA) and other government agencies. The attention called to this factor, therefore, is timely and should help to make it easier for the engineer to sell to the construction organization the desirability of placing the concrete in the powerhouse substructure in the proper sequence and at the proper intervals of time.

Messrs. Palo and Marks have not mentioned form construction, particularly the construction of draft-tube forms. It has been found convenient to build these forms on an erection floor where wood-working machinery is convenient and working conditions neither cramped nor dangerous. The forms are built in large sections and transported to the powerhouse site by truck.

Large quantities of steel reinforcement usually are required in powerhouse substructures to carry and distribute the loads into the foundation. There is a tendency on the part of some construction men (as well as some engineers), not intimately connected with the design, to claim that the amount of reinforcement used is unnecessarily large. The Palo-Marks paper calls attention to the necessity and desirability of using considerable reinforcement both for structural strength and for resisting temperature and shrinkage stresses. In view of the large amount of reinforcing steel necessarily required, careful analysis should be made of the loads acting, or assumed to be acting, on the structure simultaneously so as not to make these loads larger than is absolutely necessary.

In the design and construction of the many hydroelectric plants with which the writer has been connected, it has not been considered necessary to provide a gate at or near the downstream end of the draft tube except where the runner is located below tailwater. Operating experience over a period of about thirty years has confirmed the opinion that the need for draft-tube unwatering is very slight, and that provision for the installation of stop logs or a single panel bulkhead that can be used for any one of the units should suffice. In many cases, the omission of such downstream gates has made it possible to put the transformers on a platform on the downstream side of the powerhouse, thus making the electrical connections from the unit to the transformers very short and simple. In most cases, this has been a considerable advantage over the practice of placing the transformers at a distance, especially where the plant is in a place where it is necessary to go a considerable distance to find a large enough level piece of ground.

The concentration of load that may occur at the upstream nose of the piers in draft tubes, and the difficulty of caring for these loads, have been mentioned by Messrs. Palo and Marks. On several occasions the writer's firm has placed a short, built-up steel column at this point, with spread base and capital to take the load concentration. This column has been of aid also in supporting the form work for the draft tube.

Attention has been called to the presence of cracks in the side walls of the volute casings of three of the stations described in the second paper. These cracks were about 10 ft upstream from the center line of the unit. The similarity of the cracks in the three cases leads to the conclusion that a definite set of stresses has been the cause for the pattern of cracking. By referring to the cross sections of the station in question it will be noted that this is the point where the deep excavation starts for the draft tube. This reentrant angle into the concrete, if considered as a casting, could account for the failure, particularly if the line of excavation changed abruptly from vertical to horizontal. The writer has always attempted to excavate so that there is a fillet in the concrete and so that the change in direction is gradual.

The authors of the second paper (to which all the writer's comments are limited) are to be commended. It is to be hoped that the paper will stimulate further study and discussion of the many problems which it has raised.

William P. Creager,[13] M. Am. Soc. C. E.—The painstaking care with which the authors and their colleagues have conducted research and tests on hydraulic structures is evident in these papers.

In Mr. Riegel's paper one test is missing—namely, that for the percentage of area of the base of dams subjected to uplift pressures. For several years, the Power Division of the Society has had a Subcommittee on Uplift in Masonry Dams, whose purpose was to devise experiments and report on its findings. The subcommittee has not reported, probably because it could devise no tests that would show conclusively whether only a part of the area or 100% of the area is subject to uplift. Notwithstanding the absence of such tests, the Tennessee Valley Authority (TVA) has assumed that only two thirds of the area is subjected to uplift pressure, after taking into consideration the maximum possible effect of the grouted cutoff and drainage system. With respect to this feature the writer presumes to take issue.

Uplift pressures under dams should be analyzed strictly according to two factors: (*a*) The hydraulic gradient factor and (*b*) the area-of-pressure factor.

(*a*) *Hydraulic Gradient Factor.*—Fig. 23 indicates a typical hydraulic gradient under a solid concrete dam. The piezometric pressures at the base vary from tailwater pressure h at the toe to tailwater pressure plus a percentage C of the head H on the dam at the drains and thence to full headwater pressure at the heel. The coefficient C is an indication of the effectiveness of the grouted cutoff and the drainage system; and w is the unit weight of water.

The hydraulic gradient factor, for the TVA main river dams, has been shown by Mr. Riegel to correspond to Fig. 23 with an adopted coefficient C equal to zero. The writer has no criticism of the hydraulic gradient factor adopted for the main river dams, since subsequent tests have shown the adopted factor to be correct. Incidentally, it corresponds to 100% efficiency of the drains. However, attention is called to the fact that similar tests[14] on many other dams with grouted cutoffs indicate much less than 100% efficiency of drains. Either the nature of the rock or the excellence of the engineering has resulted in high efficiency of the TVA drains. It is doubtful if such high efficiency can be assured for all future similar dams.

---

[13] Cons. Engr., Buffalo, N. Y.

(*b*) *Area-of-Pressure Factor.*—The area-of-pressure factor for all TVA dams was assumed to be equal to two thirds of the area. The area-of-pressure factor has been the subject of much debate, ranging from about 50% to 100% of the area. The writer will not attempt to reopen arguments on this subject except to state that, by the very nature of so-called solid materials, if the area of pressure is less than 100%, the material must be capable of resisting tension.

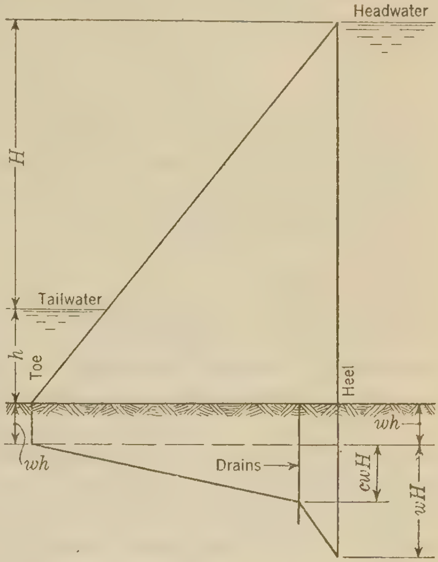

FIG. 23.—TYPICAL HYDRAULIC GRADIENT

Conversely, if the material, or any layer or bedding plane in the material, is of such a nature that it would not have appreciable tensile strength, then it should have an area-of-pressure factor of 100%.

The TVA main river dams were designed on the assumption that two thirds of the area of the base was subjected to uplift pressure. This area-of-pressure factor was adopted for "calcareous rocks with approximately horizontal bedding considered favorable to the accumulation of uplift pressures in the foundation itself." Thus, this factor is assumed to be advantageous in the accumulation of uplift pressures without a grout curtain and without drainage installation. Therefore, it is favorable to the accumulation of whatever uplift pressure remains after taking into account the full effect of the grout curtain and drainage on the hydraulic gradient.

For a river wall, supporting earth and with river depth and ground-water depth equal on each side of the wall, the use of less than 100% uplift would not be considered unless the foundation were capable of resisting tensile stresses; but this assumption is exactly what was made with respect to tailwater uplift in the TVA main river dams where the foundation is "favorable to the accumulation of uplift pressures."

The TVA criterion for uplift is not conservative when compared with what the writer believes to be common practice, and the writer cautions against adopting it without the advance knowledge that the drainage system will be permanently 100% effective and that the rock is of such a nature that 100% uplift will not occur over the area of the base.

---

[14] "Uplift Pressure in Masonry Dams," by Ivan E. Houk, *Civil Engineering*, September, 1932, p. 578.

In the case of the higher dams, Mr. Riegel states that one half of the headwater pressure was assumed at the line of drains.

It might be mentioned that, as shown in Fig. 23, the pressure at the drains must be equal to tailwater pressure plus a percentage of the net head on the dam —because the effect of the grouted cutoff and the drains is not a function of the headwater pressure but is a function of the net head in the dam. Incidentally, Fig. 3 does not show one half of the headwater pressure at the drains, as Mr. Riegel states; but it does show the correct relation of tailwater pressure plus one half of the net head on the dam.

I. L. Tyler,[15] M. Am. Soc. C. E.—The field embraced by Mr. Riegel's excellent paper in this Symposium is such a large one that only a very brief treatment of many important features could be included. In the case of "foundation restraint" (see heading, "Concrete Dams: Foundation Restraint") some amplification of the text may be desirable.

In addition to the three major methods for controlling mass concrete temperatures discussed by Mr. Riegel another method was used at Hiwassee Dam. In this case, the mixing water for concrete was artificially cooled during periods of high placing temperature. Although the reduction in maximum temperature accomplished by this means was not much (perhaps 10% of the maximum rise), its possible effect on cracking cannot be ignored, since conditions favorable to the elimination of temperature cracks were actually closely approached and even small improvements in temperature conditions may have had considerable effect. Hiwassee Dam as finally completed was unusually free from cracks considering the very limited use of embedded cooling pipes. Perhaps some credit for this must be assigned to the benefits, even though small, which resulted at critical times from the cooling of the mixing water.

Mr. Riegel's discussion of the effect of the concrete placing rate on temperature rise of mass concrete without cooling pipes may not be sufficiently detailed to clarify all the variables involved. With a concrete placing rate averaging 1 ft per day the use of 2½-ft lifts at 2½-day intervals in place of the more common 5-ft lifts at 5-day intervals does permit some greater head loss to the air, as Mr. Riegel states, even with the low-heat cement and concrete of low-cement content. However, an even greater advantage, so far as cracking from foundation restraint is concerned, comes from the improved temperature distribution vertically through foundation and dam. The desirable condition, of course, is to avoid steep temperature gradients and for this the thin lifts are preferable as shown by R. W. Carlson,[16] Assoc. M. Am. Soc. C. E.

Mr. Riegel made no comments on the effectiveness of the measures taken to minimize temperature cracking in mass concrete. This may leave the reader with some doubts as to the feasibility of reducing cracking by such precautions. It is realized that many factors other than temperatures influence cracking in mass concrete, and that to cover them all would be out of the question. However, the writer suspects that Mr. Riegel has a considerable fund of information on the relation of temperatures and cracking on many of the TVA structures, and he respectfully urges that Mr. Riegel give the matter all consideration possible in his closure.

[16] "Temperature and Stresses in Mass Concrete," by R. W. Carlson, *Journal*, A.C.I., March–April, 1938.

PHILIP SPORN,[17] M. AM. SOC. C. E.—As stated by Mr. Meyer, the civil engineering features of the design of any steam plant materially affect the ultimate cost of power generation. In the writer's experience, this has been amply demonstrated many times. However, the writer is of the further opinion that the design of both the electrical and mechanical systems, so far as arrangement of equipment and the selection of materials and methods for doing the work are concerned, are just as flexible and present just as many possibilities for savings in the initial cost of the development as do the civil engineering features. Therefore, all three phases should be considered at the same time and only when this is done and the selection of the best combination is made does the most economical design result.

Furthermore, the operation and maintenance of the plant must be given careful consideration, or the savings realized from some particular design may be quickly wiped out. This is particularly important when the present cost of labor and the trend that seems to be establishing itself in this field are considered.

The advantages of economical fuel supply, and the location with regard to load, must have been the main determinants of the location of the Watts Bar Steam Station because the other reasons given by Mr. Meyer for choosing this site are not very conclusive. The savings from combining the construction of the hydro plant and of the steam plant are small; and, from an operating standpoint, the plants are too far apart to reduce the size of the operating personnel appreciably. Possibly, if the hydro plant were electrically controlled from the steam plant, some saving in operating costs could be realized but Mr. Meyer does not mention if this was done.

The design developed by Mr. Meyer is well prepared and rationally developed. Rationalized as it is, however, some of the underlying assumptions seem open to question. At least, they run counter to the writer's experience. To illustrate: At Watts Bar, two stacks have been provided, each probably serving two units. The writer has found that the cost of this type of arrangement and the amount of critical materials employed are about the same as in the case where a separate stack is provided for each boiler. From an operating standpoint the individual stack for each boiler is preferable to the arrangement adopted at Watts Bar.

From a study of the plans, the width of the generator room seems to have been determined by turbine erection, considering that the generator rotor would be pulled parallel to the long axis of the machine. In pulling the rotor, if it were canted in a horizontal plane (as is frequently done), the width of the generator room could have been reduced. Furthermore, the writer has never found any need for carrying the track approximately the full length of the turbine room as has been done at Watts Bar. Generally, this increases the width of the generator room.

---

[17] Executive Vice-Pres. and Chf. Engr., Am. Gas and Elec. Service Corp., New York, N.Y.

Furthermore, a wall seems to have been constructed between the generator room and the heater bay. The trend in modern design omits this wall. By opening the generator room to the heater bay and boiler room it is possible to obtain not only savings in structures but better ventilation. The operating personnel avoid the feeling that the boiler room is a place for burning coal and as a result must be dirty and does not deserve the same clean care as the generator room.

Since the main basement floor is only 19 ft below the level of maximum river stage, it is difficult to understand why the foundation slabs need to be as thick as indicated in Fig. 17. For example, at the Philo Plant of The Ohio Power Company, where the bottom of the condenser pit is about 56 ft (as compared to 32 ft at Watts Bar) below ground level, and 46 ft (as compared to 19 ft at Watts Bar) below flood level, the slab was about 4.5 ft thick as compared to a slab thickness of about 8 ft at Watts Bar. Furthermore, it has been the writer's experience that, wherever there is a deep basement, it usually has been possible to arrange columns and struts so that one wall of the pit was braced against the other. As a result, the pit side walls at the Philo plant are about 3.5 ft thick as compared to the apparent 11.5-ft south wall of the boiler room basement at Watts Bar. It would be interesting to learn more about the design basis behind these differences.

Mr. Meyer states that the slab beneath the main boiler columns was continuous for 250 ft and that the design of coal-bunker framing could not allow any movement of the foundations. Obviously, if the sandy shale foundation rock would only permit a loading as light as was applied, then some, perhaps substantial, saving could have been obtained by arranging the framing between the basement and main floors as a truss and reducing the thickness of the slabs. Was this considered and, if it was, and then rejected, what was the reason?

The handling of the circulating water problem and the adoption of the gravity system of supply is very interesting. From Fig. 19 the 3,500 ft of intake, which required such a deep excavation, appears quite costly, especially since the two pipes were not run together—apparently requiring 7,000 ft of excavation. Is such an intake required for the gravity system as economical and reliable as the use of circulating water pumps, considering that any settlement might break the lines? Was any procedure in addition to the tongue on each length adopted to prevent relative movement between adjacent pipes because of earth movements? Why was such a long canal used to connect the condenser outlet with the river? A long canal permits more sedimentation than would a short one, and this has an adverse effect on the operating expense, as well as on the initial investment. Again, if the length of the canal had been decreased, the power plant could have been nearer the river—thus decreasing the length of the conveyer between the barge-unloading dock and the hopper building, which would have resulted in a saving in the cost of constructing the coal-handling facilities. Could Mr. Meyer enlarge on this subject?

The facilities that have been provided in the coal-handling yard are unquestionably ample; and, although they may be too elaborate for present capacity, they appear adequate for the ultimate capacity. Nevertheless, one is inclined to ask the reason for the choice of a drag scraper with a traveling tail tower, instead of large tractor-scraper equipment. One is also inclined to ask some questions about the coal dock, although there is not enough description included in the paper to comment on its construction. The Cabin Creek Plant of Appalachian Electric Power Company, with an installed capacity of 325,000 kw, has a sheet-pile dock about 200 ft long supplemented by pile clusters for mooring downstream from the dock. This arrangement proved to be very economical and yet substantial.

Mr. Meyer and his architectural associates are to be complimented for the fine synthesis of structural function with architectural appearance that has been incorporated into the Watts Bar plant. The writer is acquainted with no modern power plant at which this has been done more effectively and where the two functions have been more perfectly wedded. Engineer and architect have not only succeeded in developing a structure that functions properly, but have also obtained one that looks well.

JOSEPH R. BOWMAN,[18] JUN. AM. SOC. C. E.—The title of the second paper of the Symposium is rather inclusive, whereas the paper itself is primarily concerned with but one of the several types of hydroelectric power developments designed by Tennessee Valley Authority (TVA). Messrs. Palo and Marks are to be commended, nevertheless, for their emphasis on the importance of functional layout to design. The relative importance of the functions of water flow, flow of electricity, and mechanical control is generally understood and accepted by those engaged in the design of hydroelectric power stations. On the other hand, considerable difficulty is experienced frequently through failure to understand the proper correlation of the electrical control, auxiliary electrical equipment, and auxiliary mechanical equipment functions. The most desirable layout of unit and station auxiliary services can best be obtained through appropriate evaluation of the interrelation of these functions. Evidence of the value of competent functional planning is reflected in the minimum of interference of unit and station service functions presented in many of the TVA hydro plants.

To simplify otherwise cumbersome sentence construction, the writer will use the term "semi-outdoor" with the implication that it includes the "modified outdoor" station of the type used at Hiwassee Dam, as well as the true "semi-outdoor" type of station adapted to the Cherokee, Douglas, Fort Loudoun, Watts Bar, and Kentucky projects.

---

[18] Asst. Civ. Engr., Erik Floor and Associates, Chicago, Ill.

Notable among the accomplishments of the TVA program is the departure from the conventional indoor power station housing large units. Messrs. Palo and Marks cite relative economy, operating convenience, and appearance as the general bases for the selection of the various powerhouse types. In addition, they have advanced the conditions of (1) maximum tailwater above the generator floor and (2) access level above the generator floor as the criteria governing the selection of the semi-outdoor type of station. In the comparison of a number of the TVA powerhouses the writer has observed inconsistency and inadequacy in the application of these criteria. For example, these governing conditions, expected at six of the main-river, low-head developments, led to the selection of semi-outdoor hydro stations at Kentucky, Watts Bar, and Fort Loudoun; on the other hand, indoor stations were selected at the Pickwick Landing, Guntersville, and Chickamauga projects.

The appearance factor frequently exerts considerable influence on the selection of power stations employed in public power programs. Whereas some organizations direct attention to the powerhouse by the accentuation of vertical lines, the TVA has utilized accentuation of horizontal lines to direct attention from the powerhouse to other structures on the project. The effect of the latter policy is further promoted by the adoption of the semi-outdoor station.

Several factors are involved in the determination of the relative economy of the indoor and semi-outdoor stations. A considerable saving may often be obtained through the elimination of expensive superstructure walls. However, where very high tailwater conditions are expected, a weight of material equivalent to that eliminated must be added to the substructure to insure the stability of the structure. The net saving, therefore, will be determined by the unit price differential between superstructure and substructure types of construction. Another factor worthy of consideration is the replacement of the conventional roof structure by the deck-type roof used in semi-outdoor stations. The saving, if any, effected by the foregoing procedure may be offset by the increased cost of a massive outdoor gantry crane. Further economy may be obtained by modification of the crane to embrace the functions of handling intake and draft-tube gates (as adapted to the Kentucky station), thereby eliminating the need for separate cranes to perform those operations. From the viewpoint of operating economy, additional expense may be incurred in moving the massive outdoor crane, and in performing operations ordinarily not characteristic of indoor stations, such as the handling of unit hatch covers.

Floor operation (as distinguished from control room supervision) of as few as two or three large units has apparently become standard practice in many hydro plants of the TVA and other organizations. Efficient floor operation usually demands the location of unit auxiliary equipment in the immediate vicinity of the floor operator's station, which, in turn, is usually near the unit governor controls. Design for stability against extremely high tailwater results in very compact substructures in semi-outdoor stations. Consequently, a critical shortage of space for auxiliary equipment near the unit may result. As the physical size of auxiliary equipment is nearly constant over a considerable range in unit sizes, this shortage of space will become even more critical for smaller units, probably necessitating the location of auxiliary equipment some distance from the floor operation center. The compactness of the substructure of a semi-outdoor station frequently involves the elimination of a distinct turbine floor and necessitates the location of all governing equipment—actuator, sump, and pressure tank—in a compact group at the floor operation center. This is an important advantage in view of the requirements of efficient floor operation. Further operating economy is obtained by the utilization of the "twin" operation center, in which the auxiliary and governing equipment of two adjacent units is grouped into a common operation center. Indoor stations, except when modified by unusual local conditions, ordinarily utilize a distinct turbine floor. This practice frequently leads to the separation of the actuator from the governor sump and pressure tank, thereby increasing attendance requirements. The use of a separate turbine floor often creates unused or "nonproductive" space.

Protection of personnel from severe climatic conditions is frequently advanced as a basic factor governing the selection of indoor powerhouses. The semi-outdoor station appears to satisfy the normal requirements of personnel protection, and the writer believes that the relatively infrequent use of the powerhouse crane alone will not justify the use of an expensive superstructure building. Inasmuch as several outdoor stations are in operation in the northern part of the United States, it is apparent that this type of station has little respect for adverse weather conditions.

The two criteria advanced by Messrs. Palo and Marks for the selection of semi-outdoor stations are merely approximate indicators, and their application should be limited to preliminary studies. On further analysis, the basic factors of appearance, relative economy, and operating convenience will form the bases for final station selection.

As stated by Messrs. Palo and Marks, the rapid pace set in the design of hydroelectric power developments has slowed sufficiently to permit expansive discussion of this subject. The writer notes, however, that much of the technical literature published by the TVA itself has been of descriptive, rather than analytical, nature. The writer suggests that fewer limitations on the exchange of ideas could contribute substantially to the advancement of knowledge in the engineering profession.

PAUL GISIGER,[19] M. AM. SOC. C. E.—It is a pleasure to note that the commendable policy of the Tennessee Valley Authority (TVA) engineers to report on design and performance of their structures in Society publications has been continued with these highly interesting and instructive papers.

---

[19] Structural Engr., Pennsylvania Water and Power Co. and Safe Harbor Water and Power Corp., Baltimore, Md.

First Symposium Paper.—The first paper by Mr. Riegel is especially valuable because of the data presented on various kinds of observations and measurements of completed structures. In this respect, it is an excellent complement to the Symposium on Dams which was presented at the meeting of the Society's Joint Committee on Masonry Dams in Chattanooga, Tenn., on April 20 and 21, 1939.

In the first part of his paper Mr. Riegel properly states that, in the choice between different types of concrete structures, the cost of future maintenance should be a factor and that established methods of construction may also have an influence on design. The writer knows from personal inspection that the concrete in all TVA structures presents an excellent appearance and that maintenance costs in that respect should be very low. It is only fair to record, however, that, in the Tennessee Valley, climatic wear and tear on the concrete is generally less than, say, in Pennsylvania or New England. There are fewer cycles of freezing and thawing, and the same composition of concrete, which in a more northern climate might show excessive water-line deterioration in a short time, may retain its original appearance where winters are less rigorous.

The treatment of uplift conforms to conservative assumptions. As TVA dams generally are standing on sedimentary rock formations with definite bedding and cleavage planes, the policy of drilling uplift relief holes from 20 ft to 40 ft into the foundation is well justified. It has been established elsewhere[20] that even in quite compact rock formations, without such holes, uplift pressures some distance below the foundation joint may be of greater magnitude than those in the joint itself.

Although measured uplift pressures afford a good corroboration of design assumptions with regard to magnitude, they still do not settle the question as to the fraction of foundation area on which they should be considered active. The TVA assumption in this respect, considering the general character of foundations, grouting, and drainage provisions, is on the conservative side. It is highly desirable, but admittedly difficult, to find a method for removing this particular point from the realm of speculation to that of measurable fact.

Mr. Riegel makes it plain that he does not believe in the practice of grouting transverse joints of gravity dams, and the writer fully agrees. Although the reasons given for grouting the lower parts of the joints of high dams are plausible, these questions may still be in order: (1) Will the desired results be obtained? (2) Do not the departure from design assumptions and change in stress conditions thereby produced result in too high a price for the possible benefits? (3) Could not the same benefits be obtained by using drilled holes for grouting, thereby avoiding the obliteration of the contraction joints?

The results of stress measurements at completed structures under load are highly interesting. There are two explanations offered for the discrepancy between measured and observed stresses near the upstream face of some dams. Might not a third (and very probable) one be that the wetted portion of concrete near the upstream face does not shrink, but rather does expand and that the shrinking of the interior portion puts it under compression? The question is also asked whether in Fig. 7(*b*) the vertical stress curve between point 5 and the extreme toe has any basis other than assumption.

---

[20] "Uplift Measurements at Holtwood Dam," by Paul E. Gisiger, *Civil Engineering*, July, 1938, p. 449.

From these observational data, the conclusion is inescapable that much about actual stress conditions in dams under load is still to be learned and that the use of elaborate mathematics for the derivation of stresses is of questionable practical value.

The section on "Earth Dams," in Mr. Riegel's paper, gives some excellent illustrations of the principle that sound engineering consists in making the best use of the most readily available materials. It would be interesting to learn how the different materials and cross sections compare economically. Although the earth dams are somewhat overshadowed by the scope of the other structures of the TVA, they are important enough in number and size to justify the hope for a future paper to treat, in more detail, the topics of planning, construction, and performance.

Second Symposium Paper.—The general features of a modern low-head and medium-head hydroelectric unit have become fairly well standardized, and differences in powerhouse cross sections are generally limited to the following: (*a*) The powerhouse may be of the indoor or outdoor (or semi-outdoor) type; and (*b*) step-up transformers may be alongside the generating equipment, or they may be some distance from the powerhouse. Within these general types there may be other variations of a lesser order of significance, but with considerable influence on detail structural design. Such factors are: (1) Location of thrust bearing (above or below the generators); (2) location of transformers (on the upstream or downstream side of the powerhouse); (3) location of mechanical control equipment (all on the main floor, or part of it on an auxiliary lower floor); and (4) differences in complexity and space requirements of electrical apparatus in accordance with system operating necessities.

The irreducible minimum requirements of a hydro powerhouse may be assumed to be reached with a layout in which transformers are located in a separate switchyard, in which generator leads are taken directly away from the powerhouse without interposition of a low tension bus, in which all speed-control equipment is on the main floor, and in which no superstructure is provided. The Fort Loudoun powerhouse comes very close to this minimum layout. It is significant that earlier powerhouses of the TVA are more complex. In general, it will be easier to get along with a minimum of apparatus if a new development is only a fractional addition to an already existing large generating system. On the other hand, if a new development is a main component or large fraction of a power system, its layout tends to be more complicated and to require more space. Apart from the influence of operational and system requirements, personal judgment and organizational preferences may come into play, too. This may be the case to a considerable extent in the provision or omission of a generator-room superstructure. Although it has been stated sometimes that climate need not be a determining factor in deciding whether or not to provide a superstructure, it still appears significant that, to the writer's knowledge at least, no outdoor or semi-outdoor types of powerhouses are in existence in Canada or New England. In TVA territory real blizzards are not a regular feature of every winter and operational difficulties from the omission of the superstructure should not be serious. It will be a matter of great interest to learn how the operating personnel of the TVA will evaluate the relative merits of indoor and outdoor layouts. Local conditions and other features of the general layout may have a decisive influence on the saving possible from omission of superstructure. Comparison of the Chickamauga cross section with that of Hiwassee makes it obvious that in the former the omission of side walls and roof would have meant a relatively much less saving than in the case of Hiwassee.

It is to be noted that, on almost every TVA main-river development, maximum tailwater elevation is above the top of the generators, requiring massive downstream walls of great height. This necessity, although apparently typical of Tennessee River developments, is by no means general. It is quite apparent that, in case of the Pickwick and Chickamauga, this condition worked against the outdoor type of powerhouse.

A comparison of the Fort Loudoun and Chickamauga cross sections, which are otherwise very similar, suggests the question as to why, for Fort Loudoun, the semi-outdoor powerhouse was preferred.

In the section on "Substructures for Large Propeller Units," Messrs. Palo and Marks rightly stress the importance of transverse joints, the attention that should be given to the subdivision, size, and sequence of concrete pours, and the difficulties that may have to be solved to keep commitments for future units within certain limits. The writer fully agrees that, for unit spacings of 40 ft or more, there should be contraction joints between all units. Messrs. Palo and Marks mention the difficulty presented by the usual offset between center line of unit and center line of intake and the resulting nonsymmetry of the draft tube, if the contraction joints are to be in one plane and perpendicular to the powerhouse axis. If there is an electrical bay on the upstream side of the generator room (which means heavily loaded columns to be located over the ends of the intermediate intake piers, as at Pickwick Landing), there are additional difficulties from this source. The writer does not believe that serious disadvantages would result if, on account of these difficulties, transverse contraction joints should deviate from a straight line or a single plane provided that thereby their proper function (to allow volume changes in the direction of the longitudinal powerhouse axis) was not impaired.

Conflicting requirements of hydraulic streamlining and stress concentrations in the noses of intermediate draft tube as well as intake piers may be satisfied with the help of structural or cast-steel vertical members at these locations.

With regard to the complex matter of scroll-case design, the writer feels that, although the efforts of the designing engineers so far have produced acceptable (but by no means perfect) results, a real mathematical treatment never has been undertaken. Such a task is not too complex and should be accomplished some day. The conception of vertical beams between top and bottom slabs is obviously only an approximation of actual conditions. It follows from any assumption of vertical beam action that such action must be accompanied by circumferential stress; and this stress, rather than temperature, is responsible for vertical cracks in scroll-case walls. As a rule every scroll-case wall has one vertical plane of least cross section on its downstream side, approximately on the transverse center line of the unit. The writer has seen vertical cracks on a number of concrete scroll cases at this location and believes they are caused by circumferential stress from water load.

Mathematical investigation of this condition is in line with the conclusion by Messrs Palo and Marks (with which the writer fully agrees): That the field of powerhouse design is at a stage where the course of development has slowed down sufficiently to make desirable a review of present methods and practices, and application of refinements which were not feasible in the days when each new development was an advance in size and scope over preceding developments.

Messrs. Palo and Marks are to be congratulated for a capable and concise presentation of a complicated, and never fully described, phase of civil and hydraulic engineering.

Third Symposium Paper.—During the past ten years or fifteen years, the development of water power has attracted much more attention than the construction of steam power plants. Therefore, when an organization which made history in the design and construction of water power developments builds a large steam power plant, its accomplishment in this respect deserves careful study by all engineers interested in either steam or hydroelectric power plants.

The paper by Mr. Meyer, intentionally, does not include any discussion of the reasons why, even in a hydro power system like that of the TVA (which includes both a number of run-of-river, as well as high-head storage plants), the addition of a considerable block of modern steam capacity was desirable. The fact that this steam plant was built, however, indicates that a combination of hydro and steam power is very often desirable and economical and that the two kinds of power are not competitive (as is sometimes believed) but complementary.

Mr. Meyer rightly observes that civil engineering features in a steam power plant are quite important for the over-all economy of the station. It is possible that sometimes in the design of steam power plants these features have not received the attention that they should because they are usually overshadowed by the much greater cost of steam producing and generating equipment.

At first it may be somewhat surprising that the Watts Bar station is not directly on the riverbank; but convincing arguments are presented to show that the location is the most economical one after due consideration of all factors involved.

The general design of the station with the unit layout of all auxiliaries follows generally established practice in steam plant design. In view of the outdoor type of powerhouse used by the TVA at the adjacent Watts Bar hydro plant, as well as at several other hydro stations, it is of interest to note that the usual complete housing of boilers, generators, and associated equipment has been chosen for the steam plant. It is perhaps rather surprising that the superstructure of this station was made of brick, whereas the TVA, so far, has mostly used reinforced concrete for hydro station superstructures. The question may also be asked whether it would not have been preferable to put a constrction joint into the superstructure between each of the four units. It does not appear quite logical to have construction joints in the substructure but not in the superstructure, which is more subjected to dimensional changes induced by temperature variations.

The steel-frame design of the generator-room roof follows the precedents established by the hydro plants of the TVA and it is an improvement over the conventional truss layout in several ways. Mr. Meyer rightly calls attention to the ingenious design of the crane-rail brackets in which the possibilities of welded construction have been utilized fully and intelligently.

With regard to the turbo-generator foundations, the question is in order as to whether the use of reinforced concrete was dictated by wartime considerations of material priorities or whether the TVA engineers considered this type of foundation generally preferable to a structural steel foundation. It appears that, with the multitude of piping around the foundations of steam turbines and the relatively greater ease with which piping can be accommodated through and between steel foundations, and also because of the greater speed of erection, there would be considerable advantages in the use of structural steel. However, if (as Mr. Meyer states) vibrations of the completed structure in service are hardly noticeable, the designers are to be congratulated for the results achieved, considering the number of cases in which excessive vibration has occurred.

With regard to the circulating water system, it appears that the plan for taking water out of the upper pool and returning it to the tailrace of the adjacent hydro plant was the proper method for this location. In view of the situation at another steam plant alongside a hydro plant—where it was found advantageous to take circulating water from the hydro plant forebay, but to pump it back so as not to lose any hydro generation—the question may be asked whether the latter system would have been used if the steam plant could have been located closer to the hydro plant. It may be perfectly justifiable, economically, to take water away from the hydro plant for this purpose; but there is a certain suggestion of wastefulness in having to use an energy dissipator at the point where this water is returned to the river. The question also may be asked as to why two conduits were used, considering that one pipe of 9-ft diameter would have been more than equivalent to the two pipes of 6-ft diameter. Since only one intake has been provided and 99% of all troubles in condensing water systems occur either at the intake or at the pumps, it does not appear that the two conduits could be justified by any consideration of dependability.

A somewhat more extensive description of the coal unloading and handling facilities would have been welcome. Such features have a considerable influence on the operating cost of a steam power plant, but are seldom described or treated in literature.

Oren Reed,[21] M. Am. Soc. C. E.—Powerhouse design of the Tennessee Valley Authority (TVA) is presented in a very clear and comprehensive manner in the second paper of the Symposium. Most of the text and illustrations apply to the main-river plants of the TVA, where the powerhouse is an integral part of the dam. At the higher dams of the tributary storage installations, the powerhouse is at the toe of the dam but is usually separated from the dam by a longitudinal contraction joint.

The typical semi-outdoor powerhouse is an economically sound choice for the usual installation where an extremely high tailwater does not require consideration. The heavy, overhead gantry crane cannot reach anything except the generator, which is as disadvantageous for maintenance and repairs under operating conditions as it is initially during construction. It is sometimes necessary during construction to leave a part of the roof off the generator room temporarily to place certain apparatus properly. Such interferences with proper construction procedures are unsatisfactory but must often be countenanced because of late deliveries of materials.

Provisions must be made to take care of many visitors at power projects near large centers of population or on good roads. Where large numbers of visitors are expected, more attention must be paid to the architectural appearance of the powerhouse than might otherwise be justified. Both the interior and the exterior of an indoor-type powerhouse have better appearances than an outdoor or semi-outdoor powerhouse.

Powerhouse design of recent installations by the TVA has been well planned. There is no waste space but there is no evidence of overcrowding. The auxiliaries are conveniently arranged and all reasonable safety precautions have been taken. Facilities for visitors are ample and the general appearance of each installation is very satisfactory.

R. L. Smart,[22] M. Am. Soc. C. E.—The economic depression of the 1930's and World War II caused the development of hydroelectric projects virtually to stop except for the activity of certain government agencies such as the Tennessee Valley Authority (TVA). Engineers, interested in this field, have followed the developments of the TVA, and thus the paper on hydroelectric stations by Messrs. Palo and Marks is very timely. In a careful review of this paper, the advancement in ideas and methods that took place from the initial work at Pickwick Landing until the final work as represented by Fort Loudoun is described lucidly.

The various functions of a hydro station and their relation to each other are well presented. Far too many projects in the past indicate very clearly that the first function received all the attention and that the remainder became incidental—to be taken care of in almost any way. Simplicity of layout and the elimination of waste areas are of prime importance. Certainly one way to secure such a result would be to fit the installation into the topography of the site, with due consideration for the hydraulic conditions and the most logical access.

---

[21] Constr. Engr., TVA, Fontana Dam, N. C.

[22] Project Mgr., Ambursen Eng. Corp., Cons. Engrs., Houston, Tex.

If such conditions indicate a distinct advantage for any one type of structure—namely, indoor, outdoor, or semi-outdoor—that type should be chosen. Many engineers have a distinct preference for some one type of structure and have allowed that preference to rule regardless of whether that type was most suitable to the conditions. The TVA most certainly took all conditions into consideration and produced layouts to suit those conditions. All functions of such layouts were properly related for simplicity and the requirements of the project.

The proposal developed by TVA, for the acceptance of uniform waterways by all turbine manufacturers, was a most noteworthy advance and one of particular importance to those engineers who are not in a position to purchase turbines previous either to the initiation of designs, or even to the construction of certain parts of the project itself. It is not at all difficult for turbine manufacturers to agree on a uniform waterway (exclusive of the scroll itself). That one item permits the installation of future draft-tube sections at the time of original construction. By so doing the later need of troublesome, and often very costly, cofferdams can be eliminated, as such provision can be incorporated into the initial construction as part of the ultimate structure.

Modern trends in architecture have produced structures for the TVA that are most in harmony with the entire project. The function of the architect should be emphasized to the fullest degree, not only for outward appearance, but for the development of the proper features within. Although they will not admit it, most engineers are poor architects, and many a powerhouse stands today an eyesore both within and without. Rigid frames, be they steel or concrete, modern welding developments, and streamline designing are willing and able tools for the architect. By virtue of economic conditions prevailing during much of its construction program the TVA was extremely fortunate in being able to assemble a group of engineers with many and diversified lines of thought. They combined to bring forth numerous advancements in design and construction methods that it is hoped will be made available to the engineering world in general. Not all were perfect, not all will be accepted, but there are none not worth knowing.

ABRAHAM STREIFF,[23] M. AM. SOC. C. E.—An excellent and well-arranged description of seven low-head hydroelectric plants built by the Tennessee Valley Authority (TVA) is contained in the second Symposium paper. Plants with single, direct-connected vertical units have been in use since about the beginning of the century, and their design was thoroughly established when the TVA was organized. Although the plants described contain many excellent features, the writer finds many points of difference with previously established practice. Such rules as are set up by Messrs. Palo and Marks should apply only to the plants discussed, as there are some radical departures which are not at all universally accepted by engineers engaged in the design of hydroelectric stations. Some of these concern: (1) The fluctuation of the headwater elevation; (2) the low elevation of the intake sill; (3) disadvantages inherent in the combinations of items (1) and (2); (4) the depths of draft tubes; and (5) straight vertical joints between units.

---

[23] (Fargo Eng. Co.), Jackson, Mich.

(1) Headwater Elevation.—The most conspicuous point of difference with common practice in low-head design is the very large fluctuation in headwater elevation. At Chickamauga Dam, for instance, the headwater level varies 26 ft. The operating head is considerably less than the maximum head. This increases the cost greatly without corresponding return from power developed. All structures, as well as machinery, stability, runaway speed, and head gates, must be designed for a head much greater than the operating head. Therefore, although the machinery may have a high efficiency, efficiency of the plant as a power dam is low. The cost is greatly increased whereas the output is based on a lower head. This is a concession to "flood control," which the writer does not intend to discuss. The design, however, is based primarily on such large headwater fluctuation, or so-called "flood pool," and the question may well be asked as to what advantage is gained by the greatly increased cost. The areas subject to flooding are greater than before the dam was built;[24] and, over a length of 633 river miles, flood "protection" has been obtained by purchasing several hundred square miles of land subject to flooding and by removing the occupants! This result could have been achieved without building a single dam, which is precisely the method in vogue for the lower Mississippi River, the rivers of the Netherlands, the Tisza River in Hungary, and the Po River in Italy, where maximum flow lines mark the boundaries of the public domain reserved exclusively for use as floodways.

The low-head dam with varying water level, therefore, is "neither fish nor fowl nor good red herring." As a power dam its plant efficiency is low, and the same kind of flood protection for the 633 miles of the Tennessee Valley could have been achieved without building a single low-head dam.

(2) Elevation of the Intake Sill.—A second departure from usual practice in low-head design is the very low intake sill elevation. The intake sills are the lowest spot of the cross section of the river. It is well known that holes dug into the bed of a river tend to refill. In the case of a deep pool with low velocities, mud and "deadheads" will accumulate. The "deadheads" have a tendency to collect and pile up in the lowest places toward which the current is directed. The large discharge through the big Kaplan units will cause all waterlogged trash to gravitate and converge toward the lowest spot in the intake. With the large rack spacing provided, the penstocks will tend to become fouled and gate grooves may become obstructed. Gates must be designed to stand unnecessarily large pressures, and lifts must become greater. Therefore, raised sills were included in such early structures as the Keokuk (Iowa) power-

---

[24] "The Chickamauga Project," *Technical Report No. 6*, TVA, 1942, p. 30, Fig. 8.

house (1913). The argument is advanced that a short and straight intake is hydraulically preferable. However, the loss in the intake is minimal; and reduction of the already minimal intake loss is obtained at the price of several and costly disadvantages. The hydraulic passages comprise an intake as well as a draft tube. Sharp bends are allowed in the draft tube, where the velocities are really high and losses really large. It seems inconsistent to introduce a further warp or twist in the draft tube, merely to obtain straight up-and-down construction joints between units, while at the same time trying to reduce a minimal intake loss by straightening the intake.

(*3*) *Disadvantages.*—The low intake sill combined with the fluctuating headwater has a number of disadvantages. The head gates must resist a greater head and must have a higher lift. The shape of the intake precludes the use of Tainter gates, which are low in cost and can be closed quickly. Presumably to reduce the cost, a traveling crane with lifting beams, dogging devices, etc., has been adopted. This arrangement is cumbersome and slow. Heretofore much importance has been attached to rapid closure of penstocks.[25] In this connection it is of interest to refer to the Ryburg plant on the Rhine River in Switzerland. This station, built prior to the seven TVA dams (1932), contains Kaplan wheels which are larger in diameter than the largest of the TVA Kaplan runners. It also contains the same kind of head-gate system as was installed in the TVA plants; but, in describing the station,[26] it is stated that the plant does not have a single head gate! In effect, the head gates of the TVA type are emergency gates and nothing more. They are too slow and cumbersome to serve as head gates.

To make up for the absence of head gates, the Ryburg plant has a special governor system, consisting of a separate governor with its own pump and tanks for the Kaplan runner as well as for the guide case. If the governor that operates the wicket gates should fail, the runner blades would still be operated by the independent governor. In addition, a third emergency governor, actuated by an overspeed relay, and having an emergency pump of its own, would close the runner blades to a $-5°$ position, so that the runner would then act as a brake. The great friction in the trunnion bearings of the movable blades at runaway speed (the centrifugal force acting on each blade is about 750 tons at runaway speed) requires that the emergency governor have a capacity of not less than 760,000 ft-lb to assure operation of the runner blades in such an emergency. For the TVA plants apparently no special precautions have been considered necessary, as they have a standard governor layout.

The disadvantage of such low intakes becomes apparent when the cost of the head-gate system is compared with a Tainter-gate installation of equal opening. For the Chickamauga Dam, the cost of two sets of three head gates, 38 ft by 17 ft 8 in., is given as $189,361.94—not including the hoist. Each set is equivalent in area to two Tainter gates, 40 ft by 25 ft. An installation of two Tainter gates in each penstock (including the hoists) as purchased the same year for the spillway of the Buchanan Dam in Texas (1937) would have cost

---

[25] "Catalog on Quick-Closing Gates," J. M. Voith Co., Heidenheim, Germany, 1935.

[26] *Schweizerische Bauzeitung*, June 4, 1932, p. 295.

$68,022. This cost would cover the provision of permanent gates with fixed hoist for each of the three turbine units—not just for two sets of gates to serve three units and this without the hoist. Tainter gates can be closed quickly, are very reliable, and are used in many dams and at many hydroelectric stations. The sizes of the Tainter head gates, in feet, at various installations are shown by the following list:

Name of dam	Width	Height
Cooke	25	20
Alcona	25	20.5
Junction	30	22.5
Elkhart	22	17
Five Channels	26	20.5
Alpena	16	18
Loud	26	20
Foote	29	18.67
Hodenpyl	20	20
Wissota	26	24.5
Mio	29	18.67
Texas Hydro IV	24.67	20.5
Texas Hydro V	24.67	20.5
Texas Power IV	24.67	20.5

None of the foregoing head-gate installations have required the use of emergency gates, although the oldest was made in 1912 and the latest in 1932.

(*4*) *Depth of Draft Tubes.*—For plants of the size described by Messrs. Palo and Marks, the draft tubes are from 50 ft to 60 ft deep. The spillway discharge causes a great vortex in the tailrace, which carries gravel into the draft tube. A long separating wall is indicated in such cases, which can be extended as a so-called "dwarf wall."[27] Since the separating walls for the plants described seem too short, this will introduce difficulties in seating the draft-tube gates.

(*5*) *Vertical Joints.*—Much stress has been laid, by Messrs. Palo and Marks, on straight vertical joints between units. This requirement is definitely necessary only for plants on a rock foundation. For plants built on a soil foundation, no joint is needed for a length of as much as 114 ft. At the Junction Dam on the Muskegon River three concrete scroll cases form one unit 114 ft long, operating under a head of 60 ft. Cracks such as those described by the authors for the TVA scroll cases have not appeared, although the plant is thirty years old. Such unit construction results in economy as the piers do not require doubling.

When a dam is built on an unyielding rock foundation, there should be a joint between units. Why should the joints be straight up and down? Such a requirement only introduces another warp and twist in the draft tube; it complicates the form work on the draft-tube division walls and offers no visible advantage. Many plants have been built with offsets, with no indication that straight joints are desirable. The logical approach to a good design is to lay out scroll case and draft tube as they should be and then to place the joints wherever they come. In the Ryburg plant, the joint follows the outline of the scroll and draft tube.[28] The friction coefficient of concrete on concrete is very low for slow temperature changes,[29] and with proper reinforcement no difficulty is experienced in superstructures by offsetting substructure joints. The location of the joint should be decided according to hydraulic requirement. Since this has always been the case, the writer sees no reason to change the usual practice.

---

[27] "The Irrigation Works of India," by R. B. Buckley, 2d Ed., London, 1905.

Ross M. Riegel,[30] M. Am. Soc. C. E.—In regard to the discussion by Mr. Creager, TVA engineers agree with the practice advocated by him of analyzing the uplift pressure under dams according to two factors—that is, the hydraulic gradient factor and the area-of-pressure factor. However, Mr. Creager apparently takes issue with the use of any area factor less than 100%. Before proceeding with discussion of this point, it is to be noted that Mr. Creager is correct in the definition of uplift intensity as applied to the higher dams—that the drainage coefficient applied to the difference between head and tailwater elevations has a value of 0.50.

The author is convinced that the difference between a rock foundation and a granular foundation should be reflected in a difference between the areas to which uplift pressures are assumed to be applied. In the case of granular materials there is no question as to the 100% factor. The author is one of several who has demonstrated this experimentally, but, when there is cohesion and continuity in the supporting structure, the relationships involved are somewhat different.

The most reasonable approach involves two assumptions:

(1) That the uplift pressure acts through and upon certain openings, pores, or channels, in such a way as to reduce the effective weight of the supported structure; and

(2) That the reduced weight must be supported by the solid part of the foundation, which will carry this load in compression.

The assumption that two thirds of the foundation area is subject to uplift means that the compressive loads are really carried upon one third of the gross area. In this case no tensile strength in the foundation need be assumed, at least with regard to principal stresses.

The use of the two-thirds ratio cannot be defended experimentally; it is justified chiefly by a conviction that the factor must be materially less than unity. A number of engineers have adhered to the two-thirds ratio as expressing their judgment; and, in the structures referred to, this value was used as representative of current conservative practice. Although the author has referred to a certain susceptibility of bedded rocks to the development of uplift, heavy excavation has been practiced on TVA dams to secure as sound foundations as the intrinsic character of rock permitted; and these have been very good foundations indeed.

---

[28] *Schweizerische Bauzeitung*, May 7, 1932, p. 241, Fig. 14.

[29] "Sliding Joints Under Pressure," by F. Bolliger and W. Humm, *ibid.*, January 9, 1937, p. 15.

[30] Head Civ. Engr., Design Dept., TVA, Knoxville, Tenn.

Examination of the TVA main river dams indicates no cause for concern even if the assumed uplift intensities are applied over 100% of the base area. Although the margins assumed in the design would be somewhat reduced, they are still sufficient under any probable loading to avoid tensile effects at the heel. In the case of Fontana Dam, which has been made heavier because it was exceptionally high, calculations based on 100% area showed no tension at the heel under conventional calculations.

Mr. Gisiger feels satisfied with the adequacy of uplift assumptions, although he as well as others, including the author, are hopeful of sometime acquiring actual data as to effective areas and of taking this question out of the realm of assumption. The recently published investigations of Mr. Leliavsky may show the way.[31]

In regard to other questions raised by Mr. Gisiger, the extension of the stress curve in Fig. 7(*b*) from point 5 to the toe is supported by strain meter observations in the downstream face of the dam at depths, of 8 in., 20 in., and 36 in. but at 35 ft above the basic measuring section. The extrapolation of this stress curve is thus well supported, although that between point 1 and the heel is not so well supported.

It is the author's present belief that absorption of reservoir water, somewhat as suggested by Mr. Gisiger, by the concrete is largely responsible for the compressive stress observed near the upstream face of Hiwassee Dam. Certain aspects of this phenomenon are still unexplained, but it is hoped that later observations on Fontana Dam will be of value in this connection. A detailed study of the stresses in Hiwassee Dam is being prepared for publication.

Mr. Gisiger rather questions the placing of any grout whatever in transverse joints. In TVA dams the same view has generally prevailed. However, in the cases of Fontana and Hiwassee dams, the objective of curing potential cracks near the foundation level appear to warrant a departure from this policy. It is believed that no objectionable stresses arose from the limited grouting. The cracks could have been reached by drilling; but, even in this case, grout would be likely to escape into the contraction joints. As to Mr. Gisiger's hope for a further paper on earth dams, there are some prospects of publication on these lines.

Mr. Tyler asks about the relative effectiveness of various measures in the reduction of cracks. The control of actual temperatures in the concrete by cooling water circulated through pipes, as practiced at Fontana Dam, has probably been most effective. This measure may be supplemented by the use of chipped ice in the mixer during hot seasons or by otherwise cooling the mixing water so as to reduce the placing temperature. Fontana Dam is the only TVA dam in which a general program of forced cooling was conducted.

---

[31] "Experiments on Effective Uplift Area in Gravity Dams," by S. Leliavsky, *Proceedings*, Am. Soc. C. E., December, 1945, p. 1474.

Aside from Fontana Dam, Hiwassee Dam represents the best results obtained with respect to cracking in TVA practice. In the writer's judgment the most important factor in this result was the basic program of slow pouring, set up and adhered to on this job. Next in importance he would rank the use of low-heat cement with its concrete of relatively high plasticity at the early ages, and the low cement content. The cooling of mixing water, as mentioned by Mr. Tyler, was certainly also a beneficial factor.

Construction under wartime pressure with nonavailability of certain materials and shortage of man power, coupled with urgent need for completion, sometimes has required some departure from the best methods. In closing, the author would remark that a certain deliberation is desirable in the placing of mass concrete.

George P. Palo,[32] and Constant R. Marks, III,[33] Assoc. Members, Am. Soc. C. E.—The second paper of this Symposium was presented in three main parts—namely, (1) "The Functional Layout," (2) "The Superstructure," and (3) "Substructures for Large Propeller Units." It is desirable to arrange this closing discussion in a similar way.

Functional Layout.—Several of the discussions, touching upon the problems of functional layout, have added appreciably to the thoughts presented in the paper. Mr. Larned and others have stated that the paper described the layout of a large low-head station integral with the dam. Such a station was used, as an example, because it involves nearly all the elements of equipment and space requirement commonly found in a powerhouse. However, many of the principles involved can be applied with some modification to other types of plants. To detail such application for the various types of plants would have required a much longer paper.

Mr. Streiff states that the headwater level at Chickamauga Dam varies 26 ft and that low-head developments for such a headwater variation are not sound. A detailed discussion of this subject is beyond the scope of this paper; however, it should be emphasized that the actual headwater variation at Chickamauga Dam for power operations is only 10 ft. An additional 16-ft headwater rise develops in the case of the maximum design flood, and at this time the tailwater is only 3.5 ft below the headwater level. Hence, for all practicable purposes, the headwater variation at Chickamauga Dam is only 10 ft. For a power plant with a reservoir and drainage area of the size existing at this site, variation of the headwater is quite necessary for efficient use of the stream flow. Comments on the economics of providing flood pools in conjunction with relatively low-head dams, as has been done on the Tennessee River, do not seem applicable to a paper that deals with station layout and substructure design. For this reason and because this subject has been treated at great length in other places, no attempt will be made to answer Mr. Streiff's questions on this subject.

---

[32] Chf., Civ.-Architectural Design Div., TVA, Knoxville, Tenn.

[33] Chf. Design Engr., Ambursen Eng. Corp., Houston, Tex.

Mr. Streiff also refers to the low intake sill elevation as a departure from usual practice in low-head design. The cross section of intake waterways used by the Tennessee Valley Authority (TVA) on its low-head plants was not originated by that organization. The Bonneville, Wheeler (a TVA project designed by the Bureau of Reclamation), Rock Island, Safe Harbor, and even the smaller London and Marmet plants are all examples of propeller wheel installations built since 1925. All of them use a low intake sill, and all were designed by different organizations.

Mr. Streiff suggests the desirability of providing head gates suitable for rapid closure but then refers to the Ryburg plant on the Rhine River where no head gates are used but where the governor system adopts unusual protective measures. The Ryburg plant has four units, each of which is separately owned and each of which supplies its own distribution system through its own switchyard. Such conditions make Ryburg, in effect, four single-unit stations, each available for almost instant operation. The units in TVA stations, as parts of a large system, need only normal governor protection. In case of difficulty with a unit, or during periods when stream flow is insufficient for all units, a single head gate handled by a gantry crane offers adequate and amply rapid closure of the waterways.

Mr. Streiff's comment that the vortex in the tailrace caused by spillway discharge will result in deposit of gravel in the draft tube is correct provided the units are not operating. In the years of TVA experience, it has been found that river-bed gravel is deposited in draft tubes which have been completed and are ready for installation of units at some future date. No deposits have developed in draft tubes of completed units. When it has been necessary to unwater for the installation of the turbine and generator, the small additional cost necessary to clean out the gravel and set the draft-tube gates has been almost negligible as compared to the cost of extending the training wall between the spillway and the tailrace.

The writers are in full agreement with Mr. Streiff that head losses in an intake are so small that they do not justify great expense for small reductions that might be accomplished; and, in stressing the desirability of the short intake, it was intended only to emphasize that this procedure provided ample hydraulic efficiency at minimum cost.

Superstructure.—Almost all the discussers have commented on the choice of type of superstructure and have cited additional details that should be considered in making this choice. However, the items of cost, operating convenience, appearance, and access still remain the basic features to be considered in determining the type of superstructure. Mr. Bowman notes the apparent inconsistency of TVA projects in that indoor structures were used for Pickwick, Chickamauga, and Guntersville, whereas semi-outdoor structures were selected for Kentucky, Watts Bar, and Fort Loudoun. Mr. Gisiger offers the same suggestion in comparing Chickamauga and Fort Loudoun. These factors arise simply from the building schedules of the projects. The indoor projects were designed first, and not until Watts Bar and Kentucky were being considered was the concept of the semi-outdoor design fully developed. Within the writers' knowledge only one other plant in the United States, designed and built about 1923 by Mr. Larned's organization, has used the semi-outdoor scheme. TVA designs were originated without prior knowledge of this plant but did utilize knowledge of the Wetter plant in the Ruhr in Europe. Mr. Gisiger suggests that the outdoor plants must be limited primarily to warmer climates. The writers agree that in many organizations this factor will receive such consideration, but it is known that Mr. Larned's organization, which has been particularly active in the development of outdoor stations, has built such structures in Minnesota and Montana. Mr. Reed describes certain future obligations that should be considered whenever an outdoor or semi-outdoor powerhouse is under discussion. The inability of the overhead gantry crane to reach anything except the generator and interferences with construction procedures are definitely limitations to outdoor plants. It has been suggested that the entire roof sections of outdoor plants could be made removable. Such procedure would minimize these disadvantages.

In the next to last paragraph of his discussion, Mr. Bowman indicates his understanding that, in final choice of superstructure, access is a relatively minor factor as compared with economy, operating convenience, and appearance. Access can be regarded as a part of operating convenience, of course; but, whether it is a separate or a dependent factor, access in some plants must be considered the most vital single item in the choice of superstructure.

In view of the comments of the discussers, the writers would like to summarize the comparison between indoor and semi-outdoor types of powerhouse:

1. In designing for tailwater elevations more than 20 ft above the generator-room floor, the semi-outdoor type will usually offer great economy, since it avoids an excessively high superstructure, large watertight doors, or the use of a transfer crane for bringing equipment into the powerhouse;
2. For lower tailwater elevations marked economy will usually be possible only if the number of units is large so that the superstructure saving over several units can be balanced against the extra cost of a gantry crane;
3. Where the economy of eliminating superstructure is not demonstrably large, the factors of appearance, operating convenience, and more readily constructed watertight roof will generally lead to adoption of the conventional indoor powerhouse.

Substructures for Large Propeller Units.—

General.—Mr. Larned has requested a brief general statement as to the procedure adopted for securing watertight joints. TVA designs have attempted to secure watertightness, as has been emphasized in this paper, by a careful consideration of volume change so that cracks may be held to a minimum and then design of reinforcement so as to spread cracks that do form. Concrete is proportioned carefully. When the concrete is quite heavily reinforced and when $1\frac{1}{2}$ in. is the maximum size of coarse aggregate, cement content is about 1.5 bbl per cu yd. Special care is taken in the cleanup of horizontal construction joints, and steel strips are used as water stops. In vertical construction or contraction joints, copper strips are used. These strips may be a single line if they are intended as protection against leakage from occasional high tailwaters; or they form a double line if their purpose is protection against permanent headwater pressures. Where shears are transferred across construction joints, the surfaces of the joints are roughened by jackhammers, and the improved bond so obtained assists in obtaining watertight conditions.

Draft Tubes.—Mr. Streiff has objected to the offset in draft tubes to permit the use of a straight contraction joint between units. He feels that waterways should be determined according to hydraulic requirements and that the structure should be built around them. The writers, however, agree with Mr. Smart's comment that "Far too many projects in the past indicate very clearly that the first function [waterways] received all the attention and that the remainder became incidental * * *." Proper design must balance the cost of waterways together with the cost of structure and all other features in the building of the powerhouse. Actually, no turbine manufacturer has objected to the offset provided in the draft tube, and there has never been any indication of additional hydraulic losses from it. The offset does not complicate the forms beyond the fact that two or three draft-tube frames used in the elbow are not symmetrical—but this condition has no effect on the draft-tube construction. The benefits of a straight joint are considerable in the detailing not only of the substructure but of the superstructure; and these benefits far outweigh any minor complications needed to offset the draft tube. If the tried and relatively simple practice of extending the joints between unit blocks straight up through the superstructure by double columns and girders is to be followed, the problem of superstructure design presented by offset joints is very large. The writers cannot agree with Mr. Streiff that the friction coefficient of concrete on concrete in practicable structures is very low for slow temperature changes. Actual experience and difficulties of incorporating sliding seat details in field construction are such that these designs should be avoided wherever possible. The writers agree with Mr. Larned's comments that draft-tube forms should be built at a point separate from the actual construction and should be hauled by trucks to the place where they will be finally set. This has been standard TVA practice. They are also in accord with Mr. Larned's comments that draft-tube gates are almost never required where the turbine is set above low tailwater. However, experience with cavitation has tended toward lower settings of units than were prevalent some years ago. In addition, propeller wheels usually are set lower than Francis wheels. In almost all TVA projects the turbine is below low tailwater, and the draft-tube gates are used whenever the draft tube is unwatered. Both Mr. Larned and Mr. Gisiger have mentioned the use of cast-steel noses for the upstream end of the draft-tube piers. Many actual projects show the practicability of such procedure. TVA designers have preferred the use of concrete nosings, however, on the basis that plastic flow of the concrete must eventually create extremely high stresses in steel nosings with resultant high bearing pressure on the concrete at the top of the steel nosing and on the rock foundation at the bottom.

Scroll Case.—The writers have commented on the recurrent crack in the scroll-case walls approximately 10 ft upstream from the center line of the unit, and Mr. Larned has suggested that this condition may result from a sharp break in the excavation just below this point. As this crack has never appeared in the massive concrete floor of the scroll case, the writers are convinced that it is a result of temperature stress in the scroll-case walls, resulting from the restraint of the massive floor. However, Mr. Larned's warning about the danger of such reentrant angle as may be formed by a sharp break in foundation excavation is sound. Actually, TVA excavation lines have not been the sharp corners indicated on some of the drawings in the paper; and, even where a tendency for a sharp corner has existed, reinforcement has been used to control cracks. Furthermore, the steps in the excavation are not usually continuous across the unit but extend farther downstream near the contraction joints, where bedrock can be left in place between the upstream ends of adjacent draft-tube elbows. Mr. Gisiger suggests the desirability of a thorough scroll-case design instead of the admittedly approximate treatment that has been used. He states that the concept of vertical beams between top and bottom slabs must be accompanied by circumferential stress and that this stress, as well as temperature, may be responsible for vertical cracks in scroll-case walls. The writers agree fully with these comments, and all TVA scroll cases have included substantial horizontal steel to withstand circumferential stresses. The subject for a real mathematical design of scroll cases, however, involves many serious difficulties—among them the analysis of a structure of extremely complicated shape with stresses affected by many holes cut in the concrete. The temperature stresses must be analyzed properly for various possible conditions that will be met in construction. Even the usual methods for proportioning reinforcement in concrete must be reviewed, because in the heavy corner sections the stress conditions simply do not permit the proportioning of reinforcing steel on the basis that the concrete cracks to the neutral axis. The writers are convinced that such analysis must always assume a certain allowable tensile strength for the concrete. The desire for greater knowledge of stresses within scroll cases is no doubt shared by every designer. It is the writers' belief, however, that the best approach is the experimental one—probably by stress measuring devices embedded in actual scroll cases. They cannot emphasize enough, that measurement be made with fully as much attention paid to the history of stresses due to temperature changes as to those for the water loads. There are certainly many points in the scroll case where tension in the concrete due to shrinkage far exceeds that due to the bursting pressure of the water.

The writers appreciate the contributions of those who have discussed the paper and feel that they have added much to its original content.

Adolf A. Meyer,[34] M. Am. Soc. C. E.—The discussions have widened and enlarged the scope of the writer's paper; for, as Mr. Sporn states, an economical and well-performing station can be designed only when all elements—civil, mechanical, electrical, and operational—are taken under consideration at the same time and with equal weight. The design for the Watts Bar plant was developed under just such a procedure. Unfortunately, this well-integrated process of work could not be clearly reflected in the paper because, for apparently good reasons, it was agreed at the outset to limit the discussion to the civil engineering features. Based on his experience with this paper, the writer believes that a more useful and more substantial presentation could have been made by including the more important phases of mechanical and electrical design.

All the specific features of design mentioned in the discussions were the results of comparative studies, and the suggested alternatives were considered carefully during the early design stage. The most constructive procedure for this closure, therefore, will be to refer to these early studies and to state why, n each case, the adopted feature was found preferable to the alternatives mentioned in the discussion.

The station location, in its broad aspects, was governed by load requirements and fuel costs. These considerations placed it in the eastern part of Tennessee; but the specific site selection within this rather extensive area was based on advantages which were unique for the Watts Bar site: Ample transimission interconnections for the hydro plant; existing railroad siding and access road provided for the hydro plant; a construction organization; and construction facilities, such as warehouses, shops and utilities, camp facilities, and a village for operators. Together these items, which could be made usable for both plants with only small changes or additions, constitute a substantial expense. Not mentioned in the paper was the saving in operation obtained by placing the control of the main electrical switching for the steam station in a central control room adjacent to the main switchyard.

For the number of stacks used, it appears consistent with the unit design adopted for the station to provide one stack with each boiler, as suggested in Mr. Sporn's discussion. However, outages for stack maintenance are very rare, and therefore the unit principle is not essential in this regard. With one stack for two boilers, the framing of the stack base is far more economical in the narrow bay between boilers than is the framing for the two bases each over the wide boiler bay. In addition, at Watts Bar provision had to be made for the possible future addition of dust collectors. The adopted layout which provided one stack for two boilers lent itself readily to this provision whereas, for the layout with an individual stack for each boiler, this future installation would introduce considerable complications.

The width of the generator room was determined by requirements for turbine erection. Two ways of pulling the rotor were considered. One was canting in a horizontal plane as suggested by Mr. Sporn. The alternative provided a removable plate in the wall, through which the shaft could be extended beyond the generator room. This alternative required 2.5 ft less width and was therefore adopted. By adding 1 ft to the minimum clearance requirement (which was desirable from the point of view of erection, in any case) a track could be arranged parallel to the long axis of the generator room. By adopting this layout no track changes of any kind were necessitated in the yard during the three consequent construction stages.

---

[34] Head Civ. Design Engr., TVA, Knoxville, Tenn.

In the initial construction of the steam station no wall was provided between generator room and heater bay. Only after the station had been in operation for some time was it considered desirable from reasons both of operation and of architectural appearance to add this wall.

The thickness of the basement-floor slabs is the direct result of limiting the allowable compressive stresses on the foundation to 50 lb per sq in. By adopting this severe assumption the loads had to be distributed uniformly over practically the full basement area, with the slab thickness proportioned to obtain the distribution with minimum material requirements. The load limitation was adopted after observing settlements on similar rock foundations in the vicinity, which amounted to $\frac{7}{8}$ in. under a load of less than 150 lb per sq in. This and other similar observations on the behavior of the foundation rock under load invited extreme caution. Unequal settlements which would be detrimental to equipment and structures had to be avoided. A uniform distribution of the load by a continuous foundation mat was the answer to these conditions. The observed results of these measures were very gratifying; no unequal settlements were experienced.

Mr. Gisiger states that the outdoor-type of powerhouse is a possible alternative to the adopted enclosed construction. As there was very little time available for design studies, the generally proved type of steam-station layout with a fully enclosed structure was adopted at the beginning. A brick enclosure was chosen because it is more economical and more durable than a concrete superstructure. Mr. Gisiger assumes this to be a departure from the TVA practice on hydro-plant design. During flood stages almost all TVA powerhouses have tailwater above generator-room level. They must be watertight; and, for this reason, concrete was adopted. Where this criterion does not exist, TVA, since about 1938, has preferred construction in tile with stone facing for the hydro powerhouses.

Since the substructure was built without any permanent contraction joints, it was logical to omit the joints in the superstructure. The foundations for the turbo-generator units were built in reinforced concrete because structural steel was critical war material; but, apart from the necessity imposed at a particular construction period, this type of foundation would have been preferred by the TVA designers in normal times. Clearance requirements can be satisfied with concrete construction; but this construction is much better adapted to the elimination of objectionable vibrations. Such reasoning agrees with the very definite recommendations of the turbine manufacturer.

As stated in the paper, the gravity-type of circulating water system was adopted because of its superior dependability after a careful analysis of all cost elements entering the problem had shown that the pump and the gravity systems were almost identical in cost. Whereas Mr. Gisiger supports the contention of superior dependability by his statement that "* * * 99% of all troubles in condensing water systems occur either at the intake or at the pumps * * *," Mr. Sporn seems to have doubts regarding the dependability of the pipe lines. They were all placed in natural ground and carefully backfilled, and the writer can perceive no cause for any break or damage of this system.

Of course, had the actual construction sequence been foreseen at the time the first two units were installed, the two pipe lines would have been combined into one conduit—with a resultant substantial saving. However, in 1940–1941, during construction of the first two units, the need for the third and fourth units appeared to be many years off. After the Japanese attack on Pearl Harbor, Hawaii, this condition changed very rapidly; but no one could have foreseen it.

The dissipator at the end of the canal, which suggests wastefulness to Mr. Gisiger, covers the range of the normal tailwater variations. The energy involved, of course, was included in the cost analysis. It is interesting to note that this same feeling of waste led to a study of the advantages of using a small hydro unit instead of a dissipator. However, the study showed that such an installation could not be justified economically.

Mr. Sporn requests an enlargement of the previous statements of the reason why the station was moved 600 ft away from the river. He notes the cost of the long discharge canal and the long coal conveyer connecting with the coal dock.

The cost of the canal—excavation and riprap—was $26 per ft. The coal conveyer cost $33 per ft. Assuming a possible shortening of these features by some 400 ft, a saving of about $24,000 could have been realized on these items. The rock foundation at this location for the plant would have been 50 ft lower and even the natural ground level would have been below the basement level, if the station were to be built with the same conservative protection against floods. For a station at this location, the substructure costs would have been increased many times the saving realized on conveyer and canal. In addition, the yard grading would have required an enormous quantity of borrow material. The freedom which the present layout gave in the arrangement of the yard structures all around the main station would have been lost; and a less convenient yard layout would have resulted. In fact, the advantages that could be obtained by the location away from the river impressed the writer so much that in the future he would not consider a location study for a steam station complete if it did not include investigations of sites away from the immediate river shore. Of course, different conditions may result in an answer quite different from the one obtained at Watts Bar, but the prevailing notion that under all conditions it is best for a steam station to be close to the river was severely shaken by the result of the Watts Bar site investigation.

As a liability of the long canal, Mr. Sporn stresses the maintenance cost for removing sedimentation from the canal. The conditions at Watts Bar are such that no sedimentation is to be expected. The water is taken out of a reservoir 70 miles long; only during extreme floods is silt carried to the dam.

The coal-storage yard, which was designed for 200,000-ton capacity, has shown its flexibility in handling the contingencies of wartime operation. As much as 300,000 tons of coal have been in storage. Both tractor-scraper and drag-scraper systems for handling coal in storage were originally investigated. The data on performance of large tractor scrapers were still meager, and a long investigation was out of question; therefore, the well-established drag-scraper system was adopted.

The question is raised as to why the coal dock was extended over a length of 700 ft. The conditions of the river in front of the dock are somewhat special. Whenever the spillway above discharges water, the velocities are rather high. Safe operation under these conditions requires that the barges be strung in single line along the shore. Experience has shown that the dock was too short or handling large shipments. In 1946, sheet-pile cells were added upstream and downstream from the dock, giving mooring facilities over a total length of 1,400 ft.

The main dock was built with secondhand sheet piling and backfilled with slag. The cost per linear foot was $94.

FUTURE OF LAKE MEAD AND ELEPHANT BUTTE RESERVOIR

By J. C. Stevens,[1] President, Am. Soc. C. E.

With Discussion by Messrs. D. C. Bondurant, John H. Bliss, Luna B. Leopold, Carl B. Brown, G. E. P. Smith, Albert E. Coldwell, Walter B. Langbein, C. S. Howard, Charles Kirby Fox, H. V. Peterson, L. C. Crawford and P. C. Benedict, Charles P. Berkey, Stafford C. Happ, Berard J. Witzig, Hugh Stevens Bell, E. W. Lane, F. E. Bonner, Joe W. Johnson, Harold H. Munger, William Mayo Venable, Edward Gerald Smith, Clarence S. Jarvis, L. Standish Hall, and J. C. Stevens.

Synopsis

The gates in the by-pass tunnels at Boulder Dam (Arizona-Nevada) were closed February 1, 1935, and the storing of water and sediment began. In ten years following that date some 1,500 million tons of sediment passed the Bright Angel silt-sampling and gaging station in the Grand Canyon, in Arizona. Virtually all of this sediment was arrested by Boulder Dam. There is also an added contribution from the 30,000 sq miles of drainage area between the Grand Canyon Station and Boulder Dam.

Storage in Elephant Butte Reservoir in New Mexico on the Rio Grande began January 6, 1915. Before the construction of the dam a topographic map was made of the reservoir. After its completion five surveys of sediments deposited in the reservoir were made. During this period records of suspended sediments have been kept on the Rio Grande at San Marcial, N. Mex., above the highest backwater from the dam. So far as known this is the only reservoir for which a comparison of sediment inflow and sediments deposited can be made[2] in order to determine some over-all value of the reservoir space occupied by sediment deposits.

An analysis of the sediment records for Elephant Butte Reservoir is presented. Utilizing these data an estimate of the useful lives of both Lake Mead and Elephant Butte Reservoir is made. A discussion of what feasible steps may be taken to prolong their usefulness is included.

Note.—Published in May, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

Although the writer has served as Consultant for the National Resources Planning Board and also for the Bureau of Reclamation, U. S. Department of the Interior, on matters pertaining to the Colorado River and Rio Grande basins, the conclusions and opinions here reflect his personal views and are in no sense to be construed as reflecting the opinions of those agencies.

General Considerations

The term sediment, as used herein, will be understood to include all clays, silt, sand, gravel, boulders—in fact, any transported material that will occupy space in a storage reservoir. These sediments are mostly water-borne, although considerable volumes are of aeolian origin, and others are talus from the confining shores of the reservoir. The principal contributions are in the form of deltaic deposits by the main river and by the tributaries that flow directly into the lake.

Deltas.—A delta forms at the mouth of each entering stream. Only deposits at the lowest stage of the reservoir have any chance of remaining in place. All deposits at higher stages are reworked by the streams as the reservoir falls and are thus intermittently carried farther and farther into the reservoir. As these deltaic deposits are reworked they are ground finer and transported farther into the reservoir at every freshet.

The sediments brought in by steep tributaries contain much coarse material. The effect of reworking is to flatten the slope at which they were originally deposited, but such coarse material never moves far into the reservoir.

Density Currents.—The finer sediments, clays, and colloidal material remain in suspension longer than the sands and are therefore deposited well into the reservoir. Frequently such fines are carried by the muddy stream supplying them through the reservoir along its thalweg while the water surrounding this muddy stream remains clear. Such silt flows are called "density currents." By them the fines are deposited against and immediately above the dam. If low outlets are open these mud flows will pass entirely through the reservoir with no visible evidence of their presence on the reservoir surface. By this means the so-called "dead-storage" space lying below outlets may become filled readily with fines.

Talus.—A large quantity of heavy material in the form of talus accumulates from, and settles at, the bases of the steeper shores and cliffs. When exposed above water the talus weathers down into finer sediments but normally does not move far from the base of the cliffs from which it originates.

Aeolian Deposits.—Any one who has driven between Zion National Park, in Utah, and the Grand Canyon can attest to the enormous wind-borne sediments of which many of the bluffs and canyon walls skirting the highway are composed. In arid sections such as these the volume of aeolian deposits is extremely large. Compared with water-borne deposits however their volume is relatively small, yet they cannot be ignored in the long period of years that it takes to fill a reservoir with sediment.

The Life of a Reservoir.—The great complexity in the process of sedimentation in reservoirs and in the inflowing stream channels, the uncertainties regarding the space occupied by sediments, lack of knowledge regarding the contributions by water and wind from tributary drainage area, the variability of sediment inflows year by year and in wet and dry cycles, the inability to evaluate accurately between suspended sediment and bed load, all militate against the drawing of invariable conclusions regarding the useful life of any reservoir that is subject to silting.

PART 1.

ELEPHANT BUTTE RESERVOIR

Elephant Butte Dam was completed in 1916 although impounding of water began on January 6, 1915. The drainage area at Elephant Butte Dam, exclusive of the closed basin in Colorado, is 25,923 sq miles; at the San Marcial gaging station it is 24,176 sq miles. Fig. 1 is a map of the Upper Rio Grande basin on which the alluvium and sedimentary deposits are distinguished from volcanics and metamorphics. The former are largely responsible for the sediments carried by the streams. The Rio Grande is perennially muddy downstream from the mouth of Rio Chama, N. Mex. Upstream from this point it is fairly clear except at times of freshets.

SEDIMENTS DEPOSITED

Table 1 gives the results of surveys of sediments deposited in Elephant Butte Reservoir below spillway level.[3] It represents the deposits reported from all sources between the sill of the outlet gates and the spillway level. To compare this record with the measured sediments passing the San Marcial gaging station it is necessary to know the sediments deposited downstream from the San Marcial gaging station and above spillway level, as well as the deposits below the sill of the outlet gates. These quantities are not found in any publications but were ascertained by correspondence to be 13,929 acre-ft and 3,432 acre-ft, respectively. The latter value was changed to 3,218 by a recomputation of capacities made in 1940 (letter to the writer dated January 9, 1943, from Carl B. Brown, Assoc. M. Am. Soc. C. E., Head of the Sedimentation Section, Soil Conservation Service, Washington, D. C.).

TABLE 1.—SEDIMENTS DEPOSITED IN ELEPHANT BUTTE RESERVOIR IN NEW MEXICO

Period	Years	Cumulative years	DEPOSITED (THOUSANDS OF ACRE-FEET)		Capacity lost (percentage of original)
			Period	Cumulative	
Storage began January 6, 1915	....	0	0	0	0
January 1915 to December 1916	1.91	1.91	54.0	54.0	2.04
December 1916 to August 1920	3.67	5.58	86.0	140.0	5.30
August 1920 to August 1925	5.00	10.58	91.7	231.7	8.76
August 1925 to April 1935	9.67	20.25	133.5	365.2	13.8
April 1935 to September 1940	5.50	25.75	50.6	415.8	15.8

For the purposes of this paper it is necessary only to consider the first and last surveys, and to find the total sediment deposited from the beginning of storage in January, 1915, to September 30, 1940—a period of 25.75 years. In the surveys the deposits in the long arroyos of the west-side tributaries were not included. The volume of the excluded deposits is unknown but for the purposes of this paper 10,000 acre-ft have been added for this item. (An accuracy closer than the nearest 100 acre-ft is not justified by the nature of the surveys.) Following is the summary:

Where deposited	Thousand acre-ft
Above the outlet gate sill and below the spillway level	415.8
In arroyos	10.0
Below the outlet gate sill	3.2
Above the spillway level and below San Marcial gaging station	13.9
Total (19.29×10^9 cu ft)	442.9

SEDIMENT INFLOW

These deposits may now be compared with the sediments that have flowed into and through the reservoir during the same period. The records of suspended sediments passing San Marcial begin in 1897, but, since the present study is concerned with the period from 1915 to 1940, only the record for those years is given in Table 2. The data were compiled from the following sources:

[a] Nine months, ending September 30, 1940.

The period from 1915 to 1925, inclusive, was obtained from information supplied by the project engineer, Rio Grande Project, Bureau of Reclamation. The data are based on sampling in 1919 and, for the other years, on monthly silt curves prepared in 1924 from the sampling in 1919 and in years prior to 1913 (824 determinations 1905–1912). The data were compiled in acre-feet based on a specific weight of 53 lb per cu ft as used by the late W. W. Follett,[4] M. Am. Soc. C. E. The sediment load was converted to tons by the factor 1 acre-ft = 1,153 tons when $\gamma = 53$ lb per cu ft. The data thus converted were presented by the writer in a former paper.[5] Suspended sediments (in tons) since 1926 are found in the Water Bulletins,[6] published by the International Boundary Commission at El Paso, Tex.

The records for 1915–1925, inclusive, are open to question. Silt curves have been found to be only fair for the coarser sediments but may be quite inaccurate for the fines. However, the errors are compensating and, over a period of years, the totals may not be too far awry. For the years since 1925 the sediment was determined from intermittent sampling throughout each year as shown in Table 2. For some years, notably 1928 and 1930, the number of samples was too few to form the basis of a reliable estimate for the entire year. However, these are all the data in existence for the period in question.

ADJUSTMENTS

In order to compare measured deposits with sediment inflow, certain adjustments in the record of suspended sediments at San Marcial must be made:

1. Samples were secured by lowering small necked bottles "into the water at one or more verticals in the stream section, being careful to approach but not to strike the bottom."[6] The coarser sediment load increases with depth

---

[4] "Silt in the Rio Grande," by W. W. Follett, Dept. of State, International Boundary Commission, 1913.

[5] "The Silt Problem," by J. C. Stevens, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 228.

[6] *Water Bulletins Nos. 1 to 12*, International Boundary Comm., El Paso, Tex., 1931–1942.

until there is a slurry of sands moving along the bottom that is scarcely touched by the sampling bottle.

Fig. 2 is believed to represent, more or less typically, the conditions in a sediment loaded stream. The data are the results of sampling at various depths in ten verticals of the central main canal of the Imperial Irrigation District in the Colorado River delta.[7] The concentration of the coarser sediments is seen to increase rapidly as the stream bed is approached and a reasonably good concentration curve can be drawn. For the fines, however, the concentration is quite uniform from the surface to the bed.

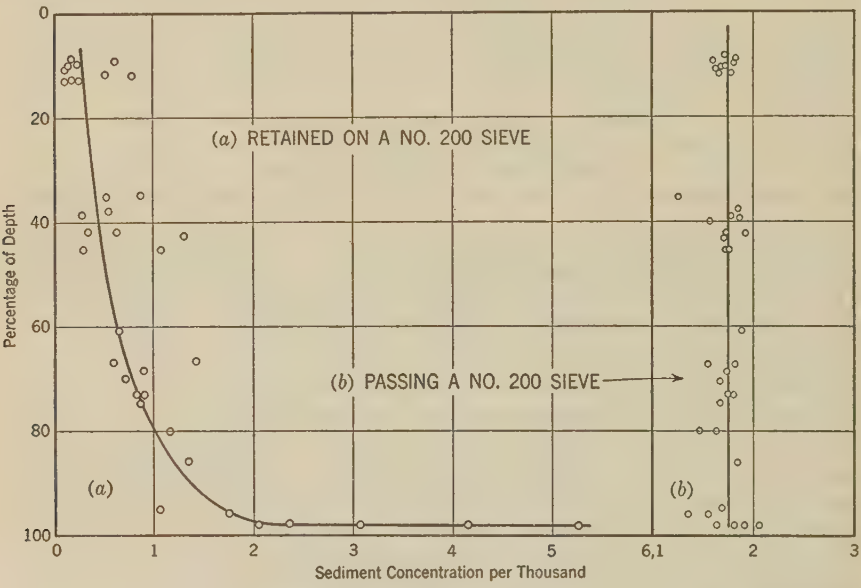

FIG. 2.—SUSPENDED SEDIMENT, IMPERIAL CANAL, CALIFORNIA

To the measured suspended load an addition of 15% was made in order to account for the unsampled bed load. The bed load would thus be 13% of the total sediment load.

2. There are 1,750 sq miles of drainage area tributary to Elephant Butte Reservoir below the San Marcial gaging station. From this arid area many tributaries flow into the lake and substantial wind-borne deposits accumulate in the reservoir (see Fig. 1).

The Soil Conservation Service has made a determination of the sediment contribution by the tributaries of Rio Grande in the valley above San Marcial[8] (see Table 3). This work has been continued since 1939 by the U. S. Engineer Department. Two methods were followed—one by an evaluation of sediment sources through mineralogical studies and the other by sampling suspended loads. The mineralogical studies were made by Gordon Rittenhause for the

[8] "The Sedimentation in the Middle Rio Grande Valley, New Mexico," by Stafford C. Happ, SCS (unpublished), 1942, Tables 11 and 12.

Soil Conservation Service between 1937 and 1941. Composite samples were collected from the bed of the Rio Grande near the mouths of the six principal tributaries and also from farther up each tributary. These samples were sized mechanically. Samples were mounted on microscopic slides for identification and the number of grains in each species was determined. With the specific gravity known, the approximate weight of each species in each size grade was computed. The relative abundance of the different mineral species was used as an index of the relative contribution from each of the six tributaries.[9]

TABLE 3.—Acre-Feet of Sediment per Year Contributed by Tributaries of the Rio Grande

Method	Tributary (see Fig. 1)						Specific weights (7)	Sediment (thousand tons) (8)	Drainage areas sq. miles (9)	Sediments[a] (10)

[a] Tons per square mile per year.

Although there are wide differences by the two methods among tributaries, the final values are close enough to justify the use of an average contribution of 1,600 tons per sq mile per yr for the area directly tributary to Elephant Butte Reservoir. The mineralogical analyses purport to show only the deposits on the valley floor; nevertheless they doubtless represent a major portion of the contribution by the tributaries.

3. The talus from the canyon walls that lodges below spillway level should be included. This represents a small volume that is very difficult to determine. Whatever it may be it is considered as included in that of adjustment 2.

4. Some sediment has passed entirely through the reservoir in the form of "density currents."[10] L. R. Fiock[11] estimated that to the end of 1934 a total of 5,000 acre-ft of fine silt had passed through the outlet gates at the dam. This estimate was based on samples some of which contained as much as 6% by weight of fine suspended material.[12] By correspondence it was ascertained that a specific weight of 53 lb was used to determine this volume. The weight, therefore, was 5.8 million tons. It was also learned from correspondence that another major silt flow occurred between August 9 and September 10, 1935, for which the writer estimated that 0.6 million tons of silt passed through the gates. The total passing out during the period of record is therefore 6.4 million tons.

[12] *Ibid.*, p. 472.

SPECIFIC WEIGHT OF DEPOSITS

For the 25.75-yr period from January 1, 1915, to September 30, 1940, the total net sediment inflow to the reservoir becomes:

Item	Source of sediments	Million tons
1	Passing San Marcial	490.1
2	Passing San Marcial as bed load (15% of item 1)	73.5
3	Contributed by 1,750 sq miles of tributary drainage area in 25.75 years at 1,600 tons per sq mile per yr	72.0
4	Total sediment inflow	635.6
5	Less sediment outflow	6.4
6	Net sediment inflow (equivalent to $1{,}259 \times 10^9$ lb)	629.2

For the same period the measured deposits were 442,900 acre-ft $= \gamma\, 19.29 \times 10^9$ lb, from which the average specific weight of the entire volume deposited is $\gamma = \frac{1{,}259}{19.29} = 65.3$ lb. An average value of 65 lb per cu ft will be used in this paper.

PROBABLE USEFUL LIFE

One undertakes a prediction of the useful life of such a reservoir with many misgivings. Nevertheless the best prediction that can be made from available data may be of considerable value even though subsequent years may prove it to have been in error.

The original capacity of Elephant Butte Reservoir was determined from a topographic map on a scale of 1,000 ft per in. with 10-ft contours, made from 1903 to 1908. The volume was recomputed in 1940 and found to be 2,634,800 acre-ft, of which 3,200 acre-ft are below the gate sill.[13]

The cumulative years and the percentage of the original capacity lost, given in Table 1, are shown in Fig. 3. If the average rate of sedimentation shown for the first 26 years should continue and all sediment should remain in the reservoir, it would appear that the reservoir would be full to the spillway level in a total of 158 years, leaving a remaining life of about 130 years more. The useful life, however, would be much shorter because the storage capacity becomes inadequate for the purposes for which it was constructed by the time half its original capacity is lost; at least its usefulness would then be greatly impaired. This would occur in about 80 years from its initial storage date, or about 1995.

These speculations, however, may not hold for the reason that the rate of depositions in the reservoir proper appears to have been decreasing materially as shown by the curved line of loss in Fig. 3. Deposits in the valley above the reservoir have been enormous so that a substantial portion of the water-borne sediments is arrested before it reaches the reservoir. The Soil Conservation Service has estimated that 59,000 acre-ft of sediments were deposited on the valley floor between Santa Fe Creek and San Marcial in the period from 1936 to 1941,[14] an average of more than 12,000 acre-ft per yr. That Service also reports that aggradation of the lower portion of this valley began eight years prior to the construction of Elephant Butte Reservoir (say, about 1907).

---

[13] "Silting of Reservoirs," by Henry M. Eakin, revised by Carl B. Brown, *Technical Bulletin No. 524*, U.S.D.A., Washington, D. C., 1939, pp. 90–92.

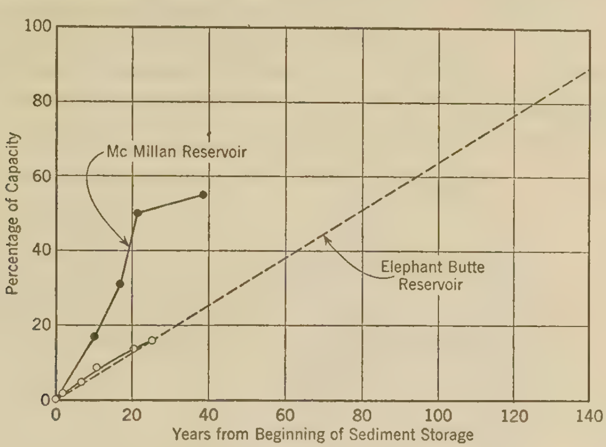

FIG. 3.—COMPARISON OF RATES OF SEDIMENT STORAGE

No very satisfactory explanation has been found for the aggradation of the valley floor. The writer believes it has been caused in part by backwater from the reservoir but mostly by the low runoff cycle the West has been experiencing since 1920. Floods have certain economic values in flushing the river channels of the sediment accumulations of previous low-water periods.

Fig. 4 demonstrates the presence of the low-water cycle. The levels of Great Salt Lake (Fig. 4(*b*))[15] are a good index of cyclic variations in the hydrologic features of the entire West. These levels show the culmination of a high-water cycle in the early 1870's and a continuous decline to 1905, a partial recovery until 1923, and a sharp decline since then.

For comparison, the 5-yr running averages of the flow of the Rio Grande at Otowi Bridge,[16] in percentages of the 52-yr mean, are also shown. The parallelism of the two curves is quite striking for the period of simultaneous records. If the Rio Grande records covered the same period as those of Great Salt Lake, a high-water cycle would undoubtedly have been disclosed between 1865 and 1880.

The Otowi record shows a gradual decline in water yield from the peak of 1909. Slight recoveries appear in both records from the all-time western recorded low of 1934.

If this is a major cause of valley filling, a succession of flood years in a cycle of greater rainfall would very likely move large volumes of the arrested sediments into the reservoir. Although the 25 years since 1920 show declining rates of sedimentation in the reservoir, a series of wet years may increase those rates to such values that the straight-line extension of Elephant Butte curve in Fig. 3 may not be amiss.

[16] "Regional Planning," Pt. 6 on "The Rio Grande Joint Investigation in the Upper Rio Grande Basin in Colorado, New Mexico, and Texas, 1936–1937," U. S. National Resources Board, Government Printing Office, Washington, D. C.

In Fig. 3 is also shown the rate of sedimentation of McMillan Reservoir on the Pecos River.[17] In 20 years the rate of filling diminished markedly. The explanation offered[18] is that a rank growth of tamarisk or salt cedar, that started about 1912, has covered the valley floor immediately above the reservoir and that this dense growth reduces velocity so much that the sediments are deposited in it. No doubt this explanation is correct and as long as the tamarisk thicket remains the sediments deposited will remain in place in spite of years of great floods.

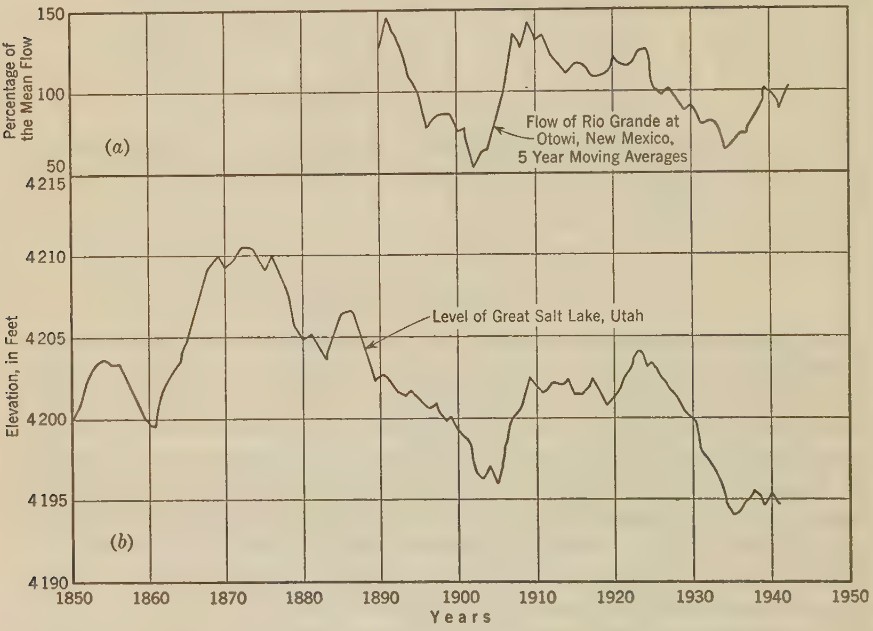

Fig. 4.—Study of Hydrologic Cycles

Such extensive growths are not prevalent on the Rio Grande, however; hence the sediments deposited in low-water cycles may very likely be moved out in high-water periods. One of two possibilities appears certain—either aggradation of the Rio Grande above Elephant Butte Reservoir will continue, or the river will again be degraded in subsequent wet cycles which will hasten the filling of the reservoir.

When the survey of Elephant Butte Reservoir was made in 1935 the lake level was so low that practically all the area above the Narrows (somewhat more than half) was mapped by plane table and stadia since the sediments were firm enough to support the men. Therefore, the water for this area had drained out of the upper layers. Without doubt, there was a zone of saturation below the exposed surface of the sediments.

Fig. 5.—Upper Colorado River Basin (Unshaded Area Represents Sedimentary Deposits)

No information is available as to the quantity of gravity water that flowed from the deposits, but whatever it was the loss of storage capacity given should be reduced by that volume. To take account of this ground water with so many other uncertainties, particularly with regard to valley deposits upstream, seems to be an unnecessary refinement.

A profile of the deposits in Elephant Butte Reservoir[19] shows that reservoir deposits are spread to a considerable extent over the entire bed of the reservoir. There is insufficient evidence to warrant the adoption of other than an average linear rate of filling. The straight line of Fig. 3, therefore, is offered as being a fair index of the useful life of Elephant Butte Reservoir according to present knowledge.

PART II.—LAKE MEAD

Lake Mead was created by Boulder Canyon Dam on the Colorado River, which forms the boundary between Nevada and Arizona in this reach. The gates in the outlet tunnels were closed on February 1, 1935, and the storage of water began on that date. Lake Mead is bordered by an arid plateau which is drained principally by the Virgin, Little Colorado, and San Juan rivers. It contributes to the Colorado River about 64% of its load of sediment but only 20% of its water.

Colorado and Green rivers are perennially muddy because of the enormous areas of sedimentary deposits through which they flow. Fig. 5 is a map of the Colorado River basin above Boulder Dam showing the great extent of sedimentary deposits. These consist of shales, friable conglomerates, and sandstone from the Jurassic to recent alluviums. All streams draining such deposits carry heavy loads of sediment.

Record of Suspended Sediments

Table 4 gives the results of suspended sediment measurements of the major streams of the Colorado River basin above Boulder Dam.[20]

The water carried past each of the sampling stations and the sediment concentration for the period of record are given in Table 5. The results for Little Colorado River (line 6) include contributions from 29,800 sq miles as determined from the difference between the records of Lees Ferry and Grand Canyon, whereas the drainage area of the Little Colorado itself is 24,400 sq miles. The record of Virgin River at Virgin, Utah (line 7), is unpublished. It was obtained by correspondence with the Bureau of Reclamation.

[20] "Suspended Matter in the Colorado River 1925–1941," U. S. Geological Survey, unpublished report. (An extension of the data in Table 4 to include 1942, 1943, and 1944 is presented subsequently in Table 13.)

It will be expedient to expand the records to represent a 16-yr period to conform with that of Grand Canyon. This was done, as shown in Table 6, by using the Grand Canyon record as an index. The method is apparent from the letter symbols in Col. 2, Table 6. As an approximate check on the validity of this expedient, the water yield is expanded as well as the sediment records; then the actual volume of water, as independently measured and reported in Water-Supply Papers of the U. S. Geological Survey, for the 16-yr period is given. The agreement for the water flow is remarkably close for all stations.

The Virgin River and Muddy River expansion (item 14, Table 6) is estimated on the basis of the 4-yr record at Virgin and the 3-yr record of flow of Muddy River at St. Thomas, Nev., from 1913 to 1916 when it was a direct tributary of Virgin River, and taking into account the differences in drainage areas. The expansion for the Virgin and Muddy basins was estimated independently of the Grand Canyon records.

10	Virgin, Utah	934	48	4.0	4,300
11	Virgin and Muddy rivers	11,040	246	15.4	1,400

There are 30,000 sq miles of drainage area between the Grand Canyon sampling station and Boulder Dam, and it is important to know how much sediment this area is likely to contribute. For this purpose Table 7 has been prepared using the expanded records for the 16-yr period from Table 6.

SEDIMENT HELD IN LAKE MEAD

Storage of water and sediment in Lake Mead began February 1, 1935. It is of interest to know the rate at which sediments have been captured by Boulder Dam since closure of the gates. These consist of (*a*) measured suspended matter at Grand Canyon, (*b*) unmeasured bed load, (*c*) sediments contributed by the 30,000 sq miles of intervening drainage area, by both wind and water, and (*d*) talus from canyon walls. From the sum of items (*a*) to (*d*) must be deducted the sediments that passed through the dam in the form of density currents.

(*a*) *Suspended Matter Measured at Grand Canyon.*—The Bureau of Reclamation has prepared a breakdown of the suspended matter measured at Grand Canyon by months since 1935. From all records the following total is obtained:

Dates	Million tons
February 1 to September 30, 1935 (Bureau of Reclamation)....	117
October 1, 1935, to September 30, 1941 (Table 4)..............	1,014
October 1, 1941, to September 30, 1942 (Bureau of Reclamation)	232
Total passing Grand Canyon...........................	1,363

(*b*) *Unmeasured Bed Load.*—The method of sampling is described in a Water-Supply Paper[21] of the U. S. Geological Survey. The U. S. Geological Survey Colorado sampler[22] held a pint milk bottle. A small weight could be released to slide down the line to make a 5/8-in. hole in the paper bottle cap at any desired depth. Usually three samples were taken at each of three verticals at about one fourth, one half, and three fourths the distance across the stream.

An analysis of the accuracy of this sampler as well as of other types is found in a report of the Iowa Institute of Hydraulic Research.[23] For present purposes it is sufficient to state that the greater concentration (particularly of the coarser sediments) is in the 1.5 ft between the mouth of the bottle and the stream bed. For this reason an addition of at least 15% to the measured suspended load for unmeasured bed load is believed to be fully justified.

(*c*) *Sediments Contributed by Intervening Drainage Area.*—Of the 30,000 sq miles of drainage area between Grand Canyon and Boulder Dam 11,040 is in the Virgin and Muddy river basins. Before the filling of Lake Mead, Muddy River was a tributary of the Virgin River, but the lake has now submerged their junction so that each appears as a separate tributary to the lake.

In the 267 miles from the Grand Canyon sampling station to Boulder Dam there are a great many tributaries, the major ones being Bright Angel Creek, Kanab Creek, Havasu Creek, Diamond Creek, Grand Wash, Hualpai Wash, Virgin River, Muddy River, and Los Vegas Wash. All contribute substantial quantities of sediment which in time are discharged directly into Lake Mead or are carried into Lake Mead by way of the Colorado River.

An examination of Table 7 will justify the assumption of an average tributary sediment inflow of 1,600 tons per sq mile per yr, the same as was found for the area tributary to Elephant Butte. This may be conceded to include whatever wind-borne material is carried directly or indirectly into the lake, below the Grand Canyon sampling station.

(*d*) *Talus from Canyon Walls.*—There is no means of estimating the space in the reservoir occupied by the talus material that falls from the canyon walls. The length of the reservoir at high level is about 115 miles, most of which consists of high canyon walls. Since this contribution is a small portion of the total sediment inflow it may be considered as included in the foregoing estimate of tributary inflow.

---

[22] "Field Practice and Equipment Used in Sampling Suspended Sediment," *Report No. 1* of "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," Iowa Inst. of Hydr. Research, Iowa City, Iowa, 1940–1943, p. 149.

[23] *Ibid.*, p. 102.

The Sum of Items (a) to (d).—The silt outflow from Lake Mead occurred after control of the flow began on February 1, 1935, and while the reservoir was filling until the diversion tunnel gates were finally closed May 1, 1936. N. C. Grover, M. Am. Soc. C. E., and Charles S. Howard proposed[10] the following estimate of silt discharged by these turbid outflows:

Silt outflow during:	Million tons
1935	6.0
1936	2.4
Total	8.4

Since closure of the diversion tunnels no turbid waters have passed through the control works. The silt brought in by the density currents is deposited in the lowest portions of the lake bed and against the dam.

Summarizing, the sediment flow during the 7.66-yr period from February 1, 1935, to September 30, 1942, is found in the third column of Table 8. A similar summary as shown in the fourth column of Table 8, may be made for the 17-yr period from October 1, 1925, to September 30, 1942, on the assumption that it is representative of future accumulations.

TABLE 8.—SEDIMENT DEPOSITED IN LAKE MEAD (MILLION TONS)

Item	Description	7.66 yr[a]	17 yr[b]
1	Suspended sediments passing Grand Canyon	1,363	3,436
2	Unmeasured bed load at Grand Canyon; 15% of item 1	204	515
3	Contributed by tributary drainage[c]	368	816
4	Total inflow	1,935	4,767
5	Outflow by density currents, 1935 and 1936	8	8
6	Net deposits	1,927	4,759
7	Average annual accumulation	252	280

[a] February 1, 1935, to September 30, 1942. [b] October 1, 1925, to September 30, 1942. [c] Contributed by 30,000 sq miles of tributary drainage in the years of record stated, at 1,600 tons per yr per sq mile.

SPACE OCCUPIED BY DEPOSITS

For the Lake Mead deposits no better estimate of the specific weight can be made than to use the composite value of $\gamma = 65$ lb found for Elephant Butte Reservoir. On that basis an average annual sediment deposit of 280 million tons per year would occupy a volume equivalent to 198,000 acre-ft.

Fig. 6 gives the storage capacities for Lake Mead. The sediments deposited have remained submerged except the upper portions of the deltas of the main and tributary streams.[24] Only in a cycle of dry years after virtually all water-consuming projects in the upstream parts of the basin have been completed is there likelihood of any substantial portion of the deposits becoming exposed, which would tend to consolidate the deposits.[25]

---

[24] "Silt Problems," by W. E. Corfitzen, *Civil Engineering*, November, 1942, p. 616.

[25] See *Report No. 9* of "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," Iowa Inst. of Hydr. Research, Iowa City, Iowa, 1943.

PROBABLE LIFE OF LAKE MEAD

If the foregoing rate of deposition should continue there would be deposited a volume equivalent to the storage capacity at the crest of spillway (28,632,000 acre-ft) in a period of 144 years from the time storage began, or 135 years from 1944.

Sediments are not deposited to uniform depths within the reservoir. Deltas form at the mouth of every tributary and at the inlet of the main stream. These are reworked at varying lake levels; yet they maintain a sloping surface toward the thalweg of the reservoir.[26] Density currents carry fines to the low parts of the reservoir bed and against the dam. The reservoir walls are continually weathering down to form talus slopes at their bases, whereas their upper reaches are being sloped back to stable angles of repose.

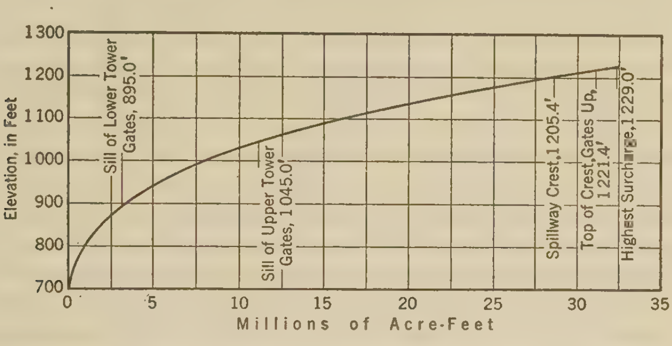

FIG. 6.—STORAGE CAPACITY FOR LAKE MEAD

The main stream has a tendency to build up its bed above the reservoir to maintain its original slope as it was before its deltaic deposits began to form. If the material is coarse the back sediment curve may extend a long way upstream, as demonstrated by the profile of Bear Creek in California.[27] If the stream joins the reservoir in a flat valley the entire valley floor will be built up to some grade commensurate with the hydrology of the region and the character of the sediments carried, such as is now occurring at the upper ends of Elephant Butte and McMillan reservoirs.

When the river joins the reservoir in a narrow canyon, there is little opportunity for the stream bed to aggrade itself because any deposits left at low and medium stages are carried away in subsequent freshets. Of such is the junction of Colorado River and Lake Mead, since the upper end of the reservoir lies generally in narrow gorges. The opportunity for extensive deposits above lake levels therefore is lacking, and practically all the sediments transported by the river as measured at the Bright Angel station in the Grand Canyon are carried into the lake and cause it to lose storage capacity.

It may be assumed that the climatic conditions over the life span of such a reservoir as Lake Mead will not change materially. The allowances that have been made for contributions by tributary areas and bed load do not seem out of place and the storage volume lost by sediment depositions in the lake is based on the best information available.

---

[26] "Sedimentation in Reservoirs," by Berard J. Witzig, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1057.

[27] "The Silt Problem," by J. C. Stevens, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 219.

There are 3,200,000 acre-ft below the lowest gate sill; but water cannot be drawn down to that level. The dead storage, therefore, may be estimated at 4 million acre-ft. At the present rate of sedimentation (198,000 acre-ft per yr), 20 years will be required for the lake to fill the dead-storage space, although encroachment on the active storage has already begun. Half the remaining volume (11,300,000 acre-ft to the spillway crest) will be occupied in about 57 years more, which will see the usefulness of Lake Mead seriously impaired for hold-over storage.

A volume equivalent to the total capacity to spillway level probably will be caught in the reservoir in about 144 years from 1935 or, say, by the year 2080, whereupon it will have ceased to exist as a storage reservoir. However, it will still be useful as a run-of-the-river power project, since 2.5 million acre-ft of storage will remain, controlled by the crest gates to El. 1221.4.

This residual 2.5 million acre-ft may be encroached upon but will not be entirely lost because the sediments will be carried through the reservoir. It will serve as regulating storage for the power such a river-run plant can generate —possibly about half its ultimate installed capacity of 1,300,000 kw.

PROLONGING THE LIFE OF LAKE MEAD

Because of the great investment and the importance of this development to the entire southwestern part of the United States, it will be prudent to adopt whatever measures appear feasible to increase the period of usefulness of Lake Mead. The measures to be considered are:

(*a*) Land management on the watershed;
(*b*) Control of density currents;
(*c*) Upstream storage for sediments and other purposes; and
(*d*) Removal of sediments.

Land Management.—The artificial stimulus given to increasing vegetal cover on the watershed, even if it were 100% effective on the areas where it can be practiced, cannot affect the total volume of sediment flow greatly. The areas where such treatment can be used are on range land and forest areas.

If grazing areas are managed to produce their maximum forage yield the erosion prevention feature will have been provided for automatically; that is, the prime objective in management of range land should be to furnish as much food as practicable for livestock on a sustained yield basis.

In areas suitable for forest cover the prime objective should be to produce continuing yields of merchantable timber. The planting and care of forests solely to prevent erosion can rarely be considered a sound financial investment.

In the Colorado River basin, or in fact in any other arid section, natural erosional forces so outweigh those attributable to man's activities that the best that man can do in the way of land management can have only minor effects in reducing the sediments naturally carried by the streams. It is doubtful if the average of 280 million tons of sediment being carried annually into Lake Mead could be reduced as much as 10% by all the proved practicable methods of land management known today even though lavishly financed.

Density Currents.—Engineers are just beginning to learn something about the stratifications of the contents of reservoirs. Layers of silt-laden waters, as well as those of varying temperatures and of varying concentrations of dissolved solids, remain intact to a remarkable degree. A nontechnical discussion of this subject was published in 1942 by the Department of Agriculture.[28]

Knowledge of such currents was not available, or at least was not recognized to be of possible value, until after Boulder Dam was completed. Facilities for handling density currents and withdrawing water at will throughout the depth of the reservoir are lacking. The technique to take advantage of the current limited knowledge of this subject has not been developed as yet to a practical science. Although it offers some promise in the operation of some future reservoirs under certain favorable conditions, it is not likely to be of much practical benefit for the two reservoirs under discussion. There is also the question as to whether these fines, if deposited on irrigated land, might not have the effect of sealing the interstices of the soil and thus prevent proper air and water drainage.

The subject is worthy of extensive study. Projected reservoirs in arid sections where such density currents and stratifications are likely to exist might well be provided with outlet gates at varying levels in order to take advantage of future possibilities in passing on inflowing sediments.

Upstream Storage for Sediments.—This subject cannot be treated in generalities but will be confined to the specific case of Lake Mead. A number of reservoirs on the Colorado River and silt-laden tributaries have been proposed. The principal ones are Bridge Canyon, Glen Canyon, Dark Canyon, and Dewey Reservoir on the Colorado River; Bluff Reservoir on the San Juan River; and Coconino Reservoir on the Little Colorado. A reservoir for silt storage should also be found on the Virgin and Muddy rivers, but all studies so far made have been concerned with irrigation and flood control, and only incidental studies of the storage possibilities for sediments have been made.

Bridge Canyon Reservoir.—This project has been proposed for additional power. The storage capacity is 2,400,000 acre-ft, of which 1,600,000 acre-ft is active. The sediment inflow to the reservoir may be estimated as follows on the basis of the 17-yr record, 1926–1942.

Item	Description	Million tons
1	Suspended sediments passing Grand Canyon	3,436
2	Unmeasured bed load, 15% of item 1	515
3	Sediments contributed by 7,400 sq miles of tributary drainage in 17 years at 1,600 tons per sq mile per yr	204
4	Total	4,155
5	Average per year	244

---

[28] "Stratified Flow in Reservoirs and Its Use in Prevention of Silting," by Hugh Stevens Bell, *Miscellaneous Publication No. 491*, U.S.D.A., Sedimentation Div., Office of Research, Washington, D.C., 1942.

On the basis of a specific weight, γ, of 65 lb, this would represent an average deposit in the reservoir of 172,000 acre-ft per yr. At this rate the dead storage would be filled in less than 5 years and the reservoir would be completely filled in 14 years. If any power equipment were installed more than that required for a river-run plant, the excess would become virtually useless in about 10 years, which is too short a time for amortization. Any power development therefore should be made with these facts in mind.

Bluff Reservoir.—This reservoir is near the mouth of the San Juan River. The suspended sediments passing this site (Table 6) are 55 million tons per year. The storage capacity has been placed at 1.5 million acre-ft. The sediments from this stream are believed to be coarser than those in the Colorado River. The loss of storage space in the Bluff Reservoir, therefore, may be placed at about 30,000 acre-ft per yr on a basis of $\gamma = 85$ lb requiring 50 years to fill this reservoir. During this period considerable power could be generated but the capacity to be installed should be considered in the light of the possibility that in 30 years the development would revert to a river-run plant.

Coconino Reservoir.—This reservoir would be located in the lower reaches of the Little Colorado River. The proposed storage capacity is 1,600,000 acre-ft. Table 7 shows the difference in the sediment flow between the Colorado River at Lees Ferry and at Grand Canyon to be about 48 million tons per year. Of this quantity 35 million tons may be conceded as coming from the Little Colorado River into this reservoir. The loss of storage space is placed at 23,000 acre-ft per annum on a basis of $\gamma = 70$ lb. Therefore, the reservoir would become filled in 70 years.

This stream would be of no value for a river-run power plant, and it would be unwise to attempt any commercial power development at this site.

Dewey Reservoir.—The dam for this reservoir is proposed on the Colorado River below the mouth of the Dolores River. Its storage capacity as projected is 6 million acre-ft, of which 5 million is active. The sediment passing the Cisco sampling station, from Table 6, was 22.5 million tons per year. If $\gamma = 75$ lb, this sediment inflow would cause the reservoir to lose 14,000 acre-ft of storage space per year. This is a relatively small volume for it would require more than 70 years to exhaust the dead storage alone and 430 years to fill the reservoir.

Glen Canyon Reservoir.—This is perhaps the largest projected artificial reservoir in the world, since it may admit of being developed for a storage capacity of 70 million acre-ft,[29] of which 60 million would be active. The dam would be just above Lees Ferry. It would be 800 ft high and would back water to the foot of the Dewey Dam, a distance of 350 miles.

If the dam were built to this height the reservoir would include the Dark Canyon Reservoir. The foundation and abutment would be in a Jurassic quartzose sandstone of uniform texture that stands in vertical cliffs 1,000 ft or more in height.[30] The crushing strength is from 2,000 to 6,000 lb per sq in.

---

[29] "Water Power and Flood Control of Colorado River Below Green River, Utah," by E. C. LaRue, *Water-Supply Paper No. 556*, U. S. Geological Survey, Government Printing Office, Washington, D. C., 1925, p. 18.

[30] *Ibid.*, p. 20.

Whether this material would support the loads for a dam 800 ft high or not is a matter for careful consideration.

If Dark Canyon Dam is to be considered, Glen Canyon Dam could only be built to a height of 400 ft and the combined storage of both reservoirs would be only about 14 million acre-ft. Thus, 56 million acre-ft of storage would be sacrificed.

At its highest level the area of the larger lake would be 300,000 acres and at its lowest drawdown 75,000 acres. The annual evaporation from this lake would approximate a million acre-feet per year.

The evaporation from Lake Mead now averages about 800,000 acre-ft per yr. During its later years, on account of increased consumptive use upstream, Lake Mead cannot be held to the high levels possible now, which will result in reducing the annual evaporation over that which obtains at present.

Glen Canyon Reservoir should not be developed to its highest level to run parallel in time with Lake Mead, but should be reserved for a future generation when the usefulness of Lake Mead has become impaired.

Irrigation must be conceded as having a decided priority over power in this region. The loss of 1.75 million acre-ft of water by evaporation, if both reservoirs were in operation simultaneously, is too big a price in water to pay for the temporary advantage in power generation. This loss would irrigate more than a half million acres of land whose value to the nation is far greater than the power that its sacrifice would make possible. Power may be had from other sources but the Colorado River is the only source of water for irrigation in this region.

The sediment flow at the Glen Canyon Dam is that at Lees Ferry (Table 6); namely, 150 million tons per year. The sediments are doubtless somewhat coarser than those at Lake Mead; hence, if $\gamma = 69$ lb, the rate of filling becomes 100,000 acre-ft per yr. This would fill the low-level reservoir of 9 million acre-ft in 90 years. If the high-level reservoir were built it would take 700 years to fill it completely, although its usefulness as a regulator of the flow of the Colorado River would be lost in half that time or less.

The power possibilities at such a high dam and with such enormous storage back of it would be very great indeed. It would probably justify as much as 2,000,000 kw of installed capacity.

Dark Canyon Reservoir.—For the height of dam of 550 ft, this reservoir would have only 5 million acre-ft of storage capacity. It would back the water up the Colorado River to the Dewey Dam and up Green River to the City of Greenriver, Utah. Its normal area would be about 20,000 acres, from which the evaporation would be close to 100,000 acre-ft per yr.

There is some uncertainty as to whether the sedimentary rocks forming the foundations and abutments for the dam would be stable under the loading. If that were decided adversely the stretch would have to be broken up into smaller reservoirs or the project abandoned in favor of the Glen Canyon project.

The sediment that would be caught may be estimated from Table 7, item 5, to be 100 million tons, representing a loss of 61,000 acre-ft per yr on a basis of $\gamma = 75$ lb. This would fill the entire reservoir in 82 years.

Power development at this site would have a useful life of 45 years, after which the generating capacity would gradually be reduced from that of a storage plant to a river-run plant, but the cost of the equipment sacrificed could be amortized.

A Schedule of Development

In order to determine the effect of sediment storage upstream from Lake Mead a schedule of development was projected from which Table 9 has been prepared. The sedimentation rate is without regard to other upstream reservoirs. The capacity lost is contingent upon the reservoirs upstream.

TABLE 9.—Computation of Storage Capacities Lost in the Reservoirs of the Colorado River Basin (1,000 Acre-Ft Units)

Years (Inclusive)		Number of years	Reservoirs (A = Annual Loss, T = Total Loss, and C = Cumulative Total Loss):														
			Dewey		Glen Canyon		Bluff		Coconino		Bridge Canyon		Lake Mead		
From:	To:		A	T	A	T	A	T	A	T	A	T	A	T	C
River			Colorado		Colorado		San Juan		Little Colorado		Colorado		Colorado		....
Year completed			1950		1970		1960		1960		1955		1935		....
Storage capacity			6,000		9,000		1,500		1,600		2,400		28,632		....
Sedimentation per year			14		100		30		23		172		198		....
1935	1950	16	..	....	..	....	..	....	..	....	..	....	198	3,168	3,168
1951	1955	5	14	70	..	....	..	....	..	....	..	....	184	920	4,088
1956	1960	5	14	70	..	....	..	....	..	....	158	790	26	130	4,218
1961	1970	10	14	140	..	....	30	300	23	230	105	1,050	26	260	4,478
1971	1999	29	14	406	86	2,494	30	870	23	667	19	551	26	754	5,232
2000	2010	11	14	154	86	946	30	330	23	253	0	0	45	495	5,727
2011	2030	20	14	280	86	1,720	0	0	23	460	0	0	75	1,500	7,227
2031	2075	45	14	630	86	3,870	0	0	0	0	0	0	98	4,410	11,637
2076	2167	92	14	1,288	0	0	0	0	0	0	0	0	184	16,928	28,565
Totals		233	..	3,038	..	9,030	..	1,500	..	1,610	..	2,391	..	28,565	....

Obviously many such schedules of development could be forecast, and for each schedule data similar to those of Table 9 could be prepared. The one shown is more illustrative than suggestive of a plan of development. The Boulder Canyon Project Act authorizes the Secretary of the Interior to prepare a comprehensive plan of development for the Colorado River basin. The first draft of that plan has been completed by the Bureau of Reclamation and it is not the intent herein to usurp the prerogatives of that agency in this regard.

In Table 9 the sedimentation periods are recorded for even years only, which explains why the total capacities lost do not check exactly with the original reservoir capacities. The time required to exhaust the entire storage capacity of each reservoir may be found as follows:

Reservoir	Years (inclusive)	Years
Dewey	....	470
Glen Canyon	1971–2075	105
Bluff	1961–2010	50
Coconino	1961–2030	70
Bridge Canyon	1956–1999	44
Lake Mead	1935–2167	233

Removal of Sediments.—No practicable method of removing the enormous volume of sediments with which this paper deals has been found as yet. Once the sediments have lodged in the reservoir, there they will remain unless some mythical Paul Bunyon and his blue ox can be found to plow them out. Lake Mead, if filled to the crest of the dam, would contain 44 billion cubic yards of sediment. Even at 1¢ per cubic yard for removal the cost would be 440 million dollars—about four and one-half times the cost of the project.

CONCLUSIONS

The cumulative totals for Lake Mead from Table 9 are shown graphically in Fig. 7. On the same drawing is shown the capacity lost at the uniform rate of 198,000 acre-ft per yr which it is estimated would occur if the present rate of filling continues. The relatively moderate effect of the upstream storage scheduled on the useful life of Lake Mead is pointedly shown by these graphs. The operation of all upstream reservoirs that could serve to withhold sediments and that now are believed to be feasible will only prolong the total life of Lake Mead 89 years or 62%.

There is a question whether the high dam at Glen Canyon would be found feasible. If it were built, however, it would continue to withhold 100,000 acre-ft of sediment per year from Lake Mead after Bridge Canyon, Bluff, and Coconino reservoirs were filled. This would extend the life of Lake Mead 173 years beyond 2075 to the year 2248—a total life of 314 years from 1935.

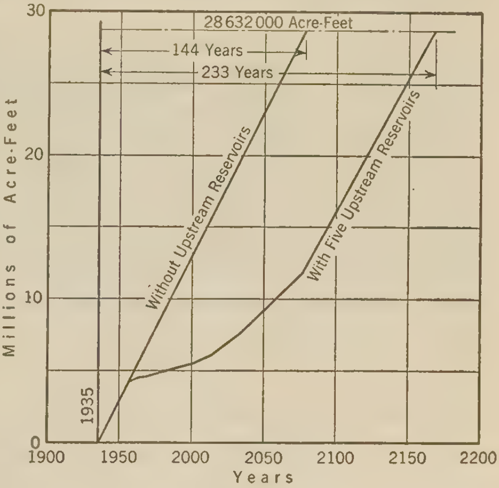

FIG. 7.—LIFE OF LAKE MEAD

If both Lake Mead and Glen Canyon high-level reservoir were operated in parallel, there would be a great loss of water by evaporation. Even if it were pronounced feasible, it is strongly recommended that the construction of Glen Canyon high dam be deferred until some future time when the storage facilities of Lake Mead shall have become seriously impaired.

Bridge Canyon Reservoir would have its life extended from 14 to 44 years by the upstream reservoirs projected, which is still a very short time in which to amortize large investments in power equipment in excess of that suitable for a river-run plant.

In this study Elephant Butte Reservoir was used primarily as an index of the average value of the specific weight of sediments in it, as well as in Lake Mead. The feasibility of constructing reservoirs upstream from Elephant Butte is doubtful. The Rio Grande Compact between Colorado, New Mexico, and Texas precludes any increase in consumptive use of the water in the Upper Rio Grande basin. Any all-year storage would add the evaporation from them to the present high consumptive use and could well be considered a violation of that compact.

The only course left, therefore, appears to be to continue the use of Elephant Butte Reservoir until its usefulness has become impaired enough to warrant the construction of a substitute reservoir. Even this might increase the present consumptive use. That, however, is a subject for future consideration.

In these studies the effect of land management in withholding sediments permanently from the reservoirs has not been taken into account because its efficacy is so closely bound up with administrative policies and congressional appropriations that its effect, even if known, lacks the essential element of assurance.

The western arid states depend upon irrigation for their very existence. Sedimentation constitutes a direct threat to that continued existence. Something must be done about it, but to do anything engineers must first have data on sedimentation in all of its phases. The available data are pitifully meager, and must be greatly enlarged before any constructive program for relief can be developed. For example, it appears that some 64% of the silt in the Colorado River is contributed by the sedimentary plateau drained by the San Juan, Little Colorado, and Virgin rivers, the area of which is only one tenth that of the Colorado River drainage basin. Here is an area where extensive research and consequent improvements would pay handsome dividends.

DISCUSSION

D. C. BONDURANT,[31] **ASSOC. M. AM. SOC. C. E.**—The irrigated regions of the United States have been developed to their present economy by reservoirs; and without such reservoirs these regions could not continue to exist in that economy. Since it may be assumed that existing reservoirs have been located at the most satisfactory sites, it follows that they could be replaced only at less satisfactory sites and that ultimately they could not be replaced at all. Unfortunately, reservoir sites are limited and the loss of an existing project may well destroy a community. It is fortunate, indeed, that a few far-sighted individuals have foreseen the seriousness of the problem and have undertaken to bring about its realization.

The writer, however, does not agree with the author that it is not feasible to construct reservoirs upstream from Elephant Butte, N. Mex. It is believed that such reservoirs are not only feasible but are necessary for the continued stability of a large area in the Middle Rio Grande Valley, in New Mexico, supporting about 17% of the population of the state. The problem confronting this region includes not only sedimentation in Elephant Butte but also aggradation of the Rio Grande which is now at or above the level of the valley floor in many places. Consequently, the water table is maintained at such high level that the productivity of the land is seriously impaired due to ineffectiveness of drainage ditches and resulting excessive alkali accumulation. Flood hazards have also increased commensurately. It is possible that aggradation of the Rio Grande is the result of a period of low flow, wherein the flows have been insufficient to carry the sediments brought in by tributary floods and that a later period of high flows may degrade the stream and carry the excess sediments to Elephant Butte Reservoir. It is believed more likely, however, that this condition is resultant from irrigation diversions reducing the flow, and the condition will continue as long as irrigation exists.

Reservoir sites are available at one of several points on the main stem in New Mexico, below the Colorado-New Mexico State line, and in the lower reaches of the Rio Chama, Jemez River, and Rio Puerco. These reservoirs could be utilized for flood control, sediment storage, flow regulation, and hydroelectric power. The sediment carried by the streams into these reservoirs would be retained and the clear water released would tend to degrade and stabilize the channel downstream, a premise which is substantiated by observed results below several operating projects. The Rio Grande below Elephant Butte Dam degraded appreciably from Elephant Butte to near El Paso, prior to the channel improvement made by the International Boundary Commission, and it is quite probable that the lack of a heavy sediment contribution from upstream has aided materially in maintaining this improvement. Recent surveys of the South Canadian River below Conchas Dam in New Mexico show that, since 1941, retrogression has been significant for a distance of more than 40 miles downstream. In the Middle Rio Grande Valley, such retrogression would notably improve the status of irrigated lands.

---

[31] U. S. Engr. Office, Albuquerque, N. Mex

Extensive investigations have been made to determine the feasibility of these projects—both singly and in combination. It has been determined that their construction and operation will in no way abrogate the Rio Grande Compact, but instead will provide a better water supply to the users. The problem of evaporation, as mentioned by the author, is more than compensated by the difference in water surface areas exposed and the difference in evaporation rates at the varied locations. At Elephant Butte evaporation is 5.364 ft per annum computed on a factor of 0.67 to reduce observed pan evaporation to probable reservoir evaporation. At Santa Fe, N. Mex., about 2,500 ft higher in elevation, the reservoir evaporation would be 3.567 ft. The water surface area of Elephant Butte, and consequently the evaporation volume, increases at an appreciably higher rate with storage exceeding 1,000,000 acre-ft than it does with storage less than that amount. During the months of high evaporation, the use of the upstream reservoirs to maintain lower pool elevations in Elephant Butte would result in a net saving of water.

The author's statement that Salt Cedar growth on the Rio Grande is not as extensive as on the Pecos River is correct. However, a dense growth of this plant exists at the head of Elephant Butte Reservoir and the incidence of Salt Cedar growth along the Rio Grande is increasing. This growth should aid in reducing sedimentation in Elephant Butte, although the quantity of water consumed and transpired by the plant is so great that the value of water lost in this manner may offset the efficiency of the plant as a sediment screen.

JOHN H. BLISS,[32] ASSOC. M. AM. SOC. C. E.—A problem common to practically all storage reservoirs—the reduction and eventual loss of their useful storage capacity due to siltation—is treated in this excellent paper by Mr. Stevens. This is a serious problem, which threatens the very existence of irrigation in the arid west.

In his paper, Mr. Stevens uses the silt data obtained at Elephant Butte Reservoir as the yardstick for determining the unit weight of sediments deposited in reservoirs. Elephant Butte is apparently the only reservoir at which a long-time record of the necessary base data has been kept. Using the 25.75-yr record from January, 1915, through September, 1940, the author derives 65.3 lb per cu ft as the average specific weight of the entire volume of silt deposited in Elephant Butte Reservoir up to the time of the 1940 resurvey. This specific weight is based (1) on the measurements of suspended silt past San Marcial station above the reservoir, adjusted for an estimated bed load and for unmeasured silt flows into the reservoir below the station; and (2) on surveys showing loss of storage space in the reservoir, the volume of silt deposited between San Marcial station and the reservoir, and the loss of dead storage in the reservoir itself. It seems as reasonable a value as may be derived in the light of present knowledge. Any specific weight used depends to a considerable extent upon the bed load that the given stream carries—or is assumed to carry—since no accurate measurements of bed loads are available for the streams in question. The author adjusted the suspended load measurements by increasing them 15% to account for the unsampled bed load. He also deduced, from measurements made on tributaries of the Rio Grande above San Marcial station, that tributary flow contributed an average of about 1,600 tons of silt per square mile of drainage area. Therefore, with 1,750 sq miles of drainage area, the unmeasured tributaries to Elephant Butte Reservoir below San Marcial were assumed to contribute an average of 2.8 million tons per year.

---

[32] Asst. State Engr., State Engrs. Office, Santa Fe, N. Mex.

Since no silt measurements were kept for the first eleven years of Elephant Butte operation, the silt inflow past San Marcial for this period was estimated from silt curves. The accuracy of this is questionable. Incidentally, using the author's method of adjustment, the period 1926–1940, when actual silt determinations were taken, yields a value of about 75 lb per cu ft as the unit weight of the deposited sediments. The International Boundary Commission derived a specific weight of 70.2, based on recorded data.[33] Adjustment of this value gives a specific weight for the sediments of well above 80. Part of the discrepancy would seem to lie in the reduced tributary silt inflows which would lessen the bed load carried during this period of below normal runoff. If these latter values are reasonable, it may be that the volume of deposited sediments in reservoirs, particularly over long periods of time, may be somewhat less than that derived by the author. The theoretical life of the reservoirs, in that case, would be extended somewhat, although their eventual demise would be no less certain.

The writer was quite interested in the statement (see first paragraph of Part II) that, although the San Juan, Little Colorado, and Virgin rivers contribute only 20% of the discharge into Lake Mead, they transport 64% of the silt of the Colorado River system above the lake. Here indeed is "an area where extensive research and consequent improvements would pay handsome dividends."

In his "Conclusions" the author makes a statement regarding the future of Elephant Butte Reservoir which is erroneous and should be corrected. The tri-state Rio Grande Compact does not preclude "any increase in consumptive use of the water in the Upper Rio Grande basin." Rather, it is an agreement between the states that provides the means for making additional and better use of the available water supply by permitting upstream storage and use of water formerly spilled from Elephant Butte Project storage. This is accomplished by converting nonbeneficial uses along the stream to beneficial uses through drainage and reclamation, by permitting development of feasible power projects, etc. Congress has already authorized construction of major reservoirs on Rio Grande and Conejos River in Colorado. New Mexico is currently introducing in Congress a bill for a $40,000,000 project on the Rio Grande and tributaries involving considerable new storage for flood and silt control, power, and re-regulation of the flow through the Middle Valley for irrigation. This project is being integrated by the Bureau of Reclamation and the Corps of Engineers of the U. S. Army and complies, in all respects, with the provisions of the Rio Grande Compact. One of the important features of the proposed project is the detention and control of silt on tributary streams, thereby reducing the average rate of silting of Elephant Butte Reservoir from about 17,000 acre-ft to about 5,000 acre-ft annually. The project will not eliminate the silt problem of the basin, of course, since it merely retains the silt load in reservoirs upstream from Elephant Butte Reservoir. It will alleviate a bad situation for many years, however, during which time it is to be hoped more adequate control measures will become available.

[33] *Water Bulletin No. 7*, International Boundary Comm., El Paso, Tex., 1937, p. 63.

LUNA B. LEOPOLD,[34] JUN. AM. SOC. C. E.—The Rio Grande and Colorado River watersheds differ somewhat from many other large basins in that normal erosion in the semiarid areas is more widespread and more obvious than in humid areas. Therefore, there is a tendency to minimize the importance of watershed management as a factor that might influence the rates of sediment production.

The author states (see heading, "Prolonging the Life of Lake Mead: Land Management") that in the semiarid areas natural erosional forces are relatively so important that the best land management can have only minor effects in reducing the sediments carried by streams. It should be emphasized, however, that continued mismanagement could increase the sediment available to streams. In a watershed such as the Rio Puerco, an important sediment-producing tributary to the Rio Grande, gullying has proceeded so far that land management alone could have but negligible effect on the lateral widening of the gully walls and the deepening of the existing arroyos in their upper reaches. In the Rio Grande and Colorado watersheds, however, there are myriad small valleys which are not yet gullied and where land management, as a preventive method, can be effective in keeping sediment out of the main channels. Flash flows tend to clog the main channel with debris that might be moved into the reservoirs by larger floods. The larger the area of watershed dissected by arroyos, the larger will be the percentage of storm rainfalls capable of producing flash flows in the tributary channels.

The history of arroyo cutting of the Rio Puerco will serve to illustrate the rapidity with which dissection of such alluvial valleys proceeds and the effect of recent erosion on the problem of sedimentation of reservoirs. The Rio Puerco comprises 23.6% of the total area above Elephant Butte Dam. The average annual runoff at its mouth[35] amounts to 62,000 acre-ft. Stream-flow records at San Acacia, just below the mouth of the Rio Salado, indicate that the Rio Puerco contributes 6.6% of the runoff and 60% of the suspended load passing that station.[36]

Prior to 1885 the Rio Puerco, an ephemeral stream, was subject to numerous small floods and occasional great ones, the water spreading over a wide and

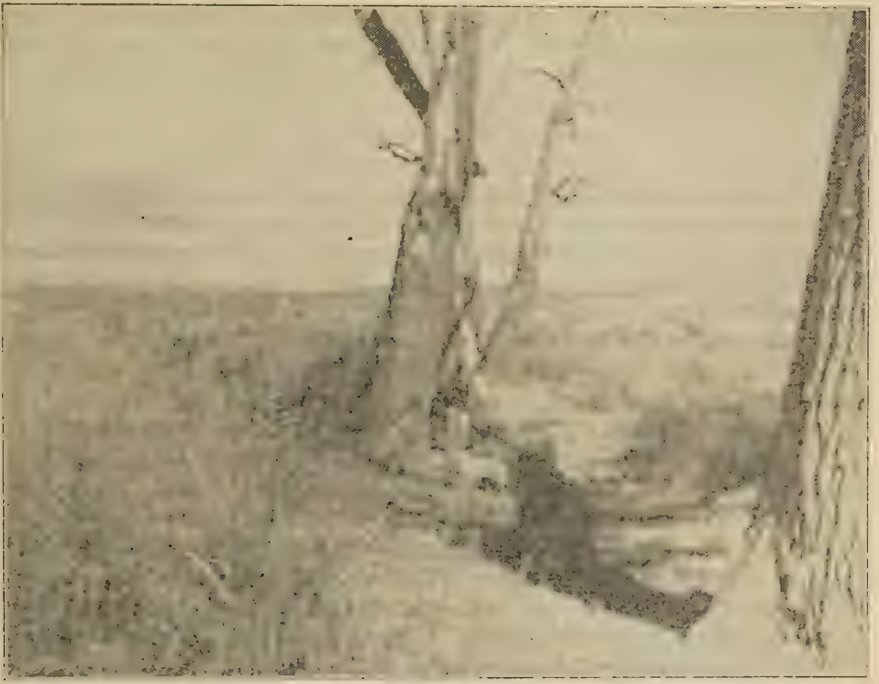

FIG. 8.—OLD STREAM CHANNEL OF THE RIO PUERCO, NEAR SAN LUIS, NEW MEXICO

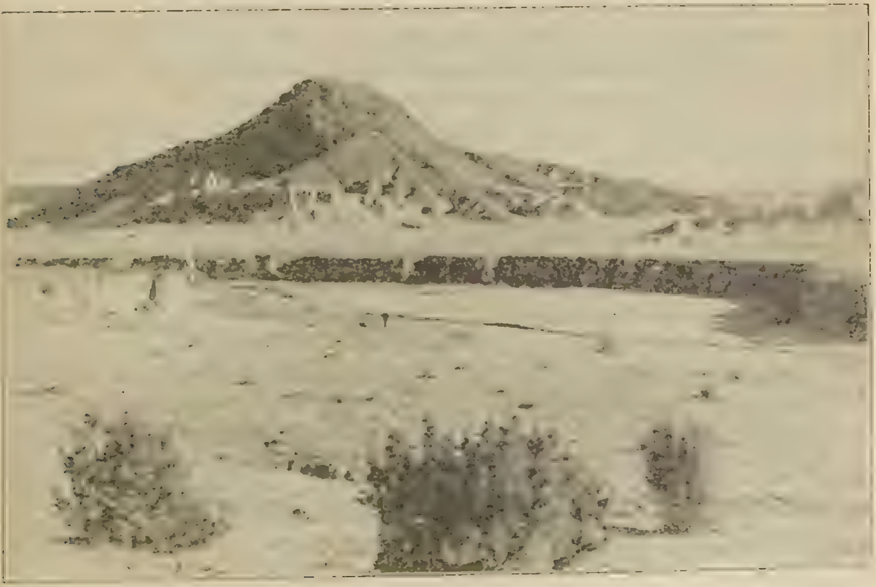

FIG. 9.—ARROYO OF THE RIO PUERCO IN 1940, ABOUT THREE MILES BELOW SAN LUIS, NEW MEXICO

grassy valley floor.[37] The flood plain was discontinuously channeled, a natural feature of such a watercourse. The continuous gully, now approximately 156 miles long, cut headward from the mouth, the greatest growth taking place in the period from 1885 to 1895.

In 1939 the writer talked to one of the original settlers of the village of San Luis, N. Mex., the late Miguel G. Dominguez, who came there in 1867 when his father settled in the Rio Puerco valley. The old man showed the writer the position of the Puerco channel as it was when he was a youth. As the present arroyo developed, many small remnants of the original channels have been left on the old valley floor. Fig. 8 was taken at the position indicated by Mr. Dominguez as the 1870 channel. As can be seen the watercourse was shallow and about 20 ft wide, lined with cottonwood trees. These trees died when the water table was lowered by the cutting of the continuous arroyo.

Mr. Dominguez said that in his youth there was a gully "head-cut" 4 ft or 5 ft deep about one mile below the village of San Luis. The gully was probably discontinuous at that time. Such evidence corroborates the picture of the valley constructed by Kirk Bryan and G. M. Post.[37]

In 1904, according to Mr. Dominguez, the arroyo at San Luis was 12 ft deep. It is now 30 ft to 40 ft deep. The magnitude of the present channel can be visualized from Fig. 9, a photograph taken by the writer in 1940.

No discussion of erosion problems of the Rio Grande would be complete without reference to the voluminous work of Kirk Bryan.[38] The classic report by Messrs. Bryan and Post[37] provides detailed data on southwestern erosion history. These men made a survey of the Rio Puerco channel in 1927 and another was made in 1939 by the Soil Conservation Service. Using Mr. Bryan's estimate of the volume of the channel in 1885 and the results of the 1939 survey, it is computed that approximately 250,000 acre-ft of material were eroded from the Puerco channel during the 54-yr period.[39]

Data on widths of the Rio Puerco channel recorded by land surveys in 1881, 1897, and 1900 were collected by Messrs. Bryan and Post and, together with later measurements by the Soil Conservation Service,[39] provide indications of the rate of widening of the arroyo. The width of the channel on six section lines in T 6 N, R 1 W where the Puerco forms the west boundary of the N. D. Chavez Grant were measured by early land surveys. The increase of width of channel, averaged for these six places, is shown in Fig. 10.

This résumé of the history of arroyo cutting in the Rio Puerco characterizes the development of recent erosion in most of the watersheds of the southwest. This discussion cannot possibly do justice to the large volume of data published on the subject; nor is this the place to discuss the relative importance of overgrazing and climatic change as causes of the present epicycle of erosion.

[39] "Rio Puerco Watershed, New Mexico," U. S. D. A. Survey Report, Flood Control, 1941, p. 218 (unpublished).

The fact remains that overuse of land has contributed to the timing and to the extent of the present erosion problem. Because there are many subtributaries in various parts of the Rio Grande and Colorado watersheds which are not yet gullied, continued mismanagement of land can still be a factor in producing large amounts of sediment which might further aggrade the main channels or be deposited in reservoirs.

The author states that the prime objective of range and forest management is to produce as much forage and merchantable timber as possible on a sustained yield basis ("Prolonging the Life of Lake Mead: Land Management"). The qualification might well be added that this assumes that the soil and vegetation will be ecologically stable under continued use. Such is the case in most areas where deterioration has not progressed too far.

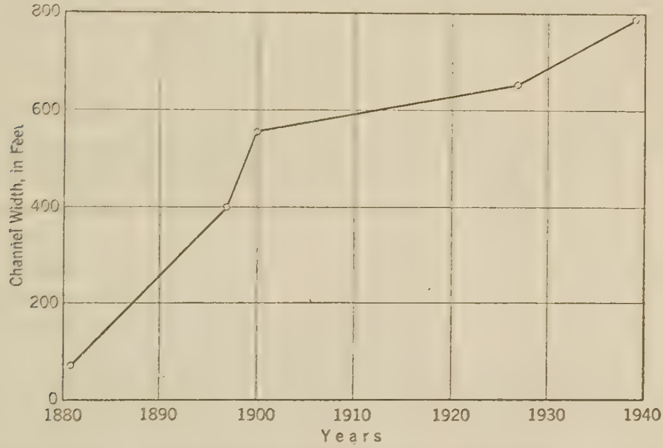

Fig. 10.—Increase in Width of Rio Puerco Channel, New Mexico, in T 6 N, R 1 W

Planting of forests solely to prevent erosion is seldom a sound financial investment, as Mr. Stevens states. This is certainly true in so far as private enterprise is concerned. From the standpoint of the nation as a whole, however, the time has already come when the value of cover on certain watersheds as relatively permanent protection for areas downstream far exceeds the actual cash value of the land itself. It is to be hoped that there will be an increasing realization of the value of watershed cover as protection for water supplies and as a factor promoting soil stability. These are separate values and no less important than the value of the merchantable produce.

The sedimentation problem brings the engineer face to face with many nonengineering aspects of land use. In many respects watershed control, including all the biological considerations of grazing, forestry, and farming, constitutes an engineering problem in that it is susceptible to engineering techniques of over-all analysis and planning. A growing number of engineers are extending themselves into biological fields, but there is still a need for practicing engineers to broaden the scope of their activities in order to apply engineering experience to the vast job of conserving the deteriorating land resource. Papers such as the one under discussion constitute a stimulus toward this end.

Carl B. Brown,[40] Assoc. M. Am. Soc. C. E.—In 1934, Mr. Stevens "focused attention on the part sedimentation will play in the future history of Western civilization." [41] In the present paper he analyzes the effects of sedimentation on the useful life of Lake Mead and Elephant Butte Reservoir. His conclusions strongly re-emphasize the urgency of the task lying ahead of engineers and conservationists to find some practicable means for conserving the limited, irreplaceable, and indispensable reservoir sites on major southwestern streams.

Lake Mead.—Previous estimates of the annual rate of silting in a reservoir on the Colorado River at Boulder Canyon have ranged[42,43] from 80,000 acre-ft to 150,000 acre-ft. A rate of 137,000 acre-ft originally estimated by Harry F. Blaney and the late Samuel Fortier, Members, Am. Soc. C. E., in 1928 [44] was quoted by the U. S. Bureau of Reclamation in 1936 with the qualification that "this amount will decrease with upstream development. It is estimated that the total silt deposits in the reservoir will not exceed 3,000,000 acre-feet at the end of 50 years." [45] However, the Bureau's Final Reports on the Boulder Canyon Project contain this statement: "Estimates indicate that before Boulder Dam was built the average rate of silt transportation through Black Canyon was about 100 thousand acre-feet per year, approximately 5 tons per second." [46]

On the basis of new data, Mr. Stevens has concluded that the average rate of silting in Lake Mead without upstream developments will be 198,000 acre-ft annually. There is considerable evidence to indicate that even this estimate is too low. The author's analysis is based primarily on the suspended load records obtained by the U. S. Geological Survey, at Grand Canyon, during the 16-yr period from October 1, 1925, to September 30, 1941 (see Table 4). His analysis contains no allowance, however, for the fact that this was a period of predominantly subnormal stream flow throughout the Southwest, although he mentions this fact several times in the text. Fig. 4 shows the rapidly declining level of Great Salt Lake and the declining 5-yr moving average of stream flow of the Rio Grande at Otowi, N. Mex., from 1925 through 1935. A cumulative curve of departure from average annual runoff of the Colorado River at Lees Ferry, presented by the writer,[47] shows that the declining trend at this station continued through 1940.

If the quantity of suspended sediment carried by a stream is related to the annual discharge, the long-term mean sediment load would not be fairly represented by a period of exceptionally subnormal flow. The annual suspended load of the Colorado River does have a fairly well-defined exponential relationship to the annual runoff as shown by Fig. 11. As calculated by the method of least squares the curve on this graph was plotted from the equation:

$$S = 0.00295\, R^{1.52} \ldots\ldots\ldots\ldots (1)$$

in which S is the annual suspended load in tons; and R is the annual runoff in acre-feet. As the exponent is greater than 1, the suspended-sediment load is shown to increase at a greater rate than the runoff. For some other streams, not in the Southwest, similar calculation has shown an exponent less than 1.

The spread of points in Fig. 11 is caused mainly by understandable natural conditions. In a year of heavy snow-melt runoff without large summer storms in the silt-producing Colorado plateaus, points may fall well below the line. When the converse is true, points may fall above the line. Over a long period the sum of all measured values should be almost the same as the sum of values derived from the curve, assuming that existing data cover the full range of probable values.

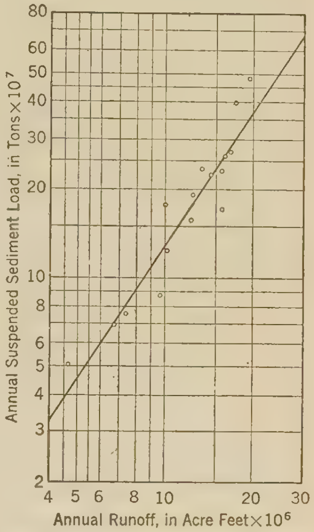

FIG. 11.—RELATION OF ANNUAL RUNOFF AND SUSPENDED SEDIMENT LOAD OF THE COLORADO RIVER NEAR GRAND CANYON, ARIZ., 1925–1941

In order to adjust the mean suspended load of the 16-yr period of predominantly subnormal runoff to a longer, more nearly average, period the following three steps were taken:

(1) An estimate was made of the probable flow at Grand Canyon for each year of the period from 1897 to 1922 by taking a value midway between values estimated by E. B. Debler,[48] M. Am. Soc. C. E., for these years at Boulder Canyon and at Lees Ferry. For a few years certain minor adjustments were made after comparison with estimates made for the same years by E. C. LaRue[49] and R. J. Tipton,[50] M. Am. Soc. C. E. It is considered that Mr. LaRue's

[49] "Water Power and Flood Control of Colorado River Below Green River, Utah," by E. C. LaRue, *Water-Supply Paper No. 556*, U. S. Geological Survey, Government Printing Office, Washington, D. C., 1925, p. 121.

[50] "Report on Water Supply of Colorado River and Allied Matters," by R. J. Tipton, *Exhibit C, Report and Proceedings*, Fact Finding Committee of the Upper Colorado River Basin States, July, 1938 (unpublished).

estimates of flow at Lees Ferry from 1851 to 1897,[49] based on a correlation with levels in Great Salt Lake, are too uncertain to warrant use in this analysis. If they were used, the indicated mean annual flow would be about 1,000,000 acre-ft larger than that since 1897. Therefore, considering the period from 1897 through 1941 as average seems reasonably conservative by comparison with the 90-yr period since 1850.

(2) Using the estimated runoff at Grand Canyon for each year of the period from 1897 to 1922 in Eq. 1, the value of S for each year was obtained. For the years 1923 to 1925, inclusive, the measured flow was used. The sum of the annual suspended sediment loads thus derived is 8,053,500,000 tons. The measured load during the period from October 1, 1925, to September 30, 1941, was 3,203,900,000 tons, making a grand total of 11,257,400,000 tons.

(3) The measured suspended load during the period from October 1 to December 30, 1925 (approximately 22,000,000 tons, which is duplicated in the preceding addition), was subtracted, and the load for the same months in 1941 (approximately 84,400,000 tons), was added. The record thus derived extends over a period of 45 calendar years, and the mean annual suspended sediment load thus computed is 251,550,000 tons. The computed suspended load for only one year—522,000,000 tons in 1909—was in excess of the 480,000,000 tons actually measured in 1929.

Bed Load.—Considering the physical characteristics of the Grand Canyon gaging station, the sediment load that can be measured with existing sampling equipment probably represents at least 95% of the total load passing the station. However, the results of experimentally-controlled tests, and field comparisons of the milk-bottle sampling equipment used at Grand Canyon, with the scientifically designed equipment developed at Iowa Institute of Hydraulic Research,[51] at Iowa City, Iowa, indicate that Mr. Stevens' addition of at least 15% to the reported suspended load is justified to compensate for bias in sampling method plus unmeasured bed load. This percentage addition to the long-term mean value of suspended load, previously derived, would give a mean annual total load at Grand Canyon of 289,282,000 tons.

Sediment from Intervening Drainage Area.—The author's estimate of 1,600 tons per sq mile for the annual sediment contribution between the Grand Canyon gaging station and Boulder Dam can be fully substantiated as a long-term average [47] if applied to the area that actually contributes surface runoff. Approximately 9,000 sq miles of the 30,000-sq-mile area between Grand Canyon and Boulder Dam comprises the surface of Lake Mead and areas such as the White River, Upper Meadow Valley, and Upper Las Vegas Valley, which so rarely contribute any water to the Colorado River that they should be excluded as areas of sediment contribution. If the sediment production is estimated as coming from 21,000 sq miles at a rate of 1,600 tons per sq mile, this additional annual contribution of 33,600,000 tons would make the long-term mean annual sediment load entering Lake Mead, in round figures, 323,000,000 tons, rather than the 280,000,000 tons estimated by Mr. Stevens.

---

[51] "Comparative Field Tests of Suspended Sediment Samplers," *Progress Report, Appendix A* of "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," Iowa Inst. of Hydr. Research, Iowa City, Iowa, December, 1944.

Space Occupied by Deposits.—The specific weight of deposits in Lake Mead needs to be studied exhaustively. The rate of compaction will affect future operation of the reservoir and should govern the timing of the construction of upstream developments. For example, a mean sediment inflow of 323,000,000 tons (assuming an average specific weight of 65 lb per cu ft) would cause an average annual capacity loss of 228,200 acre-ft. This is equivalent to the loss of the dead storage (3,207,000 acre-ft) plus half of the active storage capacity (12,742,000 acre-ft) to spillway crest (El. 1205.4) in 70 years (from 1935), by which time, according to the author, the usefulness of the reservoir for hold-over storage would be seriously impaired. However, if the final value were only 55 lb per cu ft the period would be 59 years, but at 75 lb per cu ft it would be 81 years.

The effective hold-over storage at any particular time depends on the average specific weight at that time. Practically no usable water can be obtained through compaction of sediment or effluent seepage from a reservoir like Lake Mead in any single seasonal drawdown.

TABLE 10.—RELATION OF SEDIMENT ACCUMULATION TO INFLOW IN ELEPHANT BUTTE RESERVOIR

Period	Years	Average annual inflow (thousands of acre-ft)	Sediment by volume (%)	Average annual sediment deposit since previous survey (acre-ft)
January 1915 to December 1916	1.91	1,574	1.80	28,270
December 1916 to August 1920	3.67	1,414	1.66	23,437
August 1920 to August 1925	5.0	1,130	1.62	18,345
August 1925 to April 1935	9.67	853	1.62	13,801
April 1935 to September 1940	5.5	936	0.98	9,200

Elephant Butte Reservoir.—Two factors account for the decline in the rate of sedimentation in Elephant Butte Reservoir. One is the smaller inflow for successive periods between the date of construction and 1935 as shown in Table 10.

Secondly, during the 1937 flood the river broke through its banks above San Marcial and subsequently has deposited huge quantities of sediment over its flood plain. As shown by repeated surveys along eleven ranges crossing the valley between the lower end of the Conservancy District levees and the original head of the reservoir (a distance of about 15 miles), the average annual rate of sedimentation in this area was 50% higher during the period from 1936 to 1941 than during the period from 1914 to 1926. Because of partial desilting of the river flow in this area the rate of deposition in the reservoir was materially lessened.

It is reasonable to expect that the rate of sedimentation in the reservoir will increase when the channel again becomes stabilized in the lower reaches of the Middle Valley and a series of years of heavier flow is experienced. The writer concurs in the opinion that a straight-line extension of the silting rate curve in Fig. 3 "may not be amiss" in the absence of new sediment and water-control structures in the drainage area above.

Under the heading, "Probable Useful Life," the author credits the Soil Conservation Service as reporting "that aggradation of the lower portion of this valley began eight years prior to the construction of Elephant Butte Reservoir." This should be amended to read "at least eight years."[52] Questionable data indicate that the river bed at San Marcial may have been rising since 1880. The Santa Fe Railroad bridge profile at San Marcial, surveyed in 1880, shows a channel 350 ft wide with an average bottom elevation of approximately 4,450 ft. A profile under the bridge in 1904 shows a channel 500 ft wide with an average elevation of 4,452.7 ft.

Aggradation of at least the lower part of the valley since 1906, and perhaps for a much longer period, makes it improbable that the low runoff cycle beginning in the middle 1920's can be the primary cause of this condition. Backwater effects from the reservoir and tamarisk, which the author will find in considerable abundance, have accelerated deposition in the lower reach of the valley, but did not initiate it; nor have they been responsible thus far for increased aggradation more than 25 to 30 miles above the original head of the reservoir.[53]

Although sedimentation in Elephant Butte Reservoir has decreased during successive periods since 1915, coincident with a general decrease in runoff, it does not follow that valley aggradation has resulted from lack of floods capable of flushing out the sediment accumulation of low-water periods.

Records and estimates of the discharge at San Marcial since 1890 show that:

(1) During seven months prior to, and during seven months since, January 1, 1920, the mean monthly discharge has exceeded 10,000 cu ft per sec; and

(2) In ten months prior to, and in ten months since, January 1, 1920, flood flows exceeding 15,000 cu ft per sec have been experienced. The years of largest floods in order of magnitude were 1904, 1929, 1937, and 1941.

In the writer's opinion, aggradation can be accounted for readily by the increase in volume of coarse sediment delivered to the valley by the Rio Puerco and many smaller arroyos that did not exist or were only discontinuous channels prior to 1880. Much of this sediment has come directly from trenching of the alluvial valleys; and, since their develpoment, the arroyos have served as direct flumes for transportation of sediment from gullying slopes into the Rio Grande.

Prolonging the Life of Southwestern Reservoirs.—The author's discussion of methods for controlling reservoir sedimentation leaves one with a rather hopeless feeling. The control of density currents has some potentialities, he concedes. Dredging is properly eliminated as economically impracticable. He dismisses land management in the Colorado River basin, and by implication in other arid sections, by expressing doubt (see heading, "Prolonging the Life of Lake Mead: Land Management") that "all the proved practicable methods of land management known today even though lavishly financed" would reduce the sediment load (entering Lake Mead) as much as 10%. By process of elimination, he concludes to spread the sedimentation loss through a series of major reservoirs, which would be constructed according to a schedule based partly on sedimentation rates and partly on the increasing need for stored water. In effect, this plan would throw the burden of sediment control on those very natural resources—the limited and irreplaceable major reservoir sites—that should be protected against, not exhausted by, rapid sedimentation.

---

[52] "The Sedimentation in the Middle Rio Grande Valley, New Mexico," by Stafford C. Happ, SCS, 1942, p. 85 (unpublished).

[53] *Civil Engineering*, February, 1945, Fig. 2, p. 84.

One of the most common flaws in reasoning on sediment control in the Southwest results from an assumption that most of the current sediment production is coming (1) from rain-wash erosion of barren slopes that have never supported much, if any, vegetal cover, and (2) from corrasion of rock-bound channels by stream flow. This inference may be readily gained from a cursory look at the spectacular canyons and mesas of the region. All evidence that the writer has been able to collect, however, points toward a contrary conclusion. The present sources of the great bulk of sediment, in order of importance, are the alluvial valley fill, the alluvial fans, and the colluvial and residual soils of the land slopes. In the same order of importance, these were the most favorable sites for, and originally had the densest stands of, vegetation.

When white man first came to know the southwestern country, a cycle of valley and fan alluviation was in progress, except in the canyons of the Colorado River, the lower reaches of some of its tributaries, and in the high mountains. Historical records indicate that channels were lacking or discontinuous in the tributary drainage areas [54] that are now the primary sources of sediment load in the main streams (for example: Rio Puerco and Rio Salado, tributaries of the Rio Grande; Chaco Canyon, tributary of the San Juan; San Simon and San Pedro washes, tributaries of the Gila; Upper Kanab Creek, tributary of the Colorado; Polacca Wash, and other tributaries of the Little Colorado). Erosional debris from the land slopes was deposited mainly on alluvial fans at the edge of valleys or intermontane basins; and intermittent stretches of channel in the valleys terminated in broad areas of water spreading and deposition. At various times in different parts of the Southwest during the nineteenth century, a shift began in the physiographic cycle from predominant alluviation to predominant channeling. Arroyo development has now progressed to the point where most of the western alluvial valleys are cut by deep, steep-sided trenches for most of their length. Branching trenches have extended into many of the tributaries and thousands of gullies run from them on to the land slopes.

A survey of the Rio Puerco made by the Soil Conservation Service in 1939 showed that this arroyo had a volume of 267,000 acre-ft between the mouth and San Luis Dam, a distance of 117 miles. Kirk Bryan estimated in 1928 [55] that the original discontinuous Rio Puerco channels (prior to 1885) contained less than 5% by volume of the then-existing channels. The Soil Conservation Service estimated in 1939 that the current sediment production resulting from enlargement of the main channel of the Rio Puerco was 4,600 acre-ft per yr, or approximately 40% of the estimated average annual load of 11,500 acre-ft passing the mouth of the Puerco. An erosion survey of the entire drainage area gave a basis for estimating that 3,400 acre-ft per yr, or an additional 30% of the total load, was coming from enlargement and headward extension of tributary arroyos; and 3,500 acre-ft per yr, or about 30% of the total, was derived from sheet and gully erosion on the land slopes.

---

[54] "Climate and Accelerated Erosion in the Arid and Semi-Arid Southwest, with Special Reference to the Polacca Wash Drainage Basin, Arizona," by C. Warren Thornthwaite, C. F. Stewart Sharpe, and Earl F. Dosch, *Technical Bulletin No. 808*, U.S.D.A., Washington, D. C., 1942, pp. 125–129.

[55] "Historical Evidence on Changes in the Channel of the Rio Puerco, a Tributary of the Rio Grande in New Mexico," by Kirk Bryan, *Journal of Geology*, Vol. 36, 1928, pp. 265–282.

The reduction or elimination of grazing has halted the head cutting of many smaller arroyos and gullies. Proper management of vegetation certainly can retard the acceleration of erosion. Where main drainage channels are already deeply cut, however, vegetation alone cannot control the major part of the sediment output from the watershed. Various types of water-control structures are also essential to sediment control. If the author would broaden his term "land management" to include "upstream engineering" a much different conclusion might be reached. Permanent-type minor structures throughout the watershed can (1) reverse the arroyo cycle now in progress by creating local base levels of erosion, thus forcing water to spread again over valley flats and fan slopes as it did during the cycle of alluviation which existed prior to the present arroyo cycle, and (2) utilize the enormous volume of existing arroyos for sediment storage.

The effectiveness of a barrier system of sediment control has been experimentally tested during a 9-yr period from 1935 to the end of 1943 at the 65,000-acre Navajo Experiment Station of the Soil Conservation Service, situated in the typical rolling plains and broken mesas of the Colorado plateau province, 20 miles north of Gallup, N. Mex.[56] Drainage from this area enters the San Juan River. The experiments were designed to determine (1) the effects of water spreading and sediment deposition on forage and crop yields, and (2) the effectiveness of channel barriers and water spreading in controlling arroyo cutting and reducing the sediment output from the drainage basin of a major southwestern reservoir. All of the experimental area is a direct contributor to sedimentation in Lake Mead.

In 1934 and 1935, fourteen earth-fill dams were constructed to plug the main arroyo channels. Earthen dikes were extended from the dams part way across the adjacent flood plains. The structures forced water out of the channels around the edge of the dikes and caused it to spread over a large area of flood plain. At places on the flood plains where scouring was expected or observed, wire-bound rock sausages were buried or spreader fences were erected.

The percentage of sediment by weight in the runoff from 9,470 acres above three of the fourteen dams, which were chosen for detailed studies, varied from less than 1% to more than 60%, the unweighted average being 13%. In the 9-yr period, approximately 500 acre-ft of sediment was deposited behind the three dams and on the flood plains over which water was spread. The runoff was completely dissipated on the flood plain and no sediment originating above these dams was carried out of the drainage area. The sediment deposits were equivalent to 3.75 acre-ft per sq mile per yr—a high rate of sediment production for even the Colorado plateau area. All of this sediment plus a large additional amount controlled by the other eleven dams would have been added to deposits in Lake Mead.

---

[56] "Effects of Diverting Sediment-Laden Runoff Water to Crops and Range Lands," by D. S. Hubbell and J. L. Gardner, SCS, April, 1945 (unpublished).

Complete sediment detention and runoff dissipation can be accomplished by barriers only in small drainage areas. Barriers equipped with overflow spillways can be used effectively, however, in areas up to several thousand square miles. For example, if a series of some 72 such barriers, with spillway sills set at or just above the present valley floor level and with earthen dikes 5 ft to 20 ft high extending to the valley sides, were constructed on a fixed schedule over a 50-yr period on the Rio Puerco, it would be possible:

(a) To utilize most of the 267,000 acre-ft channel cavity for sediment storage;

(b) To reduce the sediment load of the stream at its mouth by most of the 4,600 acre-ft now coming annually from scour in 117 miles of main channel;

(c) To trap approximately 70% of the total sediment output of the drainage basin;

(d) To raise the water table in the valley and increase net forage yield; and

(e) To retard flood flows.

Such a program would be little, if any, more costly than the construction of a single large reservoir near the mouth of the Puerco to do an equivalent job of sediment control.

The Rio Puerco has an average but highly variable runoff of about 60,000 acre-ft, or less than 7% of the average annual inflow to Elephant Butte Reservoir; yet it contributes more than half of the sediment deposited below its mouth in the valley and reservoir. Loss of 7% of the total inflow to reduce sedimentation in Elephant Butte Reservoir by 50% would be an economic investment. Actually, the control of sedimentation by a watershed conservation program does not involve a sacrifice of water as does the net loss by evaporation from free water surfaces of storage reservoirs. Rather, it would shift the beneficial use of a small fraction of the total water supply of major watersheds (generally in the range of 5% to 15%) to upland slopes and headwater valleys. In compensation it would permit the orderly utilization of major upstream storage sites, such as those enumerated by the author, for beneficial purposes and not for sediment storage.

Mr. Stevens should not have too much misgiving about the efficacy of land management (in its broader sense including upstream engineering) (see "Conclusions") being so closely "bound up with administrative policies and congressional appropriations that its effect * * * lacks the essential element of assurance." It is only 10 years since the effects of land management on agricultural and range land began to be studied on a scale anywhere near commensurate with the scope of the problem. Although the subject is highly complex, enough already has been learned and demonstrated to point the way. Much more research is, indeed, needed to draw the blueprints for full-scale conservation of Western drainage basins. As rapidly as sound plans can be prepared, the afore-mentioned difficulties will doubtless resolve themselves. The will of the local people for conservation of soil and water resources is already expressing itself in the rapid organization under state laws of locally-controlled Soil Conservation Districts which thus far include, for example, 25% of the land in Colorado, 49% in New Mexico, and 68% in Utah.

G. E. P. SMITH,[57] M. AM. SOC. C. E.—The paper by President Stevens is of absorbing interest. It deserves most earnest consideration in the further development of the comprehensive plan for utilization of the Colorado River, and to a lesser extent of the plans for the Rio Grande.

The rate of silt accumulation in Elephant Butte Reservoir as determined by the author is not greatly different from the rate predicted by the designers at the time of the dedication; the rate is a little less but the difference is accounted for by the difference in the value of γ. The rate for Lake Mead is greater than was assumed prior to construction of Boulder Dam.

In the realm of history, two or three hundred years is a brief period. Structures and other normal investments can be amortized in a predetermined number of years, but a population settled on land with accessory rural institutions has never yet been amortized successfully. One can picture the farmers on the Colorado River projects clinging to their homes and hoping for exceptionally well-distributed river discharge to enable them to raise a few more crops. Perhaps the present civilization has been too uncharitable in its criticism of the civilization that once flourished in the valleys of the Tigris and Euphrates rivers. In some spots the present civilization is not too secure.

An important query is whether the runoff in quantity and character during those base periods of records available to the author are indeed representative of a far longer period. Since the records of short duration have been extrapolated six to twenty times, it is essential to inquire whether these periods are reliably representative. The writer has studied the rainfall records for Utah, Wyoming, and Colorado, the three states from which runoff at Lees Ferry is derived, from 1880 to 1945. The mean annual rainfall for the three states separately, obtained from the U. S. Weather Bureau, was averaged, weighting the Colorado rainfall double. The record was then smoothed moderately in 3-yr running averages, weighting the middle one double. The resulting record, plotted as percentage of the long-time mean, is shown in Fig. 12. It appears that the rainfall for the years from 1935 to 1942, inclusive, was 105% of the long-time mean. The record in Fig. 12 is not a safe index for the Elephant Butte studies, although a similar one could be made covering rainfall of southeastern Colorado and western New Mexico. It is recognized that runoff is not indicated precisely either in quantity or character by rainfall, but rainfall is the best index available and is relied on by hydrologists when missing runoff data must be supplied.

The author refers (see heading, "Probable Useful Life") to "the low runoff cycle the West has been experiencing since 1920." It is difficult to state just what significance is here attached to the much-abused word "cycle." There are wide variations in rainfall and runoff from year to year, but no regular periodic cycles, which repeat themselves over and over indefinitely, can be proved. Even the great irregularities apparent in the rainfall record of a basin, such as the record shown in Fig. 12, do not parallel very well the irregularities of rainfall in adjoining basins. The irregularities are, therefore, largely local; if there were any governing causes, at least they would not be uniform for broad regions like "the West." The vagaries of the air circulation over the earth and of the hairspring conditions that cause precipitation are so great that any truly cyclic tendencies are overshadowed by the sequence of fortuitous events.

---

[57] Prof. of Agri. Eng., Univ. of Arizona, Tucson, Ariz.

As to the Colorado-Wyoming-Utah rainfall, it is not the drought in the thirties, but it is the generally high level of rainfall from 1905 to 1930 that is outstanding. Other sources of information confirm Fig. 12 and indicate that the long period of low rainfall began in 1870 instead of 1880. The inference is that the author's period of record for the Colorado River, although far too short, is reasonably representative, whereas the period used in the Rio Grande studies covered too many wet years. The importance of a few inches more or less of rainfall in a given year can be appreciated by plotting the quantities of sediment shown in Table 2 against either rainfall or runoff.

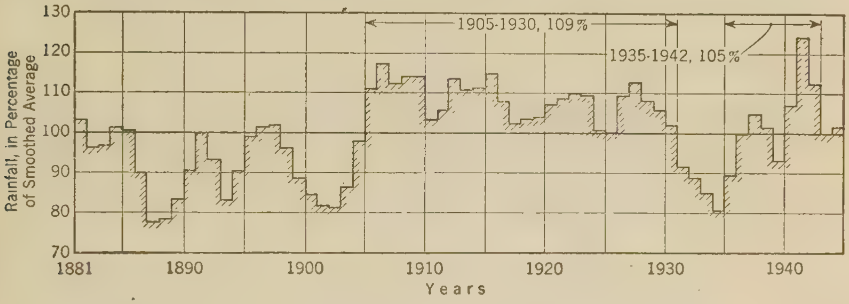

FIG. 12.—RAINFALL IN THE UPPER COLORADO RIVER BASIN STATES

The decreasing rate of siltation shown in Table 1 needs further study. A large proportion of the silt comes from the Rio Puerco. Has its bed been aggraded greatly? Also, settling and compaction of the deposited sediments in the reservoir would have the same effect on the rate as decreasing annual increments of silt. The value of γ varies within the same reservoir and tends to increase with time.

In the case of Lake Mead, various factors will operate to reduce the siltation rate. Utilization of the water above Lees Ferry, especially construction of projects to utilize the San Juan, will have that effect. Transmountain diversion of clear water, by reducing floods, will tend to aggrade some sections of the river system. The factors are not compensating.

The author proposes, under the heading, "A Schedule of Development," that the Dewey Dam be built first. This suggestion is a mark of real genius. It is desirable that the comprehensive plan for the Colorado River be revised and that the Dewey Dam be made the No. 1 project. That dam and the Bridge Canyon Dam should have been built in 1925 or before, followed by the Davis Dam, and then the Boulder Dam, and dams on the San Juan and Little Colorado rivers.

Two papers by the writer published in 1928 featured the wisdom of building the Dewey Dam first for many reasons. In the first paper[58] it was stated:

---

[58] *Western Construction News*, February 25, 1928, p. 107.

> "Canal maintenance in Imperial Valley is made difficult by the deposition of silt. This condition will be greatly ameliorated when the Imperial Canal is extended upstream and connected to the Laguna Dam, as already provided for by agreement. The same methods which protect the Yuma canal system—skimming and sluicing—will be applied to Imperial Canal water at the intake. The silt problem will be greater in the future when storage capacities are threatened than it is now; the silt cannot be stored in reservoirs forever. Revised estimates of the quantity of silt transported annually by the Colorado River are about 50 percent higher than the published estimates."

In the second paper[59] it was stated:

> "Silt storage in the Colorado River reservoirs will suffice for less than two hundred years, and then what shall be done? Silt storage has always been considered a curse. During the next decades, before the water has been put to use and while most of the water will run to the sea, the effort should be to make it carry its load of silt with it, so as to conserve the storage space."

Silt storage as a means of eliminating the silt problem at diversion points, although favored by the farmers of today, won too ready acquiescence of engineers.

The U. S. Bureau of Reclamation is now building projects to irrigate the Yuma Mesa and Imperial East Side, where the soil, or rather the sand, much resembles a sieve. If the naturally silty Colorado River water could be used for 20 or 30 years those lands would be greatly improved; but, ironically, the silt is being stored in Lake Mead where it is not wanted.

The writer often has considered the feasibility of a long tunnel within the rock wall on one side of the canyon upstream from a high dam, at a low level, with inlet tunnels every 200 ft or 300 ft equipped with control gates, but with small permanent openings to bleed off some of the silt. The purpose, of course, is to create a long settling pool and reduce the siltiness of water in the penstocks and turbines. A floating barge with whirling vanes on vertical shafts to be operated seriatim in front of the inlet tunnels might be helpful also. Boulder Dam, more than all others, should have such a tunnel, perhaps one on each side of the canyon extending a mile upstream.

The author was confronted with inadequate and uncertain data, and has had to make the most of that situation. Records were too short, and silt sampling probably was done during high water or when convenient. He has exercised much license in extensions of data, and in various assumptions, including the various values of γ, and some factors have been neglected. It is a highly exploratory study; but the computations lead to two definite answers—158 years for Elephant Butte Reservoir and 144 years for Lake Mead.

These answers will be cited and bruited, not only in technical papers, but also in newspapers and in speech until many people accept them as irrefutably exact. In one instance the author refers to his studies as "speculations." It would have been wiser to state the answers as of the order of 158 years and of the order of 144 years, or to have predicted, roughly, about 150 years, and thus leave the impression of uncertainty in the reader's mind. A case in point is that of the preliminary synthetic estimates of the water supply of the Colorado River. It is known now that those estimates were too high; but they were generally accepted to the last significant figure and much damage and injustice have resulted.

[59] "Progressive Arizona and the Great Southwest," by G. E. P. Smith, Vol. 9, Nos. 4, 5, and 6 (reprinted in the *Pan-American Geologist*, Vol. LIV, August, 1930).

ALBERT E. COLDWELL,[60] ASSOC. M. AM. SOC. C. E.—This paper furnishes a valuable and long-awaited sequel to the author's paper on "The Silt Problem."[61]

To many readers it may have been somewhat of a surprise or mild shock to learn that the estimated life of Lake Mead is less than that of Elephant Butte Reservoir. These two reservoirs, however, have such similar lengths of life that it seems desirable to examine whether that most useful tool in sedimentation studies, the capacity-watershed ratio, may be applied effectively to indicate that such similarity is reasonable. These ratios are:

Reservoir	Acre-ft per sq mile
Elephant Butte..............	$\frac{2,634,800}{25,923} = 102$
Lake Mead.................	$\frac{28,632,000}{167,000} = 171$

For reservoirs in Texas and Oklahoma, Carl B. Brown,[62] Assoc. M. Am. Soc. C. E., has shown that, on the average, the annual storage loss for reservoirs with capacity-watershed ratios of 102 and 171 may be expected to be about 0.88% and 0.85%, respectively, of the original storage capacity. Applied to the two reservoirs in question, the resultant values of 114 years for Elephant Butte and 118 years for Lake Mead are very similar; and, after due consideration is given to variation in location, climate, topography, and other conditions, these results appear to be in good agreement with the estimates of the author.

There is the possibility that either the capacity-watershed method or the linear method used by the author for estimating the lives of these reservoirs is too severe during the later portion of their lives. Large reservoirs in their early years have the ability to settle out virtually the entire inflowing sediment load, but with the passage of time the size of detention basin available becomes smaller and smaller until eventually a major portion of the inflowing sediment could be carried past the dam or deposited at elevations above the original pool level. McMillan Reservoir on the Pecos River seems to be a case in point. Much has been written, notably by the late R. F. Walter,[63] M. Am. Soc. C. E., about the effectiveness of the vegetative screen upstream from this lake, and since the writer has not had the opportunity to inspect closely these tamarisk thickets there is no desire on his part to minimize the value of this vegetation in preserving the capacity of McMillan Reservoir. The question is raised, however, as to what the condition of this reservoir would be in 1945 if the dense vegetation had not been present for the 30 years since 1915. This is an example of a small reservoir built on a large drainage area. Its capacity-watershed ratio has not at any time been more than 4 acre-ft per sq mile. Assuming an annual sediment inflow upstream from the vegetative screen of 600 tons per sq mile, approximately 183,000,000 tons of sediment (or, at 70 lb per cu ft, 120,000 acre-ft) had been deposited above lake level, in the lake, or had passed the dam in the 18-yr period from 1915 to 1932, inclusive. The capacity of the reservoir was depleted by only 5,000 acre-ft during this period. Why did not the portion of the remaining 115,000 acre-ft which passed by the vegetative screen become deposited permanently in the lake? Probably because the cross-sectional area of the remaining reservoir was so small that the velocities of sediment-laden inflows were not reduced any more by the lake than they had been by the vegetative screen. It has occurred to the writer that possibly if there were no vegetation above McMillan Reservoir its capacity would have now been additionally depleted only by an amount sufficient to insure that there would be sufficient velocity during high-water flows to carry all sizes of sediment past the dam. Floods on this river are often large enough to fill the remaining capacity of the reservoir in from one to two days, so it appears that, except for the storage of low flows, McMillan Reservoir virtually has become, so to speak, a run-of-the-river project, and possibly has been so for many years. It may be noted, as shown in Table 11,[64] that not during its life history has this lake had its capacity depleted by more than about 60%, even in its early years when the sediment problem appeared so severe. It would be interesting to know whether there are available profiles of the original and recent stream bed through this reservoir and upstream from it; and whether the volume of above-pool sediment deposits (which by now must be large) has ever been measured by valley cross sections or other methods.

[62] "The Control of Reservoir Silting," by Carl B. Brown, *Miscellaneous Publication No. 521*, U. S. D. A., p. 26.

[63] Discussion by R. F. Walter of "Silting of the Lake at Austin, Texas," by T. U. Taylor, *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1719.

McMillan Reservoir has had its life history complicated by the construction of reservoir storage upstream, as eventually may be the case with all worthwhile reservoirs on heavily-laden sediment streams. Either as the result of acts of nature or man, it appears that the rate of sedimentation of reservoirs may not be a linear function, and that at some indeterminate time during their lives such a change in rate of sedimentation will act to their advantage. In the case of Elephant Butte Reservoir and Lake Mead this may occur too late to be useful in preserving any significant capacity for much additional time. However, at Lake Mead any storage thus accrued will be that much in addition

TABLE 11.—RELATION OF SEDIMENT DEPOSITS IN MCMILLAN RESERVOIR TO POTENTIAL ORIGINAL STORAGE CAPACITY AT VARIOUS ELEVATIONS

Date	Spillway crest stage (ft, on reservoir gage)	Capacity to spillway crest level, as if no sedimentation had occurred (acre-ft)	Sediment deposits below spillway crest level (acre-ft)	Ratio of sediment deposits to capacity (%)
1894	17.3	32,500	0	0
1904	17.3	32,500	16,000	49
1910	23.5	66,000	27,000	41
1915	27.0	90,000	48,500	54
1925	27.0	90,000	52,000	58
1932	27.0	90,000	53,500	60

[64] From the discussion by R. F. Walter of "Silting of the Lake at Austin, Texas," by T. U. Taylor, *Transactions*, Am. Soc. C. E., Vol. 93 (1929), Table 8, p. 1722.

to the 2.5 million acre-ft of residual storage which the author has shown will remain available as regulating storage. The study of sedimentation of reservoirs has gained such momentum, in the ten years since 1935 (and the problem certainly deserves such study), that it may now be time for investigators to evaluate the possibility that they are swinging with the pendulum toward the tendency for predictions of too pessimistic a nature. For instance, suppose the curve of Fig. 3 were extended with only slightly decreasing rates from the last two points on the curve for Elephant Butte. How much longer a life this reservoir could then be expected to have!

It is gratifying to note that the author has treated the reservoir for sediment storage as a necessary part of river-basin development rather than as a nuisance that should be built only if storage for other purposes fails because of difficulties with sediment. There comes to mind a remark by an engineer concerning a project to the effect that "They provided enough space to store the water, but forgot about a place to store the silt." At that time the writer was not particularly concerned with sediment problems, but the cogency of this statement has been realized since then.

This paper effectively calls attention to the existence of problem areas in large river basins. Similar areas have been found in the Arkansas River basin in Oklahoma as the result of investigations by the U. S. Engineer Department. Of the total water and suspended sediment flow in the Arkansas River as it crosses the Oklahoma-Arkansas state boundary line, the Canadian River furnishes approximately 68% of the sediment but only 22% of the water; and the Cimarron River furnishes approximately 11% of the sediment but only 5% of the water. These streams drain the arid and semi-arid area consisting of northeastern New Mexico, the Texas and Oklahoma panhandles, southwestern Kansas, and northwestern Oklahoma, with only a small portion of their eastern watersheds being in subhumid territory. After entering the main stem of the Arkansas River the sediment-laden water from these rivers becomes diluted by the less turbid water of eastern tributaries, reducing the

TABLE 12.—RELATION BETWEEN SEDIMENT-CARRYING CHARACTERISTICS OF TRIBUTARIES AND MAIN STREAMS

Relative flow rates	Headwater streams[a]	Main streams[b]
(a) NUMBER OF DAYS PER YEAR REQUIRED FOR THE TRANSPORTATION OF EACH ONE THIRD OF THE TOTAL ANNUAL SUSPENDED SEDIMENT LOAD		
Highest flows	1	6
Intermediate flows	3	12
Lowest flows	361	347
(b) APPROXIMATE RANGE OF STREAM STAGE DURING WHICH EACH ONE THIRD OF THE TOTAL ANNUAL SUSPENDED SEDIMENT LOAD IS TRANSPORTED		
Highest flows	Above bankfull	Above bankfull to half bankfull
Intermediate flows	Above bankfull to half bankfull	Half bankfull to quarter bankfull
Lowest flows	Half bankfull and below	Quarter bankfull and below

[a] Before the entrance of tributaries. [b] After the entrance of tributaries.

sediment concentration but not the total load. In the course of the study of duration of heavy sediment flows a relationship between tributaries and main streams was found, which is generalized in Table 12.

The significance of this table is that in the larger streams the transportation of significant amounts of sediment is a more continuous process than in the small streams. In conducting investigations of the possibility of venting, by density currents or otherwise, some portion of the inflowing sediment through flood-control and multi-purpose dams, it is necessary to watch closely the relationship between capacity of outlet works, size of permanent and temporary pools, and the incoming rate of flow even at times when such inflow is well below bankfull capacity of the stream.

It seems wise that the author did not extend the estimated lives of Elephant Butte Reservoir and Lake Mead on the basis of land management. When put in terms of average areal soil loss, the 198,000 acre-ft of annual deposit in Lake Mead amounts to an equivalent thin layer of less than one fortieth of an inch over the entire drainage area. Every particle of soil saved at the headwaters should be gratefully appreciated by operators of downstream projects, but the latter should plan, for reasons of safety, as if conservation measures would not decrease the sediment problem. The major premise for this belief is the difference in design criteria between small agricultural structures and major river projects. Because of economic considerations, terraces, small stock ponds, and other water-spreading devices seem seldom to be expected to care for storms of greater intensity than 25-yr frequency without failure. The damage done at the time of failure may cause the loss of much soil which had been saved during previous years. It is to be noted that, when a terrace near the top of a watershed breaks, each succeeding lower terrace usually breaks. The concentration of water at the points of breaking tends to create a gully. The larger reservoirs downstream, designed to withstand much more severe conditions, must be prepared to accommodate sediment inflows caused by these intense upstream conditions.

Any reservoir that has a life of from three to twenty generations of mankind should be considered as a national asset if it provides efficiently the benefits for which it was designed during its life. Surely there are few citizens who would say that the nation would now be better off if Boulder Dam had not been built, just because it might be full of sediment 135 years from now! Is there a possibility of extending the length of usefulness of reservoirs by turning sediment deposits from liabilities into assets? This appears to be a challenge to research engineers of the future. Soil that has been washed from Oklahoma farm land should be more valuable if left in Oklahoma than if deposited in the Louisiana delta, which already has all the rich soil it needs. After extensive sediment deposits have occurred in reservoirs, is there a possibility of controlling floods on them by upstream diversion or storage and then raising crops on this fertile land? Many of the valuable bottom-land farms of this nation are the result of sedimentation caused by flooding, and on them crops are grown of such utility that the danger of flooding is worth risking. L. C. Gottschalk[65] has shown that river silt acted as an effective fertilizer when mixed with loamy sand from a cultivated field in significantly increasing the yield of a crop of millet. This experiment was made under greenhouse conditions where there were no worries about drainage, volunteer vegetation, selective deposition of various qualities of soil in layers, and other problems which would be met in trying to cultivate the delta areas of a lake. Would these deltas be good sites for fertilizer plants? Could a water-tolerant crop, such as rice, be grown successfully? Possibly the answers to such questions as these will be available by the time the students of the future have the opportunity to assess the validity of present-day prophecies as to the future of reservoirs.

---

[65] "Results of an Experiment on the Improvement of Sandy Soil with River Silt," by L. C. Gottschalk, *Special Report No. 3*, Sedimentation Sect., SCS, U. S. D. A., Washington, D. C., November, 1942.

WALTER B. LANGBEIN,[66] ASSOC. M. AM. SOC. C. E.—In projecting the short-term measurements of sediment transportation in order to estimate the life of major reservoirs, consideration of the "arroyo problem" in the Southwest is relevant. The question the writer wishes to introduce is: How representative of long-term conditions are the sediment loads now being measured in the major streams? The ultimate source of the sediment would seem to be the minor washes and their laterals which in the Southwest are only wet-weather courses. Muddy floods accompany and follow rain, but throughout the remainder of the year the stream beds are dry. Regarding their present condition, Kirk Bryan states:[67]

> "These ephemeral streams flow in valleys floored with alluvium from twenty to one hundred feet thick. The alluvium has been accumulated by the building up of the grade of the streams which, before the year 1880, ran in discontinuous shallow channels and during floods spread widely over the valley floors. After 1880 and continuing to the present, stream after stream has cut a deep channel, or arroyo, twenty to fifty feet deep into its valley floor or flood-plain. The mud excavated from these channels or arroyos is carried into the main rivers, and as the arroyos are widened by each successive flood, more mud is carried down. Because of the main streams, the Colorado, the Gila, and the Rio Grande, great reservoirs have been built, the increased load of mud will, within a few generations of men, fill the reservoirs and render them valueless for storage. This is the great 'arroyo problem.' How and at whose expense are these reservoirs to be protected?"

The significant and reasonably well authenticated fact is that these spectacular arroyos did not exist before 1870 or 1880. Many "old-timers" still remember the grassy bottom lands where fall hay cutting was a common practice and indistinct tree-lined channels meandered through valleys where today there is a vertical-walled gulley trenching the valley headward mile after mile. It is not uncommon at present to find well-defined roads leading to the walls of an arroyo and appearing on the opposite bank, showing that not many years have passed since white men forded the stream with teams and wagons or even motor vehicles. The Rio Puerco, now a dirty tributary of the Rio Grande, was once such a stream. Rio Viejo, as the Rio Puerco is fondly recalled by the natives, is well marked in many places by lines of dead cottonwoods. The entrenched Rio Puerco reaches headward for a distance of about 140 miles.

---

[66] Hydr. Engr., U. S. Geological Survey, Washington, D. C.

[67] "Erosion in the Valleys of the Southwest," by Kirk Bryan, *New Mexico Quarterly*, November, 1940, p. 228.

The present situation is plain, and there is sufficient evidence to discern the situation in Civil War days, but what induced the change?

A prominent theory advances the idea of a changing climate, suggesting that alternations from a more humid to a more arid climate in the Southwest have produced successive periods of sedimentation and erosion. Years of heavy precipitation, because of the increased growth of vegetation, are said to be times of minimum erosion by running water and consequently times of minimum silt transfer to the lower reaches of a stream. Existing conditions thereby are explained largely to have resulted from a change to a more arid climate. A widely accepted hypothesis, and certainly the most publicized, attributes the cause to man's abusive land practices—mainly overgrazing and the building of roads and trails. It is significant that both of these hypotheses attribute these abnormal gullies to the destruction of the vegetative cover, but differ as to the major cause of that destruction. Regional uplift causing rejuvenation of slopes is still another hypothesis that is offered to explain the change, although there is little to support and much to discredit such a theory.

It is a striking fact that the beginning of the arroyo cycle and the migration of cattle and sheep to the Southwest share a common date, and this circumstance has tended to encourage argument, one school arguing that the coincidence proves the guilt of man. Still another school argues that the cow is rather humble as a geologic agent and that, at worst, overgrazing was merely the trigger pull that timed the cutting rather than its cause. The engineer might well undertake as far as possible to retain a judicial view and establish any conclusions on documented evidence.

Physiographers point out that gullies are everywhere part of the landscape of arid regions and existed in the Southwest before 1870–1880. The gullies were more commonly discontinuous, as might be formed by local storms in eroding a small reach; the spreading of the water reduced the carrying capacity and the load was deposited no great distance beyond. Successive intensive storms served to carry sediments progressively downstream, but the movement was not continuous. There are indications that the present situation is quite different. Something has happened. The short discontinuous gullies in many basins have been integrated into a single gully system of spectacular dimensions.

Although fundamental, the matter has not been solved, mainly, the writer believes, because facts in the quantitative sense are few in number; and, indeed, the feeling is commonly expressed that conclusive evidence may never be established. A satisfactory working theory as to the cause would be valuable in framing a preventive and remedial policy and, more importantly, in avoiding measures that operate in opposition to natural adjustments.

Overgrazing can be indicted on its own account. The western range is a source of the major part of the nation's meat supply, but the use of the range must be adjusted to the growth of the forage if the yield is to be sustained. Thus the policy of government as expressed in the Taylor Act has been to discourage overgrazing through proper management of livestock in the public domain. The attitude here is not unlike that of a conservative landlord desirous of maintaining his equity.

Evaluation—through range surveys and mapping—of the grazing capacity of the several parts of the federal range, construction of stock tanks, drilling of wells, development of springs, and construction of fences to facilitate proper areal distribution of the grazing load in proportion to the capacity are all parts of modern range management. They can be justified in terms of meat production. The extent to which such management contributes to retardation of erosion cannot be estimated. Direct measures, such as the construction of check dams and similar structures intended to arrest the deepening or headward progression of gullies, have been widely attempted, with indifferent results in some places and an aggravation of the condition in other places. The situation has existed chiefly, it is believed, because (1) the introduction of such structures tends to upset the new balance that was being attained; and (2) the structures were built of local materials erosive by nature. Arresting the erosion of headwater gullies is attractive for its local benefits. In many places, notably Rio Puerco, streams have lowered their beds below the level of irrigable lands and subdrained the valley ground water. Any reduction of sedimentation in downstream reservoirs and elimination of other downstream damage effected are added, although highly significant, benefits. Nevertheless, no assured methods of arresting the erosion of deep gullies on widespread grazing lands of low unit value have yet been devised.

What bulk do the newly entrenched channels represent? No general surveys have been made to answer this question. Mr. Bryan and George M. Post in 1927[68] reported convincing evidence that the Rio Puerco had trenched its valley for a distance of approximately 140 miles since about 1885. They estimated that about one third of the heavy annual sediment loads delivered to the Elephant Butte Reservoir are being derived from the extension and widening of this arroyo system. In addition, the trench now serves as a great flume to carry sediment directly to the main valley. From channel cross sections they estimated that between 1885 and 1927 about 395,000 acre-ft of sediment, or an average of 9,400 acre-ft per yr, was produced by the trenching of the Rio Puerco and its tributaries.

In an effort to gain further factual information on the valley trenches, the Geological Survey, in 1934–1936, mapped three gullies near Shiprock, N. Mex., in detail. Repeat surveys in 1944 revealed only minor enlargements, the greater part of the gullies in that region showing signs of quiescence rather than aggression. Lack of activity may suggest nothing more than that few, if any, cloudbursts visited the area during the elapsed ten years. Other surveys have since been made in several areas where repeat surveys are also planned.

Most of the gullies are approaching the heads of their respective valleys (if they have not already reached there), and before long must derive all their sediment loads from side cutting. When this stage is reached there is prospect that a decrease in annual sediment load can be expected, the simple explanation being that, as the arroyos widen, there is less tendency for the flood water to impinge on the banks and hence less opportunity for the stream to load up. The lower parts of many gullies already have reached the state where there is little side cutting and the banks are showing evidence of a reduced rate of cutting. Possibly the peak annual sediment load of these streams has already passed. Unless man intervenes, the end point can be reached only when the valley sediments are removed to the level of the entrenched stream.

[68] "Erosion and Control of Silt on the Rio Puerco, New Mexico," by Kirk Bryan and George M. Post, Rept. to the Chf. Engr., Middle Rio Grande Conservancy Dist., October, 1927 (unpublished).

What of the future? Should Mr. Stevens' extrapolation be straight lines, or convex upward or convex downward?

Field evidence, substantiated by artifacts, points to several periods of erosion and sedimentation. Mr. Bryan[69] places the period between 1100 A.D. and 1400 A.D. as another period of erosion, and the period between 1400 and 1870 as one of sedimentation. Evidently erosion, like rainfall, runoff, and other hydrologic factors, follows seemingly cyclic sequences. Field evidence cited suggests a slowing rate of removal of sediment in gullied valleys. However, there are many valleys as yet untrenched or where gullies are shallow and discontinuous. Aggression in these places may initiate a new and deeper erosion cycle, so the situation is not altogether clear.

However, to the extent that man has contributed to the cause or growth of valley trenching, the situation may in time be adjusted. The wider acceptance of controlled grazing should lead hopefully to some amelioration. To the extent that nature through climate is the cause, man's influence is problematical or impotent and forecasts are difficult. The writer believes that, to the extent that experience since the building of major reservoirs may have coincided with an aggressive phase of the erosion cycle, the long-term outlook may be more optimistic than other evidence suggests. Nevertheless, without quantitative knowledge of the effect of modifying factors one hardly can find serious fault with Mr. Stevens' straight-line extrapolation.

C. S. HOWARD,[70] AFFILIATE AM. SOC. C. E.—As reported by Mr. Stevens in Part II of this paper, a large proportion of the sediment carried into Lake Mead comes from the sedimentary plateau that contributes a relatively small proportion of the water (64% of the sediment and about 20% of the water). Other computations based on the data given in Table 6 indicate that the sediment loads at the Bluff, Cisco, and Green River stations amount to about 54% of the load measured at the Grand Canyon gaging station; but the runoff for the three upper stations amounts to about 92% of the runoff at Grand Canyon. It is apparent that high concentrations and large quantities of sediment are brought into the Colorado River from unmeasured sources. The Little Colorado, San Rafael, Fremont, and Escalante rivers are the principal tributaries above Grand Canyon for which, unfortunately, sediment records are not available. It is desirable that records for those streams, and also for the Virgin and Muddy rivers, should be obtained.

Mr. Stevens has made estimates of the rate of sediment deposition in the various proposed reservoirs, using different weights per unit volume for the different reservoirs. It is doubtful if the available information is adequate for the accurate selection of such weights, but studies on the rate of sedimentation in Lake Mead should provide valuable information on the density of reservoir deposits. Such studies should include the determination of the volumes of deposits that have been formed in various parts of the reservoir and determinations of the sizes of the particles in those deposits. Correlation of the data on particle size of the deposited material and of the material carried in suspension will make it possible to predict future rates of sedimentation and, to some extent, the places of deposition.

[69] "Erosion in the Valleys of the Southwest," by Kirk Bryan, *New Mexico Quarterly*, November, 1940, p. 229.

[70] Dist. Chemist, Geological Survey, U. S. Dept. of the Interior, Albuquerque, N. Mex.

In his concluding paragraph Mr. Stevens states: "The available data are pitifully meager, and must be greatly enlarged before any constructive program for relief can be developed." The data are meager and inadequate, not only as to quantity but also as to quality; but in the past few years steps have been taken to obtain more adequate data on sediment concentrations and loads. The reports[71] to which Mr. Stevens refers describe studies that have been made through a cooperative agreement between the Office of Indian Affairs, Bureau of Reclamation, Tennessee Valley Authority, Corps of Engineers, Geological Survey, Department of Agriculture, and Iowa Institute of Hydraulic Research. Through the efforts of this group, studies were made of the existing methods of sampling and analysis of the samples. Thereafter, improved types of samplers were developed for the collection of depth-integrated and time-integrated samples. With these improved samplers it is possible to obtain accurate information on the average sediment concentration; also the sediment concentration at different points in the cross section. In addition, a study of methods of analysis[72] of particle size led to the development of a bottom-withdrawal tube method that gives promise of being a useful procedure for determining the particle size of suspended and deposited sediment.

[72] "A Study of New Methods for Size Analysis of Suspended Sediment Samples," Report No. 7 of "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," Iowa Inst. of Hydr. Research, Iowa City, Iowa, 1940–1943.

Data to supplement Table 4, for three years following 1941, are presented in Table 13. The totals and averages given are the results of combining both tables.

Storage of water in a reservoir, as in Lake Mead, affects the chemical character of the water available for use below the reservoir. Studies of the quality of water above, below, and in Lake Mead show that the water released from the lake is more uniform in concentration than is the water flowing into the reservoir; the maximum concentration of the outflow from Lake Mead since storage began has been about one half the maximum concentration of the inflow. The average concentration of the outflow, however, has been somewhat higher than the average concentration of the inflow. Studies of the chemical character of the water in the inflow, outflow, and the lake have shown an increase in the concentration of certain constituents and a decrease in the concentration of other constituents. The increased concentrations are undoubtedly caused by the solution of the soluble constituents of deposits along the lake and the decreased concentrations represent chemical precipitation of certain constituents. The records indicate that, for the period from February 1, 1935, to September 30, 1944, 15,933,000 tons of solids were dissolved and 7,237,000 tons of solids were precipitated during storage in Lake Mead. It seems likely that the rate of solution will decrease as the soluble salts become less easily available, but the rate of chemical precipitation will remain constant and after a period of time there will be a small net decrease in the capacity of the lake because of these chemical processes. The volume of deposits formed by chemical precipitation will be a small percentage of the volume of deposits of suspended sediment from the inflow and it will be many years before the deposits from chemical precipitation will form an appreciable part of the deposits in the reservoir. There is, of course, stratification throughout the lake and the concentrations of dissolved solids in different parts of the lake vary from about 600 ppm to more than 900 ppm. Through regulation of releases of varying quantities of water from the upper and lower levels, it has been possible to maintain the average concentration of dissolved solids in the lake water at a nearly constant value.

Charles Kirby Fox,[73] M. Am. Soc. C. E.—The countless silt-filled reservoirs extending from the Mediterranean area across southern Asia bear testimony that silt has been the bane of irrigationists since before the dawn of history; hence Mr. Stevens is to be congratulated for starting the discussion of this important subject.

The estimates of the silt carried by the Colorado River are many and varied, beginning at about 50,000 acre-ft of silt annually; but the later estimates have shown a decided tendency to "climb." Also, the weights of silt vary from 100 lb per cu ft (specific gravity 1.59; 2,178 tons per acre-ft) to 65 lb per cu ft (specific gravity 1.05; 1,415.7 tons per acre-ft) which would make a large difference in the estimated volume of silt carried (see Table 14).

It is to be admitted, as Mr. Stevens states, that the lower basin of the Colorado is largely composed of soft easily eroded rocks, has many narrow steep canyons, high wind velocities, and is sadly overgrazed; but there is little apparent difference between the watersheds of the San Juan, Little Colorado, and Virgin rivers and the intervening plateau region or, for that matter, the Rio Grande, whose waters carry the highest percentage of silt and which, incidentally, is the only river whose silt load has been measured in a reservoir, except the great Grand Canyon, which some engineers call the world's greatest "silt mill."

[a] Dry silt, in pounds per cubic foot.

A series of four diagrams relating to water and silt runoff are presented in Fig. 13. Supporting descriptive data are given in Table 15. In each case the lines in Fig. 13 represent the range of the records quoted. The yearly points are very scattered and in some cases, such as the Little Colorado and Virgin rivers, so few points are available as to make it doubtful if the curves represent the conditions correctly. It will be noticed that the curves relating to the silt runoff in the Colorado River at Grand Canyon and the Rio Grande at San Marcial show a decided tendency to flatten during the periods of higher runoff. This is believed to be correct. In general, the water runoff during the silt-measured years is less than the water runoff during the other measured years.

The values in Table 4, Col. 6, are given as the difference between Col. 4 (Grand Canyon, drainage area 137,800 sq miles) and Col. 3 (Lees Ferry, drainage area 107,900 sq miles) indicating that the additional silt comes from the Little Colorado River. The difference in area is 29,900 sq miles. Mr. Stevens gives the drainage area of the Little Colorado River as 24,400 sq miles, whereas the Water Resources Branch of the U. S. Geological Survey gives it at 22,100 sq miles, a difference of 5,800 or 7,800 sq miles. Other data in the paper indicate that Mr. Stevens uses only the Little Colorado area in computing the silt, which varies from 7% to 14%, this range being outside the limits of the diagram in Fig. 13. It is immaterial which area is used as both stations are in the upper reaches of the Grand Canyon, with its steep grades, high water velocities in tremendous flood volumes, and steep canyon side slopes. It is very probable that the added silt is only that part which has been churned into suspension and that, for all practical purposes, the real bed silt is unmeasured.

[a] Runoff in acre-feet per square mile. [b] Ratio of silt runoff; total acre-feet to acre-feet per
[c] Percentage of silt to

It is doubtful if a reasonable estimate of the silt volume can be made from annual runoff data without reference to the ground, slope, and cover conditions and, above all, to the flood periods. It is not believed that bed silt can be measured except in reservoirs.

The late A. H. Koebig once expressed the opinion to the writer that the average silt content of the Colorado River waters was between 8% and 12% (by volume) and sometimes his measurements ran as high as 19% for hours and 41% for short periods. In view of the wide variations of the silt estimates and the practical impossibility of actually measuring the bed silt in a retarding basin, before the construction of the reservoir, the writer made a study of old maps, records of early explorers, logs of wells, subsidences, earthquakes, and other data which might throw light on the volume of the silt deposits and the length of time required for them to accumulate.

About 1936 some 128 maps of the head of the Gulf of California, dating from 1541, were obtained, traced, and carefully analyzed. Most of the maps were drawn to a small scale, but they were as good as other maps of a like period. The latitudes corresponding to Asia Minor (23°) and Spain (36°) were approximately correct but the intervening latitudes were often overstated by a degree or more on the old maps of all explorers.

Twenty-one maps follow the Friars' interpretation of the Indians' grunt they heard on the Iturbi expedition[74] in 1615 and show California as an island at the same time that Iturbi, Capt. Geronio Maquez, Franco Vasco, and others correctly reported that it extended to the vicinity of the present Indio. MacDougall[75] gives a map, by Sykes, of the northern part of the Salton Basin, clearly showing the old tilted shore line with elevations. Data relating to the southern area have been compiled from many sources; the shore line from the Castillo map of 1541 (Castillo spent thirty days surveying that area under instructions to show what he saw) clearly shows the mouths of the Gila River, Salton Basin, and the Laguna Salada.

square mile. [c] Ratio of water runoff to silt runoff. [d] Silt runoff in acre-feet per square mile.
water in the runoff.

Four of these maps and a mass of other data distinctly show the Gulf of California as extending to the vicinity of Indio, Calif. Logs of some twenty-five Colorado Delta Wells were located and plotted to obtain an idea of the depths of the deposits. Roughly they show, from the top downward: 125 ft of silt and 40 ft of gravel; 75 ft of silt and 30 ft of gravel; 40 ft of silt and 30 ft of gravel; and 180 ft of silt and 50 ft of gravel—an average of 105 ft of silt and 37.5 ft of gravel. It is certain that every time a great gravel stratum occurs its formation was preceded by a subsidence. The increased grade of the river enabled it to transport the heavier gravels, after which the silt was moved.

Since the Salton Basin was full of water when the Spaniards arrived it is quite probable that the previous subsidence occurred about one century before, or five centuries ago. Mexican and Peruvian correspondents have

[75] "Salton Basin," by MacDougall, *Publication No. 193*, Carnegie Inst. of Tech., Pittsburgh, Pa.

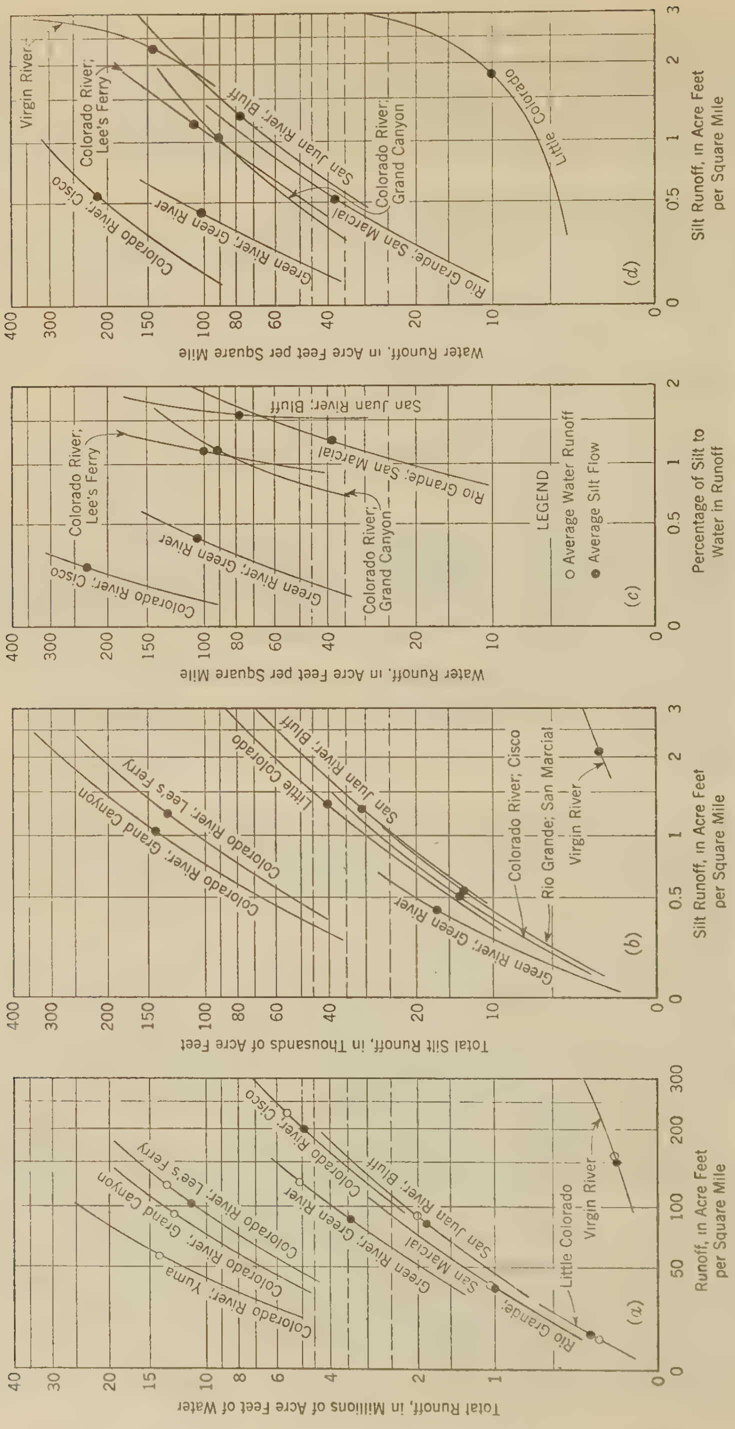

FIG. 13.—WATER AND SILT RUNOFF; COLORADO RIVER AND RIO GRANDE BASINS (SEE ALSO TABLE 14).

supplied the writer with Indian accounts of a very destructive earthquake occurring about this time. Also, in 1635, two earthquakes were recorded as being felt from Canada to Ecuador. It is quite probable that about this time the Salton Basin had lost enough water or weight to cause a readjustment which produced the tilted shore line.

As a check on the effects of the great changing weights some 5,000 to 6,000 earthquakes listed in the major catalogues were located and platted on a large map of the world. Then the centers of the great weight changing areas, with circles of radii—250, 500, 750, 1,000, and 1,250 miles—were platted. These circular arcs contained 21% of the world's land area, of which presumably one third is badly faulted and contained 93% of the plotted earthquakes. The changing volumes of some of the great lakes and the California debris (mining), with the earthquakes, were plotted with the same results.

From the aforementioned data, from a knowledge of approximate dates, from the depths of the silt and gravel deposits, and from an approximation of the areas, it is possible to approximate the average annual silt load of the Colorado River waters at something like a million acre-feet. Of course some silt has been carried to the Gulf and was not measured in the foregoing estimates. The estimate of 1,000,000 acre-ft may be a very rough approximation but is likely to prove more accurate than one which disregards or estimates the bed silt load which many geologists say amounts to from 100% to 400% of the suspended silt load, based on the measurements of many stream debris cones.

The Grand Canyon of the Colorado is about 250 miles long, narrow (the widest part being 12 miles), and deep (the deepest part being 1 mile), with a volume approximating 700 cu miles. The grade from Lees Ferry to the Bright Angel Trail, about 90 miles, averages 15.3 ft to the mile and the remainder of the canyon, 6.5 ft to the mile. These grades would cause very high velocities during floods, and the carrying power of water is supposed to vary with something like the sixth power of its velocity. Many geologists believe the canyon generally follows a series of faults. The Colorado River at Yuma usually digs 2 ft for each foot of rise in water levels.

The Elephant Butte Reservoir began to store water in 1915 and several silt surveys have been made of the reservoir site since then. Similar data should be available for Lake Mead. The actual data most probably will show that the bed silt load has been greatly underestimated due to the effects of the silt accumulated in the Grand Canyon.

Reservoirs on any of the branches or the main river above Lees Ferry will tend to regulate the flow and, if large enough, will eliminate the great floods in the Grand Canyon which are undoubtedly the greatest source of silt, thus greatly prolonging the useful life of Lake Mead.

H. V. Peterson,[76] Assoc. M. Am. Soc. C. E.—In furnishing an estimate of the probable useful life of these two reservoirs, the author has forcefully called attention to the insecure future of numerous western irrigation projects caused by the continuous reduction of reservoir storage capacity through silt deposition. Although the public in general and engineers in particular may claim just pride in the accomplishment of creating such magnificent structures as the two dams in question plus many others, an even greater task remains if the maximum possible benefits from such construction are to be attained.

---

[76] Geologist, U. S. Geological Survey, Los Angeles, Calif.

Doubtless there will be disagreement with the author's estimates. An optimist might enumerate factors that would tend to show greater reservoir lives than the estimates given and, just as consistently, one of opposite attitude might find reasons for believing them to be less. That the reservoirs will be filled at some future period is patent to all and, whether the author's estimates are correct to within a year, a decade, or even a century, it is obvious that the usefulness of these great structures is being seriously imparied at an alarmingly rapid rate. What will perhaps startle many readers is the author's statement concerning the rather insignificant effect that man's efforts in land management can produce in prolonging the life of the reservoirs. It is with this phase of the subject that this discussion will deal.

During the past few years much thought has been given to the problem of erosion, and many discussions on the subject have appeared in both the popular and technical press. Doubtless, there is some reason for pride in the accomplishment during this period; but that only a beginner's step has been taken in solving the problem, particularly as it applies to the arid western region, is evident from the author's statement (see heading, "Prolonging the Life of Lake Mead"): "It is doubtful if * * * sediment being carried annually into Lake Mead could be reduced as much as 10% by all the proved practicable methods of land management known today even though lavishly financed." Since silt movement in the Colorado River is typical of much of the arid West, it is implied that similar management plans applied to other streams in regions would have as little effect. The statement casts a dark shadow over the future of western development and irrigation, and certainly leaves uncertain the value of the heritage bequeathed to coming generations; but, in the writer's opinion (much as he dislikes admitting it), there is little evidence at present to disprove or even temper the author's conclusion.

Is this an indictment on engineers and conservators for their failure to develop a practicable scheme for controlling erosion, at least such portions of it as are amenable to man-made controls, or does it mean (as the author implies elsewhere) that, in endeavoring to establish such controls, natural laws will be encountered because the forces of natural erosion so outweigh those attributable to man's activity that the best that man can do in the way of land management can have but minor effect on silt movement? An answer to the question is important. A possible extension of only 10% in the life of the reservoirs furnishes little incentive for investigation or for setting up any program looking toward future reduction of silt movement by the streams.

An examination of the alluvial fill found in the tributary valleys of the Colorado River and the Rio Grande (and, in fact, practically any of the valleys of the arid West) reveals that the basins have passed through alternate cycles of alluviation and degradation at various periods in their past history. Cycles of alluviation result where the products of weathering—including silt, sand, gravels, etc.—are delivered to the valley floor at rates faster than the transporting agencies—including wind and streams, but mainly streams—can remove them, and conversely degradation cycles occur where opposite conditions prevail. Evidence indicates that, although weathering under desert conditions is relatively slow, it is nevertheless constant; and therefore it may be assumed that the cycles resulted from changes affecting the transporting agencies.

The effectiveness of streams would be enhanced by increasing the stream gradient or by increasing the total volumn of flow, either through higher precipitation over the drainage basin or through decreasing infiltration (which increases the percentage of immediate runoff). Because streams are by far the most important transporting agency, any such conditions would be favorable for starting a degradation or erosion cycle.

According to numerous documents, reports, histories, and testimony of many persons still living, the West has passed from a cycle of alluviation to one of degradation since about 1870; or since white man's migration to this region. The resulting change in the landscape has been startling. Available evidence shows that, prior to white man's occupancy, most western valleys presented a smooth unbroken floor in which the stream at ordinary stages followed a meandering, shallow tree-lined or brush-lined channel. Flood flows that exceeded the capacity of the channel spread slowly over the valley depositing silt and doubtless loosing an appreciable percentage of its volume to ground-water percolation. The reports that many of the present barren valleys once carried permanent streams and supported large tracts of luxurious grass that yearly was cut as hay are not inconsistant with this picture, although the contrast with present conditions makes it almost unbelievable.

Today most of these same valleys are scarred by ugly gullies that cut through almost their entire length. Ground water, which once fed the permanent streams and nurtured the grassy flats, has been drained, leaving seared strips of barren waste adjacent to either bank of the gully. Flood flows now concentrate in the channels and instead of loosing silt, as they once did, they take on additional loads from the caving banks with the result that at times the discharge might appropriately be called watery mud rather than muddy water. It is reliably reported that 111 of the 115 major tributaries of the Colorado and Green rivers above Lees Ferry are in this condition. Below Lees Ferry the Virgin River, Kanab Creek, Johnson Wash, and practically every smaller tributary valley is likewise trenched. Tributary valleys of the Rio Grande are in similar condition, the valley of the Rio Puerco being traversed by one of the best known and most spectacular of all the gullies. It is the silt derived from these valleys that is destroying the two reservoirs under discussion and unless some means can be found to prevent the continued movement of this silt any future reservoir must also be destroyed.

It is not the purpose of this discussion to take sides in the arguments concerning the cause of this recent gullying. From the observation and experience gained through a lifetime residence in the West (the past several years of which have been spent in detailed investigations having to do with land and water utilization problems in many of the arid tributary valleys of both the Colorado River and the Rio Grande), the writer has concluded that no single cause can be held responsible for the abrupt change from one cycle to another. Land misuse, principally overgrazing, climatic changes resulting in an increase or a decrease in precipitation, and tectonic movements which bring about steepening of the stream gradient have each been advanced as adequate to institute the change; but the evidence supporting any of them is too indistinct and at times too contradictory to be conclusive. It would appear that a combination of all these processes, with possibly others not yet recognized, might more consistently be considered the basis for the change; and the engineer, in his attempts to prolong the life of the reservoirs, should recognize this fact and plan his treatment accordingly. Under these conditions, what avenues can be pursued and what results can be expected from his efforts?

Controlling silt movement by correcting land misuses is especially appealing to those who subscribe in whole to the theory that abuses instituted by man are entirely responsible for the destructive erosion now taking place. Overgrazing is cited as the most flagrant of these abuses and any one who has inspected large areas in both the Rio Grande and Colorado basins, as the writer has, must admit the seriousness of this accusation. What steps will be necessary to correct the condition and how soon and to what extent tangible results can be expected are questions of vital importance in considering the merits of a corrective program of this nature.

Extremists along these lines have advocated elimination of all grazing, contending that the value to livestock of the forage produced is far less than the protective value of the vegetative growth in stabilizing and holding the soil mantle in place. Such a stand, however, overlooks the political repercussions sure to result from such a violent disruption of the society and economy centered about the livestock industry within these basins just as it ignores many other practical aspects of the problem. As an example of what such a program would involve, the case of the Navajo Indian Reservation may be cited. This reservation is considered to be one of the worst silt producing tracts within the Colorado basin. Almost its entire area is underlain by easily eroded, friable, poorly-cemented sandstones and shales. Scores of washes and arroyos, including such well-known silt carriers as Moenkopi Wash, Polacca Wash, Oraibi Wash, Chinle Creek, Navajo Creek, and Chaco River, drain these unstable areas. Each is deeply gullied and together they contribute thousands of tons of silt annually to either the Colorado, the Little Colorado, or the San Juan rivers. Some 60,000 Indians live within the Reservation, the great majority of whom are dependent on the livestock industry for their living. Overgrazing in many parts of the reservation is apparent and doubtless is contributing in considerable measure to silt movement. To cure this ill by eliminating grazing would mean moving and rehabilitating this entire group—a task approaching in cost and probably exceeding in complexity the construction of another dam on the Colorado River. Such a step is obviously impracticable under present circumstances. Even a reduction in livestock numbers sufficient to correct the most aggravated areas of overgrazing must be accompanied by some provision for maintaining the present standards of living of the Indians; otherwise severe opposition can be expected not only from the Indians but from the public at large.

The problems of other graziers within the two basins must also be appreciated if a program of range improvement is to be successful. In general, livestock operators of the West are individualists of the most independent type. Through skill, daring, hard work, and dogged perseverance they have learned to wrest a living from these forbidding desert reaches, and it is the writer's impression, gained through a rather wide acquaintance among them, that they have no intention of allowing any one to interfere with their chosen method of obtaining a livelihood. They consider their prior interest in any program having to do with river developments equivalent to or superior to the interests of the irrigator, and any plan that seeks arbitrarily to reduce or eliminate grazing within the basins is doomed to failure unless this attitude is fully appreciated and adjustments made for it.

It should not be inferred from the foregoing that stockmen have taken a narrow attitude in regard to range management. The stand taken by most independent operators and owners, and by public officials engaged in administering grazing on the public domain, well agrees with the author when he states (see heading, "Prolonging the Life of Lake Mead: Land Management"):

> "If grazing areas are managed to produce their maximum forage yield the erosion prevention feature will have been provided for automatically; that is, the prime objective in management of range land should be to furnish as much food as practicable for livestock on a sustained yield basis."

These men are fully conscious of the over-all aspects of range utilization. They appreciate that an overgrazed scar is a potential source of debris, capable of destroying reservoirs as well as destroying forage; but they are not of the type who will "go overboard" to cure that scar by retiring from the livestock business. They will cooperate, and they are cooperating, to bring about better range conditions so far as practicable; but they refuse to be concerned over erosion cycles, or to assume responsibility in inaugurating them.

Criteria are lacking for judging the results that may be expected under best range management as it relates to silt movement. Optimists are inclined to point out certain ungrazed areas and experimental plots showing a minimum of erosion as good examples of what will obtain under perfect range management. However, range experience indicates that a long period of careful husbandry will be required before any appreciable reduction in silt movement from a wide area directly ascribable to this cause can be noted.

During the past few years the writer has had the opportunity to inspect a number of fenced plots in which grazing has been excluded for periods ranging up to 10 years. These areas indicate that, while improvement in vegetative cover may be noticeable within a relatively short period, the actual establishment of a growth sufficient to form a protective stabilizing soil cover will be a slow tedious process requiring years, perhaps decades, for its fulfilment. Actually vegetative growth within these desert areas is so dependent on available moisture that other factors are of distinct minor significance. For example, if a person unacquainted with desert vegetation had examined some of the major grazing areas in both the Colorado and Rio Grande basins during the extremely wet winter season of 1940-1941, he would have scoffed at the mention of overgrazing or of inadequate cover protection; but had he returned a few months later the grim effects of drought would have been fully apparent in the sparsity of grass and forage and in the large percentage of the land exposed to the erosive action of wind and rain. Any one familiar with the desert is fully aware that drought is a greater enemy of plant growth than overgrazing. Perhaps by careful husbandry a cover capable of withstanding these periodic and prolonged dry spells can be established over a substantial part of both river basins, but the proof of this remains to the future. To date the prospects look discouraging.

Even assuming that through careful husbandry and management the range will eventually be maintained in the best possible condition consistent with judicious grazing use, the question as to what effect this will have on silt reaching the main rivers still remains unanswered. Unfortunately, no data are available on which to base even an estimate of the effect. So far as the writer knows there is at present no demonstration or experimental plot of any appreciable size within a typical desert portion of either basin where an effort is being made to study and gather data on this phase of the erosion problem. A few preliminary and fragmentary records have been obtained from one or two experiment plots established for this purpose but unfortunately the stations were discontinued before any conclusive evidence could be gathered. Without such information the conservator and the engineer must work under a tremendous handicap.

In theory a combination of structural treatment and range management would appear to offer the most effective means for preventing erosion and silt movement on the valley floors. Structures of the proper type could be used temporarily to store the silt and form it into a suitable seed bed. Thereafter the plant cover would hold it in place and by proper manipulation this cover would continue to trap additional silt until the entire gully system was refilled and healed. Experience, however, does not confirm this theory; at least it has not in a number of rather elaborately treated eroded areas located on the floors of tributary valleys of both the Colorado River and Rio Grande, which have been examined by the writer during the past few years. Except where there has been a continuous effort to maintain, correct, and improve these structural installations, and the exceptions are few, the result obtained in the way of soil stabilization and increased vegetative growth has been highly disappointing. In some instances actual damage and increased erosion have resulted from the structural treatment. Poor construction, poor design, and in some cases poor planning must share the responsibility for the failure of such treatment, along with lack of maintenance and an improper appreciation of the forces involved in the erosion processes.

A successful program for controlling silt, holding it in the valleys and out of the reservoirs, will be found, but it obviously must be based on bolder, more imaginative lines than have heretofore been thought of. Myriads of problems in engineering, geology, botany, agriculture, and the arts of land and livestock management are involved, and available information with which to solve them is woefully meager. Information is needed on the type and design of structures that can be depended on for consistent performance under rigorous desert conditions. More should be known of what can be expected from a coordinated program of structural treatment and strict range management. Methods of range control and rehabilitation need to be studied and perfected. Regions and rock formations producing excessive amounts of silt need to be segregated and analyzed as prospects for special treatment. It has been suggested that erosional experiment stations should be established where treatment programs could be developed and tested on a small scale. The similarity of the erosion problem in so many of these valleys makes this proposal both consistent and desirable. In short, what is needed, as the author stresses, is more information on the entire erosion problem. With investment on the rivers, installed and in prospect, running into hundreds of millions of dollars, it would seem consistent to spend a small part of the development cost in measures aimed at protecting the investment by prolonging its life.

L. C. CRAWFORD,[77] M. AM. SOC. C. E., AND P. C. BENEDICT,[78] ASSOC. M. AM. SOC. C. E.—This comprehensive analysis of available sedimentation data in the Colorado River basin is timely because of the increasing recognition of the need for such studies and data throughout the United States. The general considerations and conclusions have attracted considerable interest, and the indicated paucity of data is of widespread concern not only in the Colorado River basin but elsewhere. In view of the measurements of suspended sediment loads and related field work done in Iowa, with improved sampling equipment, some information concerning this program may be of interest or value in connection with the discussion of this noteworthy paper.

Mr. Stevens refers to certain reports that have been prepared and published as a part of a project involving "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams."[79] This project was inaugurated in 1939 under the sponsorship of an Interdepartmental Committee composed of representatives of the Tennessee Valley Authority, Corps of Engineers, Department of Agriculture, Geological Survey, Bureau of Reclamation, and Office of Indian Affairs in cooperation with the Iowa Institute of Hydraulic Research. Experimental models of depth-integrating and point-integrating sediment samplers, designated US D-43 and P-43 sediment samplers, respectively, were completed in 1943. Subsequently, both of the experimental models and several duplicates of the D-43 sampler have been subjected to tests under practical field conditions, alongside of, and in comparison with, other sediment samplers in current use, to determine the practicability of the new samplers, and to evaluate their sampling accuracy with respect to other samplers.[80] The comparative test data submitted in reports by thirteen field offices of various agencies have been analyzed, and a progress report[81] reproduced by the St. Paul Office of the U. S. Engineer Department. The development of a satisfactory bed-load sampler has not, as yet, been undertaken by the Committee.

The results of the interdepartmental investigation, for which the Corps of Engineers and the Geological Survey have been providing the active leadership in recent years, lead to the conviction that the needed extension and improvement of sediment data indicated by Mr. Stevens can be materially aided by the adoption of standard equipment, and methods of measurement somewhat comparable to the commonly accepted procedures[82] of stream gaging.

[79] "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," *Reports Nos. 1 to 5, 7, 9*, Iowa Inst. of Hydr. Research, Iowa City, Iowa, 1940–1943.

[80] "Preliminary Field Tests of the US Sediment-Sampling Equipment in the Colorado River Basin," by P. C. Benedict, mimeographed rept., U. S. Geological Survey, Iowa City, Iowa, April, 1944.

[81] "Comparative Field Tests on Suspended-Sediment Samplers," by M. E. Nelson and P. C. Benedict, mimeographed rept., U. S. Engr. Sub-Office, Hydr. Laboratory, Iowa City, Iowa, December, 1944.

[82] "Stream-Gaging Procedure," *Water-Supply Paper No. 888*, U. S. Geological Survey, Government Printing Office, Washington, D. C., 1943.

Therefore, and as a part of the program to standardize sampling equipment among the interested agencies participating in the joint investigation at the Hydraulics Laboratory in Iowa City, the D-43 sampler was selected for use in connection with the determination of daily suspended sediment loads in cooperation with the Iowa Geological Survey and the Rock Island Office of the U. S. Engineer Department at four stations on the Iowa, Cedar, and Des Moines rivers in Iowa. This field work afforded an opportunity to obtain further information on the field operation of the samplers. A summary of the preliminary reports of sediment discharge (in tons) for the water year 1943–1944 (ending September 30, 1944), at the Cedar Rapids, Iowa, and the Iowa City, Iowa, gaging stations, with drainage areas of 6,640 and 3,230 sq miles, respectively, is as follows:

Month	Cedar River at Cedar Rapids (tons)	Iowa River at Iowa City (tons)
1943—		
October	3,010	3,270
November	2,000	3,670
December	1,760	1,320
1944—		
January	2,950	39,700
February	26,900	115,400
March	104,500	282,100
April	61,100	328,500
May	262,400	1,121,300
June	441,200	561,800
July	68,000	131,700
August	17,600	26,100
September	8,410	4,790
Total	999,830	2,619,650

These quantitative records of suspended sediment loads are based on continuous and systematic field measurements made throughout the year, using the equipment and methods indicated in the reports prepared under the direction of the Interdepartmental Committee. The results show that the yearly suspended sediment load carried in the Cedar River at Cedar Rapids amounted to slightly less than 1,000,000 tons or 150 tons for each square mile of drainage area above Cedar Rapids; whereas, more than 2,600,000 tons, or 810 tons per sq mile for the year 1944, were determined at the gaging station on the Iowa River at Iowa City.

Studies made at the Hydraulics Laboratory of all available information on the density of deposited sediments (which included a review of the data for the Colorado River and the Rio Grande basins) indicate that the average weight of 1 cu ft of deposited sediment from the Iowa River may be taken as 60 lb.[83] On this basis, the suspended sediment measured at Iowa City during the year that included the flood waters of May and June, 1944, would occupy an equivalent space of about 2,000 acre-ft.

---

[83] "Density of Sediments Deposited in Reservoirs," by E. W. Lane and Victor A. Koelzer, *Report No. 9* of "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," U. S. Engr. Sub-Office, Hydr. Laboratory, Iowa City, Iowa, 1943, p. 38.

It is interesting to note that, although the characteristics of the Iowa River basin are widely different from those found for rivers in the southwestern United States, an average suspended sediment discharge of 810 tons per sq mile per year was measured during a flood year in comparison with the average sediment inflow (suspended and bed load) of 1,600 and 1,350 tons per sq mile per year obtained by Mr. Stevens in his analysis of the average total load entering Elephant Butte Reservoir and Lake Mead, respectively.

During the floods that occurred in Iowa in 1944 and 1945, sediment samples were also collected with the 50-lb D-43 sampler at three to six stations in the water cross section at a number of regular gaging stations. The samples were taken, in general, at or near the crest after the completion of a current-meter discharge measurement. It is recognized, of course, that data thus provided do not adequately define the flood or sediment transportation potentialities of these or other streams in similar drainage basins. However, this type of field investigation does provide a convenient and inexpensive means of reconnaissance in connection with the location of desirable sediment sampling stations. For example, a sediment discharge rate of 2,030 tons per day per sq mile has been measured for a drainage area of 130 sq miles. The maximum average concentration of sediment by weight in a cross section was 23,600 ppm (2.4%) for a drainage area of 2,800 sq miles.

Such quantitative facts together with the daily suspended loads at regular stations, if obtained over a period of years, will be increasingly helpful with reference to the author's comment concerning the pitifully meager status of available sedimentation data for the proper consideration of a variety of problems relating to agriculture, conservation, land-use practices, and to the future of reservoirs. Furthermore, standardization of equipment and methods will assist in consolidating engineering effort (the Hydraulics Division of the Society has a joint committee on sedimentation in reservoirs) on all phases of sedimentation data, the need for which has been effectively demonstrated by Mr. Stevens.

CHARLES P. BERKEY,[84] HON. M. AM. SOC. C. E.—Although the principles involved in the paper by Mr. Stevens are well known, it is not certain that the implications are fully appreciated by many even in responsible relation to them. The factual data had been long known to the writer, but no statement before this one had brought so forcibly to mind their importance and bearing on long-range planning. This does not apply only to Elephant Butte or Boulder, but to the entire enormous undertaking of recovering lands by irrigation. The United States has virtually set up an empire on impounded and redistributed water. The nation is encouraging development, on a scale never before attempted, of lands that are almost worthless except for the waters that can be delivered to them by the works of man. There is building up, through settlement and new population, a line of industries foreign to the normal resources of the region and they appear to be doomed to a limited life.

The situation reminds one of the "finds" of archeologists indicating that civilizations have flourished while climatic conditions were favorable and have disappeared when the skies withheld rain. The factual accounts of R. Pumpelly [85] and E. Huntington [86, 87] in western Asia abundantly prove that even civilized peoples of some ingenuity could not withstand persistent drought. Eventually, of course, a cure was found and heralded as a new kind of salvation. Men had learned to impound such waters as there were and to carry them to their parched lands. On one occasion the writer found evidence of settlements along the streams which, in an earlier epoch, had been completely obliterated by steadily increasing aridity. Even fishing and hunting, which must have been the chief occupations of these people, had dwindled to the vanishing point while the winds drove drifting sands over their dwelling places until the last man gave up. Still later, in another age and in another valley nearer to the mountains, where mountain streams still carried waters far out into the adjacent desert, they learned to irrigate a little land; but the people of that valley also had to give up when their ditches ran dry. One could trace the faint lines of the distribution system to their garden plots where not a soul remained in this day to till them. In yet another valley its people built a dam to impound the dwindling water supply; but even that failed to save them and the surrounding structures built of granite lie around in ruins. The people who built them are gone.

---

[84] Newberry Prof. Emeritus of Geology, Columbia Univ., New York, N. Y.

These instances, to be sure, are not quite parallel to the present effort to reclaim lands; but in capturing silt-laden rivers engineers are facing an equally devastating natural danger. So much silt is impounded with the water that it literally crowds out its assumed long-time promise. This danger is much more imminent than climatic change.

Effort to use water on desert lands is not a new adventure by any means; but a program involving development of a great region—inviting thereby a large new population under conditions that carry elements of certain future destructive encroachment in limited and computable time—that is new. Not only is it new, but in some of the implications it is fairly astonishing. As a public policy probably nothing like it has ever been faced—certainly not on such a scale. The nearest thing in that respect was the settlement of the western high plains in earlier days by people who believed that these dust-bowl lands could be farmed in the same manner as those they came from in the Central Mississippi Valley, and no voice was raised to warn them. That was to be a vast and prosperous empire, too.

For the first time, after reading this paper, the long-range significance of the suffocating effect produced by accumulating silt in all these reservoirs was borne down on the writer. He had been so much taken with the fine things being done that he had not fully appreciated the fact that the program carries elements of destruction sure to bring some kind of ending. It was always evident, of course, that there were severe limitations, but it was too easy to overlook or belittle this element of damage from within.

The experience of founding, in difficult surroundings, settlements which finally grew into influence and power is not new; and neither is their decline, and even their ending. In the past, however, none of them carried along, with the agents that built them up, such relentless elements of destruction as in the present reclamation of arid lands. The astonishing thing is that the life of these relief works promises to be so short. One could forget it if the time vista were indefinite, or if there were promise of a thousand years. In that time most human subsistence and economic lines take new turns and become adjusted; but in some of these projects, typical of the average more or less, the beginnings of decline loom already and will certainly grow into a serious problem in three or four generations: One wonders how many settlers gathering around these projects appreciate what it means.

Of course, if one is able to divorce his interest from the future, there is nothing to worry about. In this generation, and the next and the next, an upgrade can be maintained. One can claim (and it is true) that much has been added to the world; but the longer range view in this field, as in many others, is threatened by apparently incurable ailments and this one of slowly choking to death with silt is the most stubborn of all. There are no permanent cures. All are familiar with the simple elements of the matter; but the writer had faced all of that evidence without feeling greatly disturbed. The thing that did most to create a real shock was the figure on Bridge Canyon. The only time that site was visited, after mushing through thirty miles of silt-laden soupy river to get there, such close attention had to be given to the dam site itself that the silting of the proposed new reservoir was almost forgotten; but the paper by Mr. Stevens brings it out, and is a fair and timely reminder, that this is a problem of the first magnitude. Although there are ways of postponing the end stages of these developments, there is no permanent cure, for the final contest transcends engineering skill. It has all the elements of a last stand.

Stafford C. Happ,[88] Esq.—The approximate sediment loads of the Rio Grande and Colorado rivers are fairly well known from existing records; and there is no apparent reason to doubt the order of magnitude of Mr. Stevens' computations of past and probable near-future sedimentation rates. Projection of these rates so far into the future, however, seems questionable unless greater allowance is made for the normal effect of delta growth in reducing the rates of capacity loss. There is also need for clarification of the values given for rates of sediment delivery from major Rio Grande tributaries above Elephant Butte Reservoir.

Delta growth is one of the most important factors in reservoir sedimentation. The history of Lake McMillan is perhaps the best known example. Growth of salt cedar has often been cited as the cause of the remarkable decrease in the sedimentation rate in Lake McMillan, but this was secondary to the effect of delta development. The salt cedar has been very effective as a sediment screen on the top-set delta beds, because there the capacity of the Pecos River channel has been reduced by sedimentation and most of the flood waters are forced overbank through the salt cedar thickets. The rate of capacity loss would have been reduced by the delta development alone, although there is no doubt the salt cedar has been an added influence of considerable importance. Elephant Butte Reservoir had a much larger capacity relative to drainage area and inflow, so that its delta has been deposited more largely within the original reservoir basin, and the rate of capacity loss has been retarded less rapidly; but it is only a matter of time until the Elephant Butte delta will reach such size that its further growth will be largely outside the reservoir proper. Salt cedar was growing abundantly on the Elephant Butte delta in 1936 and 1941, although less conspicuously than at Lake McMillan because interspersed with larger proportions of willows and cottonwoods, and there undoubtedly will be sufficient vegetation to stabilize most of the Elephant Butte delta deposits.

---

[88] Geologist, U. S. Engr. Office, Kansas City, Mo.

Surveys in 1941 showed that the effect of delta growth had extended approximately 15 miles upstream from the head of Elephant Butte Reservoir, to the lower end of the Middle Rio Grande Conservancy levees. From 1936 to 1941, the average annual deposition in this 15 miles of valley was about 12.5 million tons. Less complete, but apparently representative, survey data indicate that the 1936–1941 rate of sedimentation in the lower half of this area was about 2½ times as great as that from 1914 to 1936. The rate of increase in sedimentation was probably even greater in the upper half of the area, but data are not adequate for quantitative comparisons. The average rates of sedimentation in the reservoir, according to Mr. Stevens' paper, were about 27 million tons annually from 1914 to 1935, and about 13.5 million tons annually from 1935 to 1940. Suspended loads in the Rio Grande at San Marcial, approximately at the head of the reservoir, were about 11 million tons annually for both the 1935–1940 and 1936–1941 periods; so it is reasonable to compare the 1914–1935 and 1935–1940 rates of reservoir sedimentation with the 1914–1936 and 1936–1941 rates of sedimentation immediately above the reservoir. Such comparisons show that sedimentation in the area of delta influence, upstream from the reservoir, was about 48% of the combined total from 1936 to 1941, but only about 15% from 1914 to 1935.

The rate of sedimentation in the delta area was greatly increased by several channel avulsions between 1936 and 1941, but such phenomena are normal alluvial processes and are especially common on large deltas. They will not be equally effective every year in the future, but, in general, they will occur with increasing frequency and their effect will extend progressively farther upstream. Some of the sediment already deposited above the reservoir certainly will be moved downstream by floods from time to time; but, in general, the proportion of Rio Grande sediment deposited above the reservoir will certainly increase as more of the delta is built above reservoir pool elevation. Mr. Stevens suggests that increased runoff may counterbalance the tendency toward greater deposition above the reservoir, but there is no certainty either of increased runoff or of greater sediment production if the runoff does increase. Most of the Rio Grande water is derived from winter precipitation in the mountains of northern New Mexico and southern Colorado, which contribute relatively little sediment. The summer flash floods on intermittent tributaries in central New Mexico contribute most of the sediment, concentrations as high as 68% by weight having been reached in suspended load samples from the Rio Puerco in 1941; but these summer floods contribute very little of the total annual runoff. Under these conditions an increase in total runoff obviously might not involve any increase in sediment production, and might even be accompanied by a decrease in the total sediment load.

In contrast to such uncertain factors as future changes in runoff, and their effect on sediment transportation, the only question concerning delta growth is the magnitude of its effect. The data now available afford a reasonable basis for estimating this effect. If the 1914–1935 and the 1935–1940 rates of reservoir capacity loss are plotted as decreasing functions of the combined sedimentation in the reservoir and the 15 miles of valley affected by delta growth, and if a smooth curve is drawn through points representing the average values for these two periods, projection of this curve indicates that the "most useful life" of the reservoir as defined by Mr. Stevens, or the time until it will be half filled with sediment, will be about 90 years from the present, or nearly twice as long as that predicted by the straight-line projection. Further projection of the curve would indicate even greater increase in the total life of the reservoir, but projection so far into the future is of doubtful validity. The major importance of the factor of delta growth is fully emphasized by the indicated increase in the "most useful life."

Table 3 appears to show close agreement between suspended load records and the writer's estimates, based on surveys and mineralogical studies of the sediment contributions from five major Rio Grande tributaries above Elephant Butte Reservoir. The close agreement between these figures is fortuitous, however, and possibly misleading. The estimates of contribution to Rio Grande valley deposits should be nearly doubled if allowance is made for sediment carried into Elephant Butte Reservoir. The mineralogical data are not directly applicable to the sources of reservoir deposits, but reasonable extrapolations from available data suggest that the average rate of sediment contribution from these tributaries should be about 2,500 tons per sq mile per year, instead of 1,500 which includes only that part deposited above Elephant Butte Reservoir.

The average contribution computed from suspended load measurements also is probably too low. Apparently this is based on Soil Conservation Service sampling from 1937 to 1941, which was too infrequent and too irregular to provide more than rough comparisons between different streams. The summer flash floods, which obviously carry most of the sediment, were not sampled sufficiently to provide a reliable measure of the total annual load, except possibly for the Rio Puerco during 1941. An average of 1,700 tons per sq mile would indicate that these major sediment contributing areas produced only about four times as much sediment, per unit area, as all the remainder of the Rio Grande drainage area above Elephant Butte, most of which obviously produces negligible quantities of sediment. Such a relation appears unreasonable, in the light of all other evidence; but the suspended load records are not adequate to determine whether or not the rate should be as high as 2,500 tons per sq mile, as indicated by the surveys and mineralogical studies.

It does not necessarily follow that the contribution from direct tributaries to Elephant Butte Reservoir and Lake Mead should be estimated as high as 2,500 tons per sq mile, or that the average specific weight of 65 lb per cu ft for Elephant Butte deposits, as derived by Mr. Stevens, should be raised accordingly. The nature of the terrain suggests, on the contrary, that 1,600 tons per sq mile may be more reasonable for these areas than the true figure, whatever it may be, for the five major Rio Grande tributaries above Elephant Butte. However, there is a serious sediment problem in the Rio Grande valley above Elephant Butte Reservoir, and remedial measures are urgently needed there. It is important that the major sources of Rio Grande sediment be correctly evaluated, within reasonable limits, in order that remedial measures may be wisely concentrated where they will be most effective. Mr. Stevens has recognized that the rates based on surveys and mineralogical studies, as listed in Table 3, do not represent total sediment output, but he has not indicated the magnitude of variance. It should be understood that those rates are probably only about half the actual average rates of sediment contribution to the Rio Grande from the Rio Puerco, Rio Salado, Jemez Creek, and Galisteo Creek.

Data are not yet available for quantitative estimate of the effect of delta growth on the rate of capacity loss in Lake Mead; but there is no apparent reason why the same principles will not apply there as in Elephant Butte Reservoir, although the magnitude of effect may be less.

BERARD J. WITZIG,[89] ASSOC. M. AM. SOC. C. E.—Although the forecast for the future appears pessimistic, the paper presents a logical determination of the theoretical useful lives of two large reservoirs essential to the economic well-being of the Southwest. The lately emphasized concern of the engineering profession over the apparently inevitable decadence of the nation's river control resources is not new, but the mounting accumulation of records indicates that irreplaceable reservoir storage will be destroyed by sedimentation within a few generations.

Merely from a theoretical basis, the writer questions whether it is proper to assume a linear rate of loss of reservoir storage. If such factors as the method of reservoir operation, cyclic variations of rainfall and runoff, and changing erosion conditions are neglected, it seems reasonable to expect that the annual sedimentation rate would decrease with storage and with the effectiveness of the reservoir as a sediment trap. Available data for Elephant Butte Reservoir, plotted in Fig. 3, indicate that the rate of loss to 1940 was not linear. A more optimistic estimate of the life of the reservoir would be obtained if these data were extended by some exponential function, although the aforementioned omitted factors render such an extension highly academic. Linear extension undoubtedly results in the most conservative estimate of the probable useful life of the reservoir.

---

[89] Engr. (Civ.), U. S. Engr. Office, Buffalo, N. Y.

The average specific weight of the sediment deposited in Elephant Butte Reservoir, estimated by Mr. Stevens at 65 lb per cu ft, is probably as correct a value as can be determined from available data. However, the validity of applying this value to Lake Mead is questionable in view of other data,[90] which indicate that Colorado River silts vary in specific weight from 37 lb per cu ft to more than 100 lb per cu ft.

Also, an estimate of the specific weight of sediment, based only on observations, probably errs on the low side, and the value thus computed is applicable only to the period of record and to the more or less immediate future. Additional sediment, to be deposited in the future, will impose a consolidating load on earlier deposits; and it is probable that the ultimate average specific weight of the deposits in their entirety will exceed the average for a shorter period during the earlier life of the reservoir. The older deposits will undoubtedly weigh more per unit volume than the newer deposits. Fluctuations of reservoir levels will also cause greater shrinkage in the sediments near the head and in the higher elevations of the basin than in those deposits which are continuously submerged.

Expectation of an increase in the specific weight is supported by the fact that, in 1913, the late W. W. Follett,[4] M. Am. Soc. C. E., used 53 lb per cu ft for silt in the Rio Grande; in 1935, the Soil Conservation Service[91] used 60 lb per cu ft; and Mr. Stevens adopts 65 lb per cu ft. The writer believes that within a few years the average specific weight of sediment in Elephant Butte Reservoir may exceed 70 lb per cu ft and may eventually approach 85 to 90 lb per cu ft. If data are available for the purpose, it would be of interest to learn the estimated ultimate specific weight based on the method proposed in 1943[25] by E. W. Lane, M. Am. Soc. C. E., and Victor A. Koelzer, Jun. Am. Soc. C. E.

The specific weight adopted for estimating future sedimentation rates may greatly influence the predicted useful life of a reservoir. Thus, if the average specific weight approximates 75 lb per cu ft at the end of the useful life, the reservoirs under discussion may actually have useful lives 15% longer than those estimated by the author.

However, differences of opinion on specific weights of sediments or on the estimated lives of the reservoirs do not reach the crux of the problem. The best and most economical reservoir sites have already been, or soon will be, utilized, and "a reservoir begins to die the day it is born."

Mr. Stevens suggests several measures to prolong the useful lives of Elephant Butte Reservoir and of Lake Mead. The writer agrees that land management is probably not a panacea for erosion ills, at least within economic limits, since it would probably be impracticable to reduce erosion rates below the natural norm prior to the influence of man-made conditions. Even if improvement in land management practices could decrease sedimentation rates by 50%, instead of by the 10% estimated by the author, the all-too-short estimated life of a reservoir would merely be doubled.

[90] "The Silt Problem," by J. C. Stevens, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 222.

[91] "Silting of Reservoirs," by Henry M. Eakin, revised by Carl B. Brown, *Technical Bulletin No. 524*, U. S. D. A., Washington, D. C., 1939, p. 99.

The possible use of density currents to void suspended silt before deposition through properly designed and located outlets in the dam has not yet been practicably demonstrated, and is generally not applicable to existing dams and reservoirs. Outlets in future dams, where silting is expected to be serious, should be provided to explore this possibility. Further field and laboratory research on density currents in reservoirs appears to be a professional imperative.

The writer does not consider the suggested provision of upstream silt storage as more than a temporary expedient. Such a measure would merely postpone the inevitable reckoning, and would only transfer the destruction of reservoir storage to other locations. The one recommendation for this expedient would be that it might decrease erosion rates and silt loads by decreasing the effective stream gradients. The plan for developing the upstream storage suggested by the author for the Colorado River would extend the useful life of Lake Mead from an estimated 80 years to about 233 years. Probably something like this will be done, but it should be recognized that the problem is thus merely being postponed and not solved.

Hugh Stevens Bell,[92] Esq.—This generation and the next almost certainly will develop every desirable large reservoir site west of the Mississippi River. In effect, this generation is in the midst of reaping a priceless harvest. The crop is not like grain or timber which can be grown again, but like gold or petroleum; and, as Carl Sauer of the University of California, at Berkeley, has stated, when the supply of a particular mineral is exhausted, the harvest of all geologic time has been reaped.[93] Among American engineers, Mr. Stevens is apparently the most thoroughly aware of the fact that this philosophy applies also to reservoir sites and that it places definite obligations upon the generations that harvest them.

Under the heading, "Space Occupied by Deposits," Mr. Stevens writes,

> "For the Lake Mead deposits no better estimate of the specific weight can be made than to use the composite value of $\gamma = 65$ lb found for Elephant Butte Reservoir."

By using this value to calculate the life of Elephant Butte, the author apparently makes the assumption that these sediments will not increase in density with time. By using it to estimate the life of Lake Mead he implies, at least, that it is the future value; and, judging by the assumptions made for Elephant Butte, the present value also.

How much space will be occupied by a given tonnage of sediment is, perhaps, the most perplexing question that must be faced in estimating the life of any reservoir. Consequently, it is unfortunate that no extensive sediment surveys, like those for Elephant Butte Reservoir, have been made at Lake Mead However, the Bureau of Reclamation and the U. S. Geological Survey have collected many pertinent data and there are certain others now available which, although they are not adequate for determining definitely the specific weight of sediment deposits at Lake Mead, furnish a basis for comparing these deposits with those at Elephant Butte. After studying these data the writer has come to the conclusions that: (1) At present, sediment deposits have a considerably lower specific weight at Lake Mead than at Elephant Butte, and (2) the appropriate value of γ for use in estimating the probable life of Lake Mead may be less than 65 lb, the value used by the author. A somewhat detailed analysis of the volume-weight problem and a discussion of sedimentation at Lake Mead during the ten years ending in 1945 are presented in the following paragraphs, accompanied by data and the writer's interpretation of them.

---

[92] Soil Conservationist, Cooperative Hydraulics Laboratory, California Inst. of Technology, Pasadena, Calif.

[93] "The Relation of Man to Nature in the Southwest: A Conference," *The Huntington Library Quarterly*, Vol. VIII, No. 2, February, 1945, p. 123.

The Volume-Weight Problem.—There are several reasons why the present sediment deposits in Lake Mead should have a lower mean specific weight than do those at Elephant Butte. The manner in which a reservoir is operated, the conditions under which sediments are laid down, the size of the particles, the age and thickness of the deposits, and other variables, such as the degree of flocculation, influence the rate of compaction and, consequently, the unit weight the deposits will have attained at any particular time. Where obvious differences in these factors are found, they almost invariably indicate conditions favoring greater specific weight at Elephant Butte.

Reservoir Operation.—The extent to which a reservoir is drawn down during normal operation is an important factor in determining the specific weight of deposits. Regarding Elephant Butte, the late Henry M. Eakin wrote,

> "During low-water stages in the average year most of the reservoir basin above the Narrows is uncovered. Sediment deposits dropped here during floods are exposed to air and hardened."[94]

Approximately 40% of the basin lies above the Narrows, so it is probable that at least half of the reservoir bottom is exposed sometime during the average year. Frequently the reservoir is filled to less than 50% of capacity; occasionally it is filled to less than 25%.

The situation at Lake Mead is very different. Since June, 1938, there has never been a time when less than 73% of the capacity to spillway-crest elevation was occupied, or when less than 80% of the basin was submerged. As will be shown in discussing the conditions of sedimentation, this is of greater importance than the ratio of the exposed areas indicates.

Clay and colloidal particles, especially if they are flocculated, form deposits having very low specific weights. When sediments of this kind are brought to the dam by density currents, as they are at both reservoirs, they sometimes are discharged at Elephant Butte but they always are stored at Lake Mead. If the 6.4 million tons of fine material that passed through the outlet works during the period of record at Elephant Butte had been stored, they would have occupied enough space, at 35 lb per cu ft, to have reduced the specific weight calculated by the author from 65.3 lb to 64 lb—a change of 2%.

---

[94] "Silting of Reservoirs," by Henry M. Eakin, revised by Carl B. Brown, *Technical Bulletin No. 524*, U. S. D. A., Washington, D. C., 1939, p. 94.

Conditions of Sedimentation.—The Rio Grande, upon entering the reservoir, often spreads out over broad areas covered with willow, tamarisk (salt cedar), and cottonwood. This encourages the deposition of even the finest particles at levels normally exposed to the atmosphere. Mr. Eakin states that the upper part of the basin is covered with above-crest deposits and that the surface sediment is characteristically very fine textured, containing a high percentage of true clay and colloidal matter.[94] Although drying makes little or no difference in the specific weight of deposits of sand, it makes important changes in that of the finer sediments. From data available to them, E. W. Lane, M. Am. Soc. C. E., and Victor A. Koelzer, Jun. Am. Soc. C. E., have estimated that fine sediment, deposited under conditions where it has ample opportunity to dry out, will reach the same specific weight in a short time that it would under less favorable conditions in a 1,000-yr period.[95] At Elephant Butte, fine deposits in the upper basin have ample opportunity to be compacted by drying and, although they may be wet at a later date, and may expand somewhat, they will not reach their former bulk. Furthermore, there is little likelihood that they will be reworked and redeposited at some later date in areas where they will remain permanently submerged and, consequently, have a comparatively low specific weight at any given time.

At Lake Mead, however, the situation now, and for many years to come, is entirely different. The upper 40 miles or so of the basin lie in Lower Granite Gorge down which (see Fig. 14) the Colorado River advanced its delta approximately 39 miles during the first 10 years of storage. Despite this great length, the mean width is somewhat less than 1,000 ft—a feature that encourages the rapid reworking of deltaic deposits and the washing out of a high percentage of the fine particles which are subsequently deposited in areas that are permanently submerged.

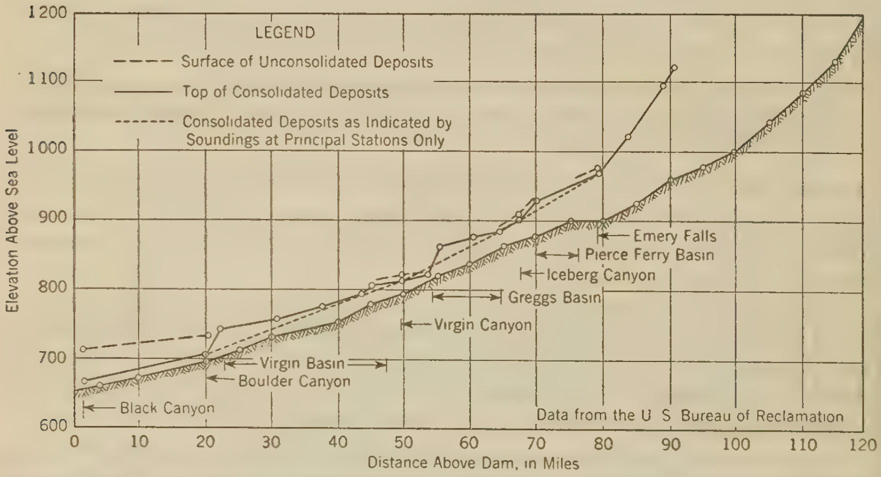

FIG. 14.—DEPTH OF SEDIMENT DEPOSITS AND LOCATION OF DELTA FRONT AT LAKE MEAD, 1938–1945

---

[95] "Density of Sediments Deposited in Reservoirs," by E. W. Lane and Victor A. Koelzer, *Report No. 9* of "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams," U. S. Engr. Sub-Office, Iowa Inst. of Hydr. Research, Iowa City, Iowa, 1943, p. 51.

In 1941 Thomas C. Mead of the Bureau of Reclamation sent the writer a sediment sample taken 2 ft above water level from the bank of a channel the river had cut through delta deposits about 100 miles above Boulder Dam. An analysis, made after the sediment had been dispersed with sodium oxalate, showed 60% sand ($> 50\ \mu$), 39% silt ($< 50 > 5\ \mu$), and 1% clay and colloidal material ($< 5\ \mu$). Upon drying out, a sediment of this composition experiences an 8% to 10% increase in specific weight, but delta deposits at Lake Mead tend to remain moist because, although the delta is perhaps 40 miles long, its area is only from 6 sq miles to 8 sq miles, including the channel of the river.

At Lake Mead, then, any increase in the specific weight of sediment deposits resulting from exposure to the atmosphere may be considered to be almost negligible for many years to come, whereas at Elephant Butte drying has been and, apparently always will be, an important factor.

Particle Size.—Analyses of more than 600 samples from each stream, taken under comparable circumstances, indicate a strong similarity in the sediment-size composition. The Rio Grande samples contained 22% sand, 37% silt, and 41% clay; and samples from the Colorado River, 28% sand, 69.2% silt, and 2.8% clay. Because the former were deflocculated before analysis and the latter were not, the data for silt and clay content are not comparable, but there are good reasons for assuming that actual differences are small. However, the samples are weighted neither for sediment concentration nor for stream discharge and, consequently, do not give a true picture of the actual composition of the total sediment load. Unpublished computations by Carl B. Brown, Assoc. M. Am. Soc. C. E., show that proper weighting of the Colorado River samples indicates the actual composition was 49.4% sand, 13.3% coarse silt, and 37.3% fine silt, clay, and colloids. This corresponds very closely with unpublished estimates by the U. S. Geological Survey which show that the suspended load passing the Grand Canyon gaging station in 1935 was composed of 45% sand, 15.2% coarse silt, and 39.8% finer material.

Mean Age of Deposits.—In 1945 the mean age of deposits in Elephant Butte Reservoir was about three times that of those in Lake Mead. Apparently time makes little or no difference in the specific weight of deposits of sand and coarser sediments, but becomes increasingly important as the size of the particles diminishes. On the basis of time alone, then, the deposits in Lake Mead should now be less dense than those at Elephant Butte; but, since the life of each reservoir, under present conditions, is estimated to be approximately a century and a half, the eventual difference from this cause is negligible.

The Thickness of Deposits.—Lake Mead is more than two and one-half times as deep as Elephant Butte Reservoir and, consequently, the possible increase in density due to the weight of the overlying sediments should be greater. It has been assumed that the sediments entering the two reservoirs are similar, but it has been shown that the venting of clay and colloidal material transported by density currents at Elephant Butte is a factor that tends to increase the specific weight of deposits there by about 2%.

Since the fine particles are highly flocculated at both reservoirs, it might seem that no difference in specific weight can be attributed to this factor. There is some evidence, however, that flocculation materially decreases the rate of compaction of submerged deposits. If so, it would tend to decrease the mean specific weight at Lake Mead more than at Elephant Butte because practically all fine sediment is retained and remains submerged in the former, but not at the latter.

Summarizing, a comparison of the factors involved indicates that the sediments deposited at Elephant Butte Reservoir should now have a mean specific weight greater than do those at Lake Mead. Eventually this difference will be reduced to an unknown degree by the mere passage of time and, perhaps, to a greater extent by the accumulation of much thicker deposits at Lake Mead. Although a value of $\gamma = 65$ lb per cu ft is now probably too high for Lake Mead, it may be approximately correct for the year 2075 and, therefore, is an acceptable value for use in calculating the life of the reservoir.

Nature and Extent of Sediment Deposits in Lake Mead.—Data on the depth of deposited sediment and on particle size have been gathered for several years at a number of stations in Lake Mead by the Bureau of Reclamation. Fig. 14 shows the depth of sediment deposited at these stations as of February, 1945, ten years after storage began. Fig. 15 is a map of the reservoir and shows the location of the principal sampling stations: Emery Falls, Iceberg Canyon, Virgin Canyon, Boulder Canyon, and near Boulder Dam. All stations are located at narrow places. Because the velocity of density currents tends to be somewhat higher at such locations, the quantity of deposition there is less than elsewhere, as is shown by Fig. 16.

Fig. 15.—Map of Lake Mead Showing Location of Principal Sampling Stations and Position of Delta Fronts on the Colorado and Virgin Rivers in February, 1945

By using these data, the contour maps of Lake Mead prepared by the Soil

Conservation Service, the author's estimate of the incoming sediment load, and various bits of pertinent data from the U. S. Geological Survey, a rather general picture can be constructed of sedimentation during the ten years ending in 1945. It also becomes possible to make rough estimates of the probable mean specific weight as of 1945.

Volume of Delta Deposits.—In February, 1945, the delta was approximately 40 miles long and had a cross-sectional area of slightly more than 5 acres at its lower end. A conservative estimate of the volume of the delta can be computed on the basis of a wedge as wide as the river at the upper end of the delta and with a base of 2.3 acres, and two pyramids each having a basal area of 1.35 acres—all with heights of 40 miles. These have a combined volume of 432,000 acre-ft. Irregularities in Lower Granite Gorge, and deposits laid down during high reservoir stages, could account for an additional 20%. The author has stated that the opportunity for extensive deposits above lake levels is lacking when the river joins the reservoir in a narrow canyon. Perhaps it should be emphasized that, although this is true at Lake Mead now, the advance of the delta into the various basins, and particularly into Virgin Basin, will afford a future opportunity which now is lacking. Sediment storage of this kind probably deserves consideration in any attempt to predict the life of Lake Mead.

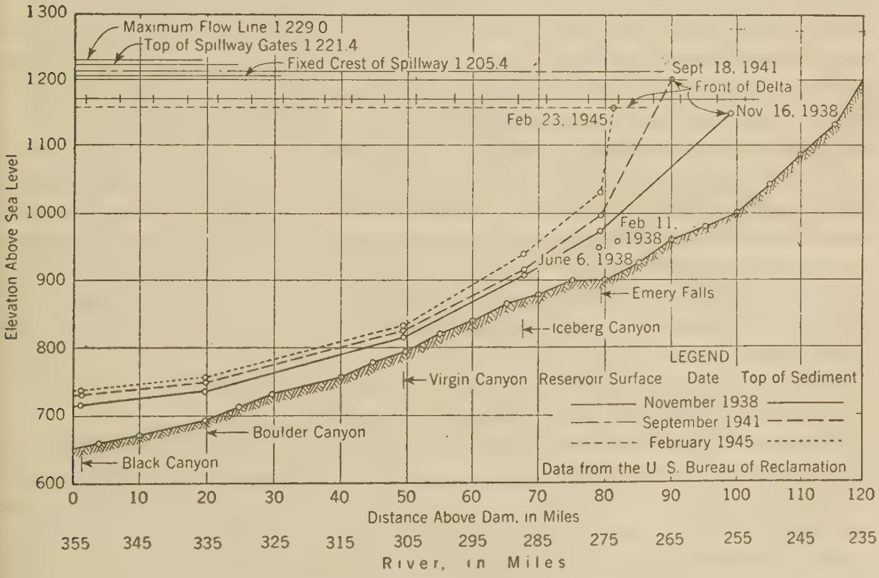

FIG. 16.—SEDIMENT DEPOSITS, LAKE MEAD, IN MAY, 1940

The writer is of the opinion that the delta contained at least 500,000 acre-ft in February, 1945. Although storage had been in progress for 10 years, the delta represented the accumulation of sediment during only 8.75 years. In February, 1945, the toe of the delta had reached a point at which the original bottom elevation was 900. On June 26, 1935, less than 5 months after storage began, the reservoir surface had reached that elevation and was at El. 905.2 as late as April 14, 1936. Never since June 11, 1936, has it been below El. 1000.

During the first 15 months of storage, therefore, sediment of the kind which subsequently formed the delta was being laid down as bottom deposits downstream from the point reached by the toe in February, 1945. On the basis of the estimated volume of the delta, this sediment should occupy approximately 70,000 acre-ft.

Mr. Stevens, in Table 8, estimates the average annual accumulation of sediment in Lake Mead for the period from February 1, 1935, to September 30, 1942, to be 252 million tons. Of this total, according to Table 7, the Virgin and Muddy rivers contribute 15.4 million tons. The contribution of other streams entering Lake Mead below the delta may be expected to increase this quantity to 25 million tons. Their deltas, and delta-like deposits laid down while Lake Mead was filling, are assumed to have a volume of 65,000 acre-ft, making a grand total of 635,000 acre-ft for such deposits during the first 10 years of storage.

Specific Weight of Delta Deposits.—From numerous specific-weight determinations, the late Samuel Fortier and Harry F. Blaney,[44] Members, Am. Soc. C. E., derived an average value of 84.5 lb per cu ft for Colorado River deposits near Yuma and Laguna Dam. Subsequently the U. S. Geological Survey made determinations (reported by Messrs. Lane and Koelzer) on 105 samples of Colorado River channel and flood-plain deposits from Lees Ferry to Yuma. These have an average specific weight of 87.5 lb per cu ft. Of the 105 samples, fifty six were taken between Grand Canyon and Parker Dam and of these forty three seem most likely to represent delta deposits under present conditions. Their average specific weight is 89.4 lb. All had been exposed to the atmosphere; but, since they contained an average of 73% sand, 24% silt, and 3% clay, and few were in locations that would have permitted thorough drying, their specific weight could have been increased only slightly by exposure. Any increase from this source might be more than offset in the delta deposits by compaction attributable to time and the weight of overlying sediment. The writer estimates the mean specific weight of delta deposits at approximately 90 lb per cu ft. At this value the estimated volume, 635,000 acre-ft, would weigh nearly 1.25 billion tons, which is slightly less than 50% of the 2.52 billion tons of sediment of all sizes which are estimated to have reached the reservoir during the first 10 years of storage.

Volume of Density-Current Deposits.—Sediment carried beyond the delta is transported by density currents and must be composed very largely of silt and clay because the velocities are too low, ordinarily, to keep sand particles in suspension. Before reaching Boulder Dam, these currents must pass through a series of basins in which they have an opportunity to spread out and greatly decrease their velocity. It would be surprising if much sand is carried beyond Pierce Ferry Basin. Apparently most of the silt is deposited in Greggs and Virgin basins (Fig. 15), because samples taken since 1942 at Boulder Canyon and Black Canyon indicate that less than 3% of the sediment in the lower 20 miles of the lake is coarser than 15 μ.

Estimating the volume of the deposits beyond the delta is made extremely difficult because the sampling stations are located in canyon sections where velocities are comparatively high and the opportunities for deposition correspondingly low. Almost no data are available for basin areas where deposits are broadest and deepest. Soundings were made in the basins during May, 1940, however, and the data have been used in Fig. 16 which illustrates nicely the difference in thickness of deposits at narrow and at wide sections. The basins actually contained much more sediment than was indicated by data from the regular stations.

The Soil Conservation Service has prepared topographic maps of the entire Lake Mead area on a scale of 1 : 12,000. By using these maps with data from the regular stations the writer calculated that, in February, 1945, deposits below the delta had a volume of 860,000 acre-ft. Because the data are from canyon sections only, the calculated volume is probably at least 50% too low; it should be increased to 1,290,000 acre-ft, of which 70,000 acre-ft are sandy bottom deposits already accounted for in discussing the delta.

Specific Weight of Density-Current Deposits.—Of the sediment that is assumed to have reached the reservoir during the first 10 years of storage, slightly more than 50%, or 1.27 billion tons, apparently has been transported by density currents. If this occupies 1,290,000 acre-ft, as estimated in the preceding paragraph, it has a specific weight equal to 47.5 lb, and the mean for all sediment in the reservoir is 62.5 lb per cu ft.

There is considerable evidence to indicate that the mean specific weight of density-current deposits is less than 47.5 lb. Of the large number of samples taken above Boulder Canyon by the Bureau of Reclamation prior to February, 1945, only two had greater concentrations, three others showed more than 45 lb, four had between 40 lb and 45 lb, and seventy three had less than 40 lb. Of the hundreds of samples taken from Boulder Canyon to the dam, only four had concentrations greater than 30 lb and the heaviest of these showed only 32.75 lb.

Fig. 17(*a*) shows generalized curves of sediment concentration with respect to time and elevation at Boulder Dam (mile 354.7) during the period from May, 1937, through December, 1943; and Fig. 17(*b*) shows similar curves for the station at Black Canyon (mile 353.5) from January, 1944, through June, 1945. Each small circle shows the elevation and date of collection of a sample that was analyzed for sediment content; the samples marked × (Fig. 17(*a*)) in the first few months represent known silty water but analyses are lacking. The sediment concentration, expressed as percentages by weight, was determined by dividing the weight of the sediment after drying by the weight of the original sample. For convenience the concentration is shown also in pounds per cubic foot.

The curves indicate an increasing specific weight at a lessening rate with time, and follow the general pattern that would be anticipated for clay compaction curves. The apparent inconsistency of the 35% curve during 1939 and 1940 probably reflects difficulties encountered in developing a sampler and a sampling technique that could be used effectively in concentrations greater than 30%. The 40% curve is wholly extrapolated, but it is reasonable to assume that such densities now exist. A specific weight of 30 lb per cu ft is approximately correct for 225,000 acre-ft of sediment deposited between Boulder Canyon and the dam prior to February, 1945.

The curve showing the top of the silty water is a succession of peaks rising sharply on the left when density currents reach the dam and subsiding during

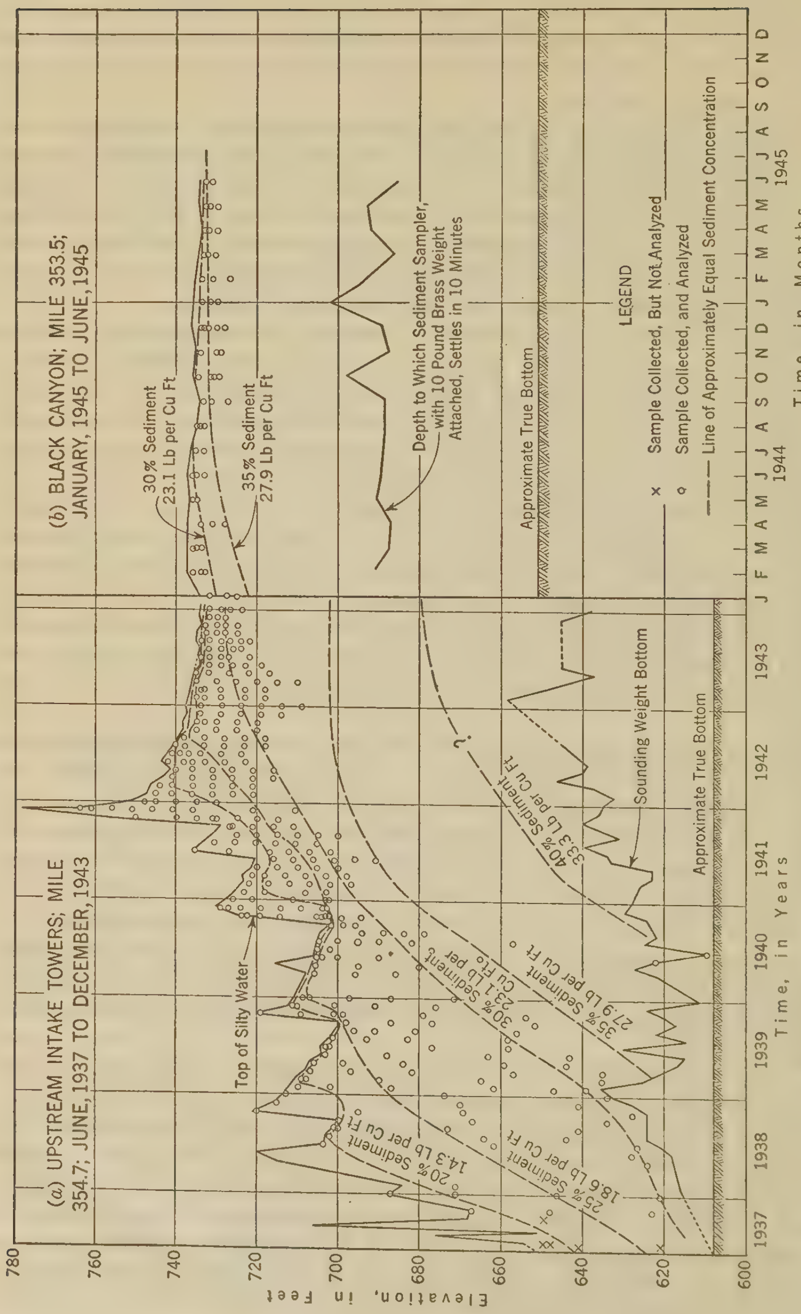

FIG. 17.—SEDIMENT CONCENTRATION IN LAKE MEAD WITH RESPECT TO TIME AND ELEVATION

months devoid of major density flows. The curve of bottom depths is erratic, probably because of differences in the types of sounding weights used and in the time allowed for settlement. Until 1944 "bottom" was the point to which a 10-lb weight would settle in 10 min. The weight usually was brass, but a lead one was used occasionally. Since 1944 the brass weight has been attached to a sampler and the pair has been allowed to settle as usual. This accounts for the greater elevation of the "bottom" as indicated in Fig. 17(*a*).

Since 1938 samples have been taken at several depths each time the Bureau of Reclamation has investigated the sediment concentration at the various stations from Boulder Canyon to the delta. Because of the inability of the sampler to penetrate to all depths, the densest sample taken on each occasion has been assumed to be most nearly representative of the mean specific weight for all sediment deposited at the station being investigated. An average value for each station has then been determined from these selected samples, and the results are shown in Table 16. The specific weight shown for the Boulder Canyon station is approximately 82% of the 30 lb which more complete data seem to indicate is probable for sediment of the same composition near the dam; and the average value increases with distance from the dam. Col. 5, Table 16, shows the average depth the sampler penetrated the deposits; and, since these values are small compared to the total depth, they justify the assumption that the samples are somewhat less dense than the mean value for the sediment at the location. Col. 4 indicates that sediment becomes coarser with distance from the dam; and Col. 5 shows that the firmness of the deposited sediment, as indicated by the depth the sampler penetrated, decreases as the particle size decreases. Deposits at Virgin Canyon apparently do not conform, possibly because that is the point of minimum deposition.

Adjusted specific weight γ for all density-current deposits (lb per cu ft)...							....	....	....	39.2

Because firmness and coarseness give a measure of the specific weight, the writer has adjusted the values recorded in Col. 6 by assuming that these represent a percentage, shown in Col. 8, of the probable mean specific weight for the various stations. These adjusted values, which are admittedly only the writer's best guess, are shown in Col. 7, Table 16. The average of these for each pair of adjacent stations is taken as representative of the mean specific weight of the sediment deposited between those stations, as indicated in Col. 9. From his previous estimate of the volume of density-current deposits, the writer distributes them as follows: From the delta to Iceberg Canyon, 20%; from Iceberg Canyon to Virgin Canyon, 16%; from Virgin Canyon to Boulder Canyon, 37%; from Boulder Canyon to the dam, 27%. This distribution yields 39.2 lb per cu ft as the mean specific weight for density-current deposits and 54.4 lb for all deposits in the reservoir.

Summary.—This discussion, perhaps, has shown the hopelessness of the task of finding the correct or even a convincing answer for the volume-weight problem from the data now available for Lake Mead. The writer believes that the answer, for the present, lies somewhere between 54 lb per cu ft and 58 lb per cu ft, possibly rather close to the former. He believes also that 62.5 lb per cu ft, the value suggested by Mr. Blaney in discussing this problem in 1929,[96] might well be used as the basis for calculating the life of the reservoir.

E. W. Lane,[97] M. Am. Soc. C. E.—The future of Lake Mead and Elephant Butte Reservoir is of major importance to many people; and it is therefore very desirable that, as far as it is possible to do so, the future of these reservoirs be accurately predicted. The author should be commended for bringing this important subject up for discussion, and for collating the widely scattered data on which such a study must be based.

From the standpoint of sediment deposits, the future of these reservoirs depends principally upon three factors: (1) The amount of sediment brought down by the streams supplying the reservoirs; (2) the amount of sediment that will pass out of the reservoirs; and (3) the position in which the sediment will be deposited upstream from the dam. The author has collected many data on the amount of sediment which the streams have brought down in the past, and therefore may reasonably be assumed to bring down in the future. As far as the first factor is concerned, the paper seems to be quite complete. The second factor is covered by the assumption that all the sediment brought down will be deposited above the dam and that none of it will pass through to the river below. The third factor is also covered by an assumption—that all the material brought down will be deposited in the reservoir below the maximum flow line. These latter two assumptions are those ordinarily made in studies of the life of reservoirs, but the writer believes that, if a degree of accuracy is desired in the estimate of reservoir life comparable with that obtained in the estimated quantity of sediment inflow, a detailed examination of these two assumptions is necessary to be sure that errors of considerable magnitude are not introduced. The importance of an accurate estimate should justify such an examination, and the writer's discussion will be confined largely to this subject.

The assumption that all the sediment is deposited in the reservoirs is correct for the present conditions, but will become less so as the reservoirs are filled with sediment. As soon as Lake Mead is filled up to the bottom of the gate towers, sediment brought down by the underflows may begin flowing out through the turbines. In fact, this may occur even before the filling reaches this height, since the momentum of the movement of the underflows may cause the underflows to rise considerably upon reaching the dam, because the force of gravity acting on them is so nearly balanced by that acting on the surrounding clear water. As the reservoirs fill, the slope of the bottom will be increased, since the level at the outlet end will remain stationary and the length of the reservoir will be reduced. The velocity of the underflows will therefore be increased and more fine sediment will be transported to and through the dam. Since the underflows in Lake Mead under present conditions are known to carry very large quantities of sediment, the sediment outflow from this reservoir may eventually become a considerable part of the inflowing sediment.

---

[96] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1139.

[97] Eng. Bldg., Iowa City, Iowa.

The discharge of the fine sediment carried by the underflows tends to decrease the filling rate not only because a certain weight of sediment is eliminated but also because the unit weight of the part deposited in the reservoir is greater than the average. Mr. Stevens proposes a value of 65 lb per cu ft. Assuming that this value is correct for the average density of all the inflowing material, if considerable quantities of the fine sediment pass through the dam, the unit weight of the remainder will be somewhat greater than the average (since the unit weight of the fine material is considerably less than the average); and the space that the sediment will occupy will therefore be less than the use of the 65-lb weight would indicate.

The assumption covering the third factor—that the sediment will all be deposited below the level of the maximum flow line—is equivalent to the assumption that the sediment in the water will move as readily as the water alone. This is not the case, and such an assumption may introduce errors of considerable magnitude. The fact that the sediment upstream from a dam is not deposited on a level surface like the water surface of a reservoir, but is deposited on a slope, has been stated by the author. In the case of Bear Creek in California, the deposits above the level of the dam were of the order of 10,000% of the water storage capacity of the basin. Since, above water level, storages of such great magnitude can occur, it appears unsafe to dismiss this factor with a mere assumption. The author states (see heading, "Part I. Elephant Butte Reservoir: Probable Useful Life"):

> "Deposits in the valley above the [Elephant Butte] reservoir have been enormous so that a substantial portion of the water-borne sediments is arrested before it reaches the reservoir."

In the future, as the deposits in Elephant Butte Reservoir extend farther into the reservoir, the proportion of sediment that will be deposited above the water level will increase. This deposit not only will occur within the original area of the reservoir, but will eventually extend many miles upstream beyond this area. The valley above the reservoir is wide and is thickly covered with willows and brush. At times the river breaks into this densely covered area and deposits large volumes of sediment. Although tamarisk growth does not appear to have reached the density of that above the McMillan Reservoir, the growth is reported to be increasing rapidly along the Rio Grande, and before long may considerably retard the sediment inflow into the reservoir. The construction of flood control reservoirs upstream may reduce the sediment inflow further. For these reasons, the writer believes that (assuming that the years of record indicate an accurate average sediment flow) the straight line in Fig. 3, giving the percentage of the capacity of the reservoir occupied by sediment at various times is not justified; that the curve would probably be convex upward, as the portion based on actual records indicates; and that the life of the reservoir would be considerably longer than predicted by the author.

The writer is also unable to agree with the author's statement that, because the river joins the reservoir in a narrow canyon, the upper end of Lake Mead would not aggrade above the reservoir level. When the reservoir is filled, the river will flow the entire length of the reservoir in a channel through the sediment and will have a cross section of the same order of magnitude as it had before the reservoir was constructed. If the deposits are no higher at the upper end of the reservoir than at the dam, the river will have to flow the entire 115-mile length of the reservoir with no fall. Obviously, this will not occur. At a number of places along its course below the Grand Canyon, the Colorado River flows through canyons, similar to those at the upper end of Lake Mead, on a slope which does not differ greatly from the slope where the valley is wider. In times of flood, the bottom of the river may scour deeply but it refills as the flood recedes. When the reservoir is nearly filled with sediment, the slope of the deposits through the canyons at the head of Lake Mead should not differ greatly from that in the canyons below Lake Mead. Because the valleys in the upper end of the basin are narrow, the volume of the sediment deposits above reservoir level in this region will not be relatively as great as in the case of the Elephant Butte Reservoir; but, before the reservoir is filled, the sediment level in the upper end of the reservoir will probably be materially above the high-water level. In any event, there are large areas in Lake Mead, at considerable distances upstream from the dam, where the reservoir is wide and sediment will be deposited to a considerable height above the maximum water level before the reservoir is filled with sediment.

Some deposit of sediment above maximum water level in the reservoir is practically certain to occur eventually in any reservoir into which sediment-laden water flows. Whether or not deposits will build up rapidly enough to cause trouble in a sufficiently short time to be important depends upon the amount and size of the sediment brought in, the volume of storage space available, the condition of confinement of the stream, the fluctuation of water levels in the reservoir, and possibly other factors. Each reservoir is a special case and must be studied in detail to make certain what the result will be.

When such special studies were made, it may even be found that the effectiveness of the reservoir may be destroyed by less material than is necessary to fill the reservoir to the maximum water level, and this condition can result from the same cause as that which produces deposits above the maximum water level—namely, sediment will not move as readily as water. This action will take place to a certain extent in the Virgin-Muddy Creek branch of Lake Mead. The data given by the author indicate that about 7% of the total sediment coming into the reservoir is brought in by the Virgin-Muddy branch and rough computations indicate that about 20% of the capacity of the reservoir is in the Virgin-Muddy branch. Since comparatively little sediment brought down by the Colorado River will flow up into the Virgin-Muddy branch of the reservoir, the Colorado River branch and the reservoir below the junction of the two branches might be filled with Colorado River sediment before the Virgin-Muddy branch is filled. When this occurs, the useful life of the reservoir, from a storage standpoint, will end, since the Virgin-Muddy branch will become a lake, the surface of which cannot be fluctuated by varying the water level at the dam. Therefore, such a lake would have no useful storage. Rough computations indicate that in dry years the flow of the Virgin River may not even supply the evaporation on this lake and that if this occurred the lake would sometimes be entirely cut off from the Colorado River.

Without a detailed study, it is not possible to determine whether the magnitude of the deposits above the high-water level plus the discharge of sediment in the underflow passing through the turbines, will be greater than the space which will not be filled by sediment in the Virgin-Muddy branch. However, sufficient data are available to make a detailed study to determine with reasonable accuracy, not only what the useful life of Lake Mead will be under present conditions, but also what the conditions will be in the reservoir at any future date. The technique for such studies has already been largely developed in connection with investigations of other reservoirs. To explain it in detail would exceed the reasonable scope of discussion. Briefly, it consists of dividing the future record into periods and estimating the volume of the deposits in the various parts of the reservoir for the first period from available data on actual deposits or from the size composition of the sediments. A similar estimate is then made for the second period for the altered conditions of the reservoir brought about by the deposits in the first period. The process involves considerable computation; but, in view of the importance of the conclusions, it should be justified.

The fact that reservoir deposits tend to consolidate with time introduces an uncertain factor in reservoir life determinations. The density value of 65 lb per cu ft observed in the Elephant Butte Reservoir is for sediment with an average consolidation period of about 13 years. If the life of the reservoir is 158 years, as estimated by the author, the deposits would have an average consolidation period of 79 years and should, therefore, be somewhat more dense. Data for estimating this rate of consolidation are not readily available, but considerable new knowledge could no doubt be obtained by the use of the consolidation analysis methods developed in soil mechanics.

F. E. BONNER,[98] M. AM. SOC. C. E.—Another notable contribution to the subject of reservoir siltation in the Southwest is made by this paper. The comprehensive estimate of the silt yield of Colorado Basin from recently collected data is particularly interesting. Although the related forecast of storage depletion is less optimistic than earlier estimates, the difference is not enough to justify widespread alarm. Since ample space has been provided in the past for the writer to expound his views on this subject,[99,100] the present discussion is confined to only one phase which deserves more consideration.

[100] *Ibid.*, Vol. 101 (1936), p. 261.

As alluvial debris accumulates in Lake Mead, the space so occupied is not wholly lost for water storage. Even in that dim, distant day when the lake may be almost filled with gravel, sand, and silt, it will not have ceased to exist as a storage reservoir. Instead, it will have been transformed into a vast ground-water storage reservoir. True enough, the capacity will be reduced, but it will still be substantial. According to the author's estimate, the debris will be consolidated to a specific weight of 65 lb per cu ft. On such a basis, the void ratio will be 60% and therefore the actual water-holding capacity of the reservoir will never be reduced by more than 40% of the original capacity.

The specific yield of the deposit will depend on the composition, but it appears safe to guess that, for long-term withdrawals, it should be equal to at least half the porosity. Therefore, effective storage capacity of 30%, or about 7,500,000 acre-ft, plus several million acre-feet of open storage provided by the gates above spillway crest, will always be available.

This volume of storage combined with that of proposed reservoirs upstream will be fairly adequate, even assuming that all the reservoirs are filled and operating as ground-water reservoirs some 250 years hence—the runoff being diminished by that time (through Upper Basin consumptive use and diversions) to about 50% of the water supply currently available at Boulder Dam. When Boulder Dam and other surface reservoirs become ground-water reservoirs, the very large evaporation losses that now occur will be avoided. Such conservation may be considered very desirable practice in succeeding generations. In any event, practicable solutions of the silt problem will be available to engineers of the future, and present-day developments dependent on regulation of the Colorado River are not necessarily doomed to eventual extinction.

JOE W. JOHNSON,[101] ASSOC. M. AM. SOC. C. E.—In estimating the probable useful life of Lake Mead and Elephant Butte Reservoir, the author has utilized the results of rather extensive suspended-sediment observations. To arrive at a value of total sediment load, the bed load was assumed to be 15% of the suspended load. This estimate of the amount of bed load has proved of interest to the writer, not because of the magnitude of the value assumed, but because it appears that the observed suspended load at the Grand Canyon station may approximate closely the total load in the Colorado River at that point. Sufficient data are available, also, to make a computation of the annual bed load passing San Marcial, N. Mex., on the Rio Grande and thereby check the assumed value of 15% of the suspended load.

In a sufficiently long and uniform stretch of an alluvial stream there exists a relationship between the discharge and the rate of bed-load transportation, and this relationship can be determined by direct measurement or by application of a suitable formula. Except for relatively small streams, direct measurement is impractical; however, this method now appears unnecessary, even on small streams, since the development of the bed-load formula by Hans Einstein,[102,103] Assoc. M. Am. Soc. C. E. The Grand Canyon reach of the Colorado cannot be classed as an alluvial stream; it is a "rock-lined trough" in which velocities are probably high enough to transport (mostly by suspension) that sediment which is delivered to the canyon section by the upstream alluvial tributaries. During high discharges when the larger percentage of the annual load is transported, samples of suspended matter taken throughout the depth, down to as near the bottom as practicable, probably give a reasonably accurate measure of the total sediment load. Since the total sediment load of a stream is not a function of discharge, a continuous sampling program is the only method, known at present, for determining the sediment load entering Lake Mead.

FIG. 18.—RIO GRANDE VALLEY AND RIVER CHANNEL IN THE VICINITY OF SAN MARCIAL, N. MEX.

The Middle Rio Grande, on the other hand, is an alluvial stream in which the average annual bed-load transportation can be estimated by application of the Einstein bed-load formula. Computations by this formula require a reasonably straight reach of the river in which the channel dimensions, bottom slope, the mechanical composition of the bed material, and a flow-duration curve are known. A reach in the vicinity of San Marcial appears ideal for such a computation because of the proximity of the San Marcial gaging station from whose records a flow-duration curve can be constructed. Fig. 18 shows a map of the Rio Grande Valley near San Marcial with the sedimentation ranges used in the surveys of S. C. Happ. Bottom profiles plotted from Mr. Happ's report[104] are shown in Fig. 19 for the reach of the valley between ranges 999 (K) to 1006.8 (A). Inspection of Fig. 18 indicates that the reach of the river from just below range 1003 (G) to 1005.7 (C) is relatively straight and uniform in width. For this same reach Fig. 19 indicates that the average bed slope is fairly constant despite the yearly variation in the absolute position of the bed. Cross sections of the various ranges are available to obtain data on channel dimensions. Numerous bed samples were taken in connection with the sedimentation survey and have been analyzed for mechanical composition. The mechanics of computing the average annual bed-load transportation from these available data has been described in detail elsewhere.[105,106] The method can be used to compute the total volume of bed load transported during the period discussed by the author (1915 to 1940), as well as for periods in the future. As in the case of the Colorado, future estimates of suspended load transported by the Rio Grande can be made only by continuous sampling.

[104] "The Sedimentation in the Middle Rio Grande Valley, New Mexico," by Stafford C. Happ, SCS (unpublished), 1942, Table 3.

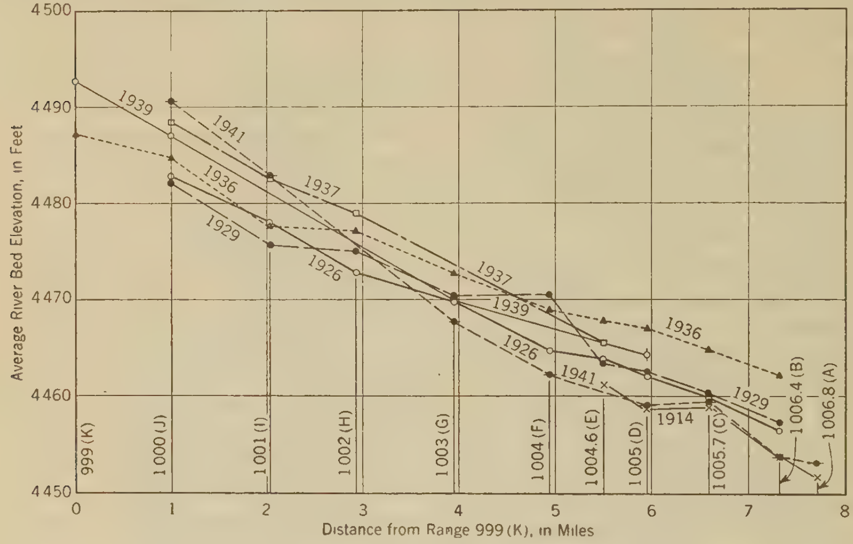

Fig. 19.—River Bed Profiles of Rio Grande at San Marcial, N. Mex.

The foregoing remarks refer to a factor which the author assumes to affect his result by approximately 15%. This is an accuracy which, if approximately correct, is well within the limits of error to be expected in an investigation of this type and probably is on the conservative side, especially for Lake Mead. For the Rio Grande, a computation of the annual bed-load transportation might be desirable to determine the general magnitude of this factor.

It is of interest to note that it is the bed load which is the primary source of the sediments which are deposited in the delta and in the stream channel (above the spillway level) within the limits of the backwater curve.[107] As long as the water level in the reservoir remains near the spillway crest, these deposits of relatively coarse sediments extend farther upstream as time progresses. The existence of a vegetative screen is merely to accelerate the process by trapping some of the finer sediment that otherwise would be carried into the

reservoir as suspended load. Large variations of the reservoir level, however, cause readjustments of these deposits. For instance, a flood occurring during a time of low-water level in the reservoir will cause an abnormal quantity of the above-spillway deposits to be moved to below the spillway elevation. Comparison of the bed profiles for the years during the period from 1914 to 1941 (Fig. 19) indicate the nature of the readjustments of these deposits of relatively coarse material.

HAROLD H. MUNGER,[108] ASSOC. M. AM. SOC. C. E.—A vast collection of valuable data, for those who must assume the responsibility for measures to be adopted in the endless battle for the preservation of the irrigation empire of the southwestern states, has been assembled by the publication of this paper. However, a number of factors have been ignored, or treated lightly, which may well prove to be the most significant elements in the long-time handling of the problem. The purpose of this discussion is to call attention to four factors that may seem trivial but that will loom larger and larger as the passing decades continue the inevitable process of reservoir silting.

1. The problem treated in this paper involves many elements that transcend economics. From time immemorial governments have expended huge quantities of man power and material to defend even minor provinces against human enemies or destructive natural forces. There is no sound reason to doubt that history will repeat itself in the Colorado and Rio Grande valleys and that generation after generation of engineers will devote itself to the struggle with only the most perfunctory regard for economics.

2. The storage capacity of a reservoir is by no means "destroyed" even when the basin is "entirely filled" by silt, if suitable details have been provided in the construction of the dam. The voids in silts are seldom less than 20% and often more than 30%. This space is still available for water storage. No great imagination is required to visualize a concrete dam containing in its base an infiltration gallery similar to those occasionally used in water works practice. Horizontal well points, inserted through suitable fittings in the upstream face of the dam, would tap the supply of ground water in the filled reservoir and provide a uniform year-round flow in many streams that, under present conditions, are alternately dry arroyos and sediment-laden torrents.

3. The silt-storage capacity of a reservoir is much greater than the water-storage capacity. Intermittent, silt-laden streams will aggrade their channels to a slope of 1:100, or steeper, above the spillway of a dam. The formation of the delta above Elephant Butte Reservoir illustrates the early stages of this process. Eventually, a lake 20 miles long may be expected to fill to a level of 1,000 ft above spillway elevation at the head of the lake, and the slope will finally extend up the valley until it intersects the stream bed. The available silt and water storage in a properly designed system of reservoirs on the major silt-producing tributaries of a river like the Colorado or the Rio Grande is practically unlimited.

4. It must be remembered that the cost of a system such as the author proposes will be spread over a period measured in centuries rather than in years,

---

[108] Instr. and Research Engr., Dept. of Applied Mechanics, Kansas State College, Manhattan, Kans.

or even in decades, and that each succeeding generation will measure the cost of construction in its time against the total accumulated value of the empire received from predecessors.

William Mayo Venable,[109] M. Am. Soc. C. E.—The general problem of the disposal of silt created by erosion is involved in this paper; and the problem is not limited to the preservation of storage in reservoirs, although that is important.

Apparently, the only permanent method of preventing silting in a reservoir would be to by-pass the silt so that it cannot settle in the reservoir, because in a reservoir it is impossible to keep the silt in suspension. In most cases, the silt carried by a rapidly running stream is much greater in proportion to the quantity of water flowing during flood seasons than when the water flow is small; in fact, in the case of many large rivers that have their source in mountainous districts (such as the Ohio River), the water in the lower parts of the river is particularly free of suspended undissolved matter in the summertime during low water. Therefore, it is possible to keep silt from accumulating in upstream reservoirs within certain limits by suitable engineering works constructed to by-pass the water only when it is heavily silt laden; and by creating channels that will maintain the silt in suspension until it has passed the main reservoir. Whether this has been suggested, or whether it would be applicable to the Colorado River, is not known. Of course, in some reservoirs, at high elevations where the water is used for power purposes, the outlet from the water to the turbines is so low that silt could not accumulate above the outlet level; and the efficiency for the reservoir, for power purposes, is not destroyed with such accumulation as does occur within the reservoir.

Where the water is to be used for industrial purposes, for water supply, or for irrigation, the removal of the silt from the used water is necessary both because of the industrial purpose to which the water is put, and because the presence of excessive silt in irrigation ditches results in impairing the irrigation system. Thus, even if the silt be by-passed from the main reservoir, it must cause increased sedimentation in the valley below, which would not take long to become manifest in an alluvial valley.

Thus the problem under discussion is intimately connected with such problems as the control of the Mississippi River. All who are familiar with the Mississippi River problems know that, since the settlement of the Mississippi Valley and the placing of levees to prevent overflow of the river in adjacent lands (which are effective except during times of excessive floods and disaster), the silt is carried to the Gulf of Mexico; and the length of the channels from New Orleans to the outlets in the delta have increased many miles during the period of observation. The Gulf of Mexico, a few miles beyond the outlets of the Mississippi, is very deep and the rate at which the delta is being extended is said to be diminishing; but it is being extended, and the valley floor is not being built up. It would appear that, in rivers such as the Mississippi, the lower reaches at all times carry all the silt in suspension that they are capable of carrying; and this is probably true of all other rivers that flow some miles from their outlets through valleys, the floors of which have been produced by the river's own overflow—including the Nile, the Euphrates, and possibly the Colorado. The utilization of the water of the Colorado River at Lake Mead, therefore, must have serious effects upon the valley below where the maximum velocity flow in that vicinity, before the reservoir was constructed, was relatively high—sufficiently high to carry, at all times, all the silt that was washed into the river. By-passing the silt without excessive water would affect the valley and irrigation works.

---

[109] Cons. Engr., Blaw-Knox Co., Pittsburgh, Pa.

If the point in the ocean where the silt finally comes to rest is not extremely deep, it would be difficult to prevent, permanently, the building up of the valley floor by means of levees or other artificial works. Some proposals made in the past are intended for the benefit of future generations rather than for the immediate comfort of the present one. Similarly, it would seem that the effect of providing means for accumulating sediment in one part of the valley and raising the valley floor for long periods of years, and doing the same thing in other portions of the valley, during other periods, would promise to be of sufficient benefit to future generations in various parts of the world to justify such projects being considered seriously by national and international action. As suggested by Herbert Hoover, Hon. Am. Soc. C. E., former President of the United States, agriculture could be restored in the valleys of Mesopotamia if the silt problem were solved, and irrigation reestablished.

Edward Gerald Smith,[110] Assoc. M. Am. Soc. C. E.—The analyses of the futures of two reservoirs, where the sedimentation problem is notably important and on which some of the most complete data on the subjects of sedimentation and closely related retrogression have been recorded, is a thought-provoking treatise, timely because of the proposals pending approval by Congress for complete development of several watersheds where similar problems are faced.

A learned analysis was made by the author to arrive at the conclusions on the probable life of Elephant Butte Reservoir. A historical reference is made to a news article published in 1916,[111] in which it was predicted that Elephant Butte Reservoir would have a service life of 233 years. The records used were computed by the late W. W. Follett, M. Am. Soc. C. E., covering the period from 1897 to 1912. Weight of sediment per cubic foot was determined by sampling started in March, 1916, of deposits formed by the high water of June and July, 1915. Beds for sampling were chosen at various locations to represent average conditions. The results from seventeen samples showed dry weights per cubic foot ranging from a maximum of 101.18 lb to a minimum of 87.90 lb. The average weight was 92.34 lb per cu ft. From these data was determined an average annual inflow into the reservoir of 11,336 acre-ft of sediment. Mr. Stevens' predictions, arrived at in a different fashion, indicate a reservoir life of 158 years, an annual rate of sediment inflow of 17,200 acre-ft, and an average specific weight of 65 lb per cu ft.

This is not the best type of comparison but will serve to introduce the next thought concerning the accuracy of basic data Sediment loads in rivers, as determined by past field methods, are of doubtful accuracy on all heavy sediment-laden rivers, primarily because such methods have been deficient in supplying data to obtain the true mean concentration of sediment in the flow cross section. It is doubtful if there are comprehensive data on any stream showing the distribution of sediment in the portion of flow near the stream bed which would include the saltation and bed loads. This information is especially lacking for the highest 20% of flows when 75% of the suspended sediment load is carried on large rivers increasing to more than 90% for smaller tributaries. Because of the tractive force required to begin bed-load movement the percentage of time and bed-load disparity is even more evident. This lack of information is due largely to field problems. Experiments made in late 1944 and 1945 on the Arkansas River at Van Buren, Ark., and Little Rock, Ark., with experimental devices for attempting to measure the bed load contradicted some important theories of bed-load movement and denied the practicality of using bed-load formulas. However, the experimental nature of the information precludes formation of definite opinions until further data have been obtained and studied. However, there is proof to indicate that significant quantities of gravel as large as from 1 in. to 2½ in. are moved several feet above the stream bed even at moderate stages. With the Texas type sampler, which may sample much less than the true load at high concentrations, many results have been obtained showing sediment concentrations one foot above the bottom five times that at 8/10 depth and higher in the vertical. Similar data have been obtained by other departments on other rivers. These data emphasize the concentrated loads carried near the stream bed. To obtain accuracy comparable to that obtained in measuring river discharge, it is necessary to use procedures more involved and expansive than those required for obtaining discharge, since sediment load is a function of discharge and many other variables.

---

[110] Asst. Engr., Hydrology Section, U. S. Engrs., Little Rock, Ark.

[111] "Elephant Butte Reservoir to Serve 233 Years," by R. R. Coghlan and V. E. Lieb, *Engineering Record*, September 16, 1916, p. 349.

Sediment measurements, which are usually taken too infrequently for obtaining reasonably accurate definition of sediment hydrographs, and, concomitantly, sediment loads, must be taken much oftener than required for discharge measurements because of the greater inconsistencies in the character of sediment flow and because of the sharp irregular changes in sediment hydrographs in general.

Test data[112] show that none of the types of samplers tested is without serious deficiencies. Results showed sampling ratios of samplers compared to the depth and point integrations varying from 0.31 to 2.50. Errors are particularly large during periods of high flow and heavy concentration.

The writer draws the conclusion that, in addition to the possibility that field determinations of bed and saltation loads may some day require large additions to past records of sediment determinations to determine total sediment loads, development of accurate samplers and improved field practices also may demand substantial increases to past records. All these findings suggest the possibility that adjustments for basic data being deficient in quantity load could result in a weight per cubic foot of dry sediment in the range of values determined by the 1916 field data.

---

[112] "A Study of Methods Used in Measurement and Analysis of Sediment Loads in Streams, Progress Report, Comparative Field Tests on Suspended Sediment Samplers-December, 1944," planned and conducted jointly by TVA, Corps of Engrs., Dept. of Agriculture, U. S. Geological Survey, Bureau of Reclamation, Indian Service, and Iowa Inst. of Hydr. Research, published at St. Paul Dist. (Minn.) Sub-Office and Hydr. Laboratory, State Univ. of Iowa, Iowa City, Iowa.

Prolonging the Life of Reservoirs.—It is an obvious necessity that all feasible measures be adopted for prolonging the life of each project. The need for these measures is emphasized by noting that, in most reservoirs, the greatest quantity of sediment is deposited in the higher pools, especially in the first few generations, where the loss in storage causes a direct and immediate economic loss. In many reservoirs the amortization period may elapse before considerable deposits appear in the lowest portions of the storage. Reviewing the measures proposed for lengthening the life of Lake Mead with a view to applying lessons learned to other developments exposes great weaknesses in all proposals. Of the four measures proposed for prolonging the life of Lake Mead, three have been eliminated as possibilities for significant contribution to lengthening the useful life of a large reservoir. Removal of sediments after deposition is economically infeasible. It is unlikely that density currents in large reservoirs will ever result in carrying significant quantities of sediment. Then too, the material carried may be of the finer silts and clays which would deposit as "bottomset" beds in lower parts of reservoirs and handicap use of reservoir storage less. A large reservoir may be operated for two or more conflicting purposes. To attempt to operate the reservoir for an additional variable in order to utilize density currents for removal of sediment may be infeasible. Land management assumes a position of doubtful value when it appears that the sediment load could be reduced by no more than 10% by most careful applications of the principle. Then too, drought, an uncontrollable force of nature, may exercise more effective control over vegetation than a plan of land management can be expected to accomplish. In addition to the upstream storage, which will be discussed later, a program for bank stabilization would aid materially in preserving downstream reservoir storage. "Notes on Experiments on Meandering and Bed Load Movement"[113] emphasizes the importance of caving banks in conbributing to sediment loads in streams, especially of the larger grain-size sediments which deposit readily in pools. Stabilization of banks is especially necessary in the meandering reaches of river developments.

Upstream storage, as a reservoir storage protection measure, has many ramifications, possibilities, and flaws. In a longer range view, the construction of an upstream sediment-storage basin will lengthen the life of a particular reservoir. In a much longer range view both basins will be full of sediment and all resources in both areas permanently disabled. The point of view depends upon whether the engineer looks into the future in terms of decades, centuries, or larger units of time. In each valley development engineering studies for providing upstream storage involve difficulties in obtaining satisfactory sites close enough to the reservoir to have considerable effect, so that intermediate sediment runoff and retrogression of beds by clear-water releases will not eliminate much of the effect of a sediment-storage project. Clear-water scouring channels will move the bed material, composed of larger grain-size material, which deposits readily in pools. It is necessary to evaluate the actual contribution to the life of the protected reservoir. In most instances, the sediment-storage project must be located so far upstream that benefits become small. Furthermore, the capacity of sediment-storage pools necessary to perform the required quality of sediment removal performance by detention of flows has yet to be determined within reasonable dimensions.

---

[113] "Notes on Experiments on Meandering and Bed Load Movement," Mississippi River Commission, U. S. Waterways Experiment Station, Vicksburg, Miss., May 1, 1945.

Benefits below sediment-storage pools are provided by retrogression of channels below dams providing greater channel capacity, and stabilization of channels accomplished by eliminating the supply of material, the latter being pointed out in model tests.[113] However, even these benefits are offset by increased flood and other land damages upstream from the pools caused by aggradation of sediments upstream from the deltas that are formed at the heads of reservoir pools.

CLARENCE S. JARVIS,[114] M. AM. SOC. C. E.—One of the essentials in solving such momentous problems as those now facing the profession is to adopt a realistic attitude concerning reservoirs, instead of maintaining the complacency so prevalent only a few decades ago. For example, the residents of San Marcial, N. Mex., only a few feet above the proposed maximum water level of Elephant Butte Reservoir, and only a few thousand feet upstream, were calmly advised, and seemingly assured, that no harm would come to them from flooding as a result of the storage enterprise. The subsequent aggradation of the river channel necessitated repeated revisions of railroad and bridge elevations, and the eventual displacement of the town from the alluvial plain to the higher mesa—within a decade after the beginning of storage. Likewise, although seemingly authoritative estimates had consigned the dead storage of Lake Mead to the accumulation of sediment for the first 200 years of its normal life, conclusive evidence is presented that the useful span of its existence may be less than two centuries unless countermeasures are adopted promptly and executed with vigor.

Obviously, the bed-load contribution has upset the early estimates for both Lake Mead and Elephant Butte Reservoir. It is well known that the coarser materials constituting bed load may contain such high percentages of voids that one third or even one half of their volumes may still represent usable storage space. Only when finer sediments intrude to form a matrix for the coarser grains or pebbles, or to seal the coarse deposits in lenslike bodies, are such voids rendered useless for further storage. Inasmuch as the fine sediments may be transported readily by density currents, and may thus be withdrawn from the reservoir basin and delivered by canal systems to irrigated land areas, there to increase the fertility and to improve the soil tilth, the outlook is not entirely hopeless. Some of the views expressed in the writer's discussion of "The Silt Problem of the Zuni Reservoir," by H. F. Robinson, are readily applicable today in the light of later experience. For example:[115]

> "Proper manipulation of the outlet gates, * * * together with judicious use of hydraulic pumps and jets from hydraulic giants mounted on a barge for use around the edges of the reservoir * * * reducing the larger deposits of silt and maintaining a turbid outflow, could be adjusted so as to keep

[115] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 883.

pace with and correct the silting process. The alluvial silt thus distributed upon the irrigated land would be of immense value as a fertilizer; the canal system would have less percolation losses, and there would be less likelihood of the canal breaking than where clear water is used."

Costs and Values.—Regardless of the low cost of the land acquired for a highway, a parking space, or for other construction, it is not uncommon these days to see great mounds of earth representing the topsoil that has been stripped from the surface, pending later distribution on selected areas where fertility and dense vegetal cover are more important than incidental costs. It is quite conceivable that the successive handling of such topsoil may cost hundreds of dollars per acre-foot, far exceeding the original cost of the land involved; yet the values may warrant the high outlay. Likewise, the investment of a few cents (or even much more) per cubic yard in fine silt to be removed by sluicing and by density currents through Lake Mead or other storage reservoirs—even though the original volumes for such storage were provided at the low cost of some fraction of a cent per cubic yard—might prove advisable and profitable in terms of fertility, storage values, and assessed valuations downstream.

Could it be that the author has dismissed the idea of "Removal of Sediments" without due consideration? By way of contrast with this view, most of his comments and conclusions are beyond challenge. The writer has witnessed sediment removal from stock-watering ponds and other small reservoirs by ordinary scrapers, or even by wagon haulage, to choice garden spots, without much regard to cost per acre-foot. The main concern seemed to be the value per cubic yard, which was generally more than a dollar when wage scales were but a fraction of those that now prevail. The usual types of desert soil, with sand as a prominent ingredient, seem to need the fine sediments that are readily conveyed throughout the distributing canal systems. The coarse granules associated with bed load would ordinarily be restricted to construction projects, after screening and washing. Fortunately, these heavy deposits are not often encountered far from the canal intakes; they are not likely to move by natural processes through an extensive reservoir basin. If only the coarser sands, gravels, and cobbles should lodge in the shallow upper reaches of the reservoir, and should provide usable storage space representing some 40% of the original volume (exempt from the usual evaporation losses because of the reduced exposure), it might be feasible to retain some 50% of the original storage volume indefinitely, even though eventually the reservoir might be filled to spillway crest. One of the prime essentials would be the exclusion of fine sediments and ordinary mud from the retained filling. These materials not only would impair the normal void spaces in sand and gravel bars, but also would retard the inflow and outflow of "bank storage." The probable maximum yearly inflow to bank material in Lake Mead is apparently more than 640,000 acre-ft; at Elephant Butte Reservoir, some 370,000 acre-ft; and at Coolidge Reservoir on the Gila River, 144,000 acre-ft—or, compared with total original usable storage, some 2.5%, 17%, and 12%, respectively. Computed on same bases, the maximum yearly withdrawals from bank storage for those same reservoirs (derived or estimated from official records, yet incapable of exact determination at this time) were found to be about 390,000, 190,000,

[a] Calendar years end December 31 and water years three months earlier, or September 30. Records of individual water years are omitted, except the substitution in 1943 which is for the water year ending September 30, 1943. [b] The corresponding drainage areas are: Gila River, above Calva, Ariz., 11,490 sq miles; San Carlos River above Peridot Ariz.—drained, 1,040 sq miles and ungaged, 360 sq miles; and Coolidge Dam, drainage area, 12,890 sq miles. [c] Before 1928, the discharge downstream from the present dam site. [d] These quantities are estimated or derived. [e] Bank storage added (+) or withdrawn (−).

and 37,000 acre-ft, respectively—or, in percentages of original total usable storage, 1.5%, 9%, and 3%. Naturally, the yield from bank storage may continue at nearly the maximum rate for two or more years in succession, keeping pace with the drawdown of reservoir surface. Tables 17 and 18 contain basic hydrologic data to support this discussion.

Taking into account the miles of drillings that must accompany the development of other storage projects to replace those destined to lose most of

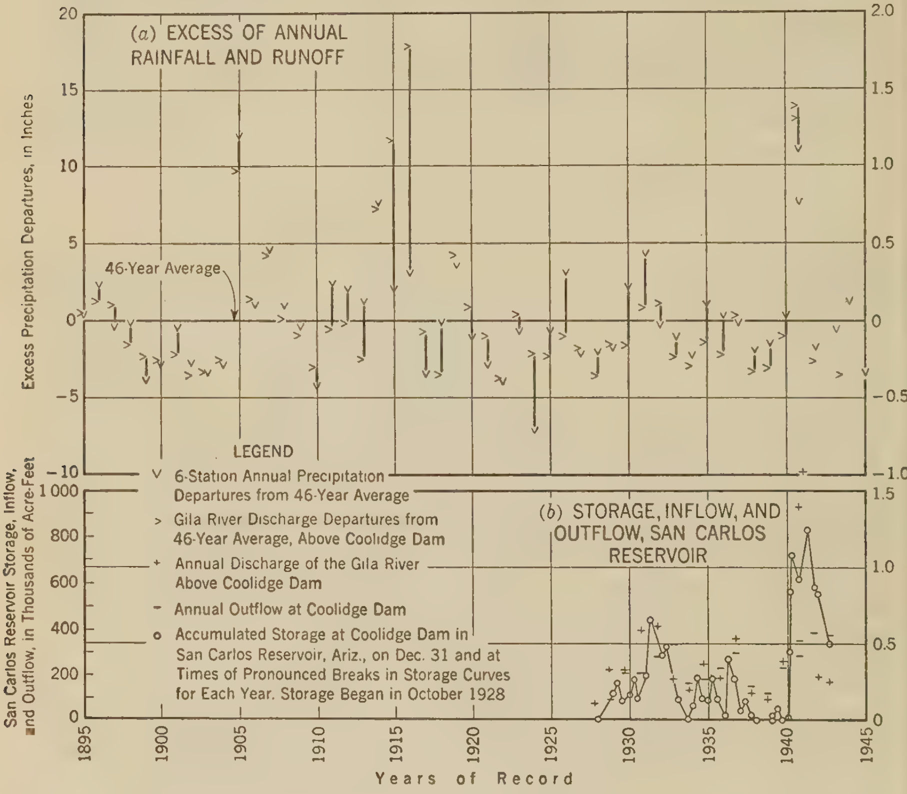

FIG. 20

their capacity within a few decades, engineers could well begin part of the drilling in an effort both to locate and develop lateral underground storage and to supplement the known "bank storage" now functioning. Geologists might thus find dikes or other impervious barriers, beyond which are structures capable of receiving and then releasing great volumes of stored water, if suitable access could be provided by blasting the formations at appropriate depths—in accordance with practice in both petroleum, and other deep-well, drilling. These studies would also locate the critical areas to be protected against sedimentary deposits from the suspended fine materials within the reservoirs (in case the program should be restricted to selected and limited areas) such as the intake or recharge channels leading to the most promising underground storage adjacent to the open water surface of the reservoirs. Too little attention has been accorded to "bank storage" as supplementing the measured capacities of reservoirs.

Probably no precise determination of either reservoir losses by evaporation or diversion to bank storage is possible at major reservoir projects. However, comparison of total inflow and outflow, together with the annual change in storage volumes, leads readily to quantities representing apparent loss, which is actually the evaporation plus the addition to bank storage or minus the volume withdrawn from bank storage. A tentative allocation of these separate factors by the writer shows that, for the 31-yr period of storage record at the Elephant Butte Reservoir, the sum of annual accretions to bank storage was nearly 1,200,000 acre-ft, or slightly more than half of the original storage capacity below spillway crest. On the other hand, the total withdrawals from bank storage were 1,125,000 acre-ft. The apparent annual losses ranged from a maximum in 1920 of 648,400 acre-ft to an actual gain of 47,800 acre-ft, representing the excess of bank storage withdrawal over annual evaporation in 1940. To the mean apparent annual loss of 200,300 acre-ft should be added

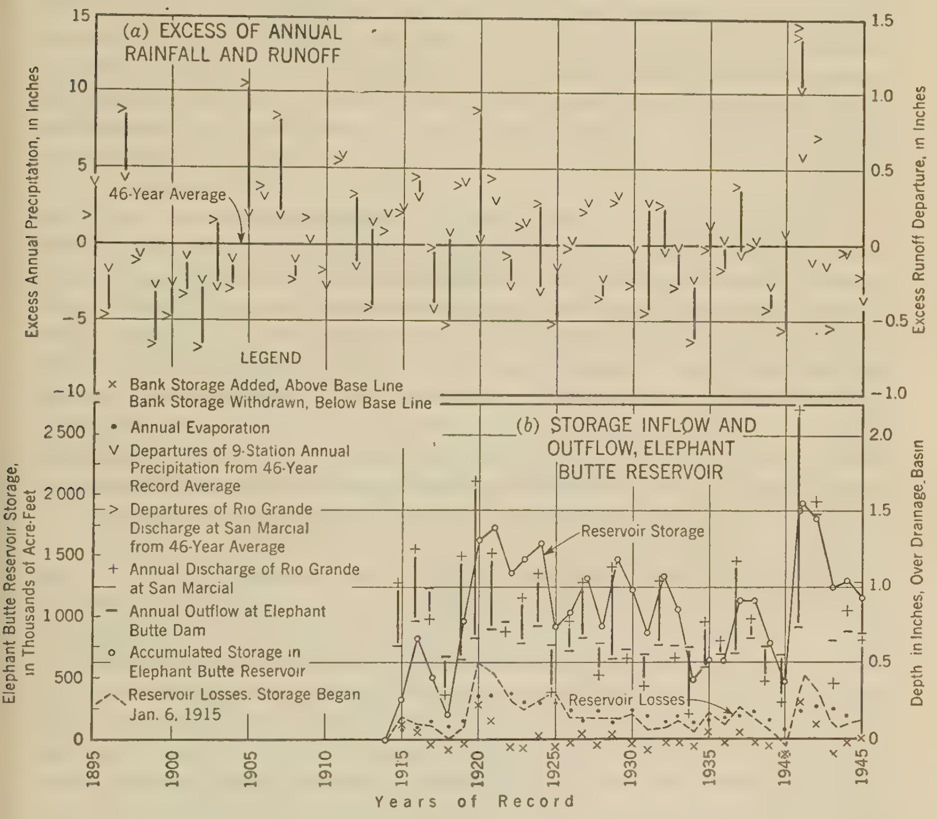

FIG. 21

the mean annual yield from the ungaged 1,750 sq miles of drainage area between San Marcial and the dam—or nearly 7% of the total. If the runoff yield should prove to be as low as 1% of the total, or about 11,000 acre-ft per yr from the ungaged 7%, the mean annual evaporation from the partly filled reservoir would be about 211,000 acre-ft, which conforms very closely with the values plotted in Figs. 20 and 21.

Similar computations showed mean annual evaporation of 633,000 acre-ft for the 11-yr period of storage ending with 1945 for Lake Mead—or fully 400,000 acre-ft per yr for the previous decade. Likewise at Coolidge Dam, the computations showed some 39,000 acre-ft yearly for the sixteen years of record storage, from 1928 to 1943, but only 9,000 acre-ft yearly for the three years immediately preceding the record storage. The volume of bank storage and release was naturally limited to lesser quantities for channels before storage began in the reservoirs.

If the yield from the ungaged 25,560 sq miles of drainage area about Lake Mead had been neglected, instead of being estimated at about 80% of that recorded for the Virgin River at Littlefield, Ariz., the apparent annual losses from river channels between Bright Angel station and Boulder dam site would have been more nearly 250,000 acre-ft for the decade just prior to 1935. Even with that reduction, it appears that the inherent difficulties of stream gaging under such natural conditions as prevail along the Colorado River may account for a part of this factor. It is difficult to conceive more than 100,000 acre-ft actually being lost from the river channel as it was before the existence of Lake Mead; but annual bank storage along the natural channel usually appears to have been from 100,000 to 200,000 acre-ft or more, assuming a high order of accuracy for the river gagings.

Continuing the same assumption and observing the successive annual additions to bank storage for Lake Mead, Elephant Butte, and San Carlos Reservoir back of Coolidge Dam, 1,940,000, 500,000, and 170,000 acre-ft capacities of bank storage seem to have been utilized at the respective sites, representing about 7%, 22%, and 14% of the measured original usable storage volumes. Conservation and possibly extension of those bank-storage capacities, together with from 30% to 40% of the original measured reservoir volumes within the coarser sedimentary deposits of a nearly filled reservoir (assuming that utmost use of density currents and other practicable methods for removing the finer sediments shall be developed forthwith, as outlined herein) might readily insure retention of at least 50% of the originally gaged usable storage volumes indefinitely. To the capacities below spillway crests may be added the storage volumes above the existing crests or above the crests that may later be safely developed—including the accompanying lateral bank storage.

L. Standish Hall,[116] M. Am. Soc. C. E.—This timely paper by Mr. Stevens has rendered a great service to the engineering profession by focusing attention on the relatively short life of reservoirs. The author has perhaps taken a more pessimistic viewpoint than is warranted in order to arouse engineers and conservationists to the need for intensive studies of the problem of sedimentation to the end that a solution may be found for the future of irrigation in the arid West. With the progressive depletion of water-storage resources, it is none too soon to begin the collection of data that will ultimately lead to a better understanding of the problems involved.

---

[116] Prin. Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

The sediments produced by erosion from the Rio Grande and Colorado watersheds are not so extremely large when compared with the size of the respective drainage areas. Many streams in the United States produce, annually, sediment loads per square mile of drainage area from two to five times as great as those produced by the Rio Grande and the Colorado rivers. However, if the sediment load is reduced to terms of annual runoff, probably the quantities produced on these two streams would rank well up on the list.

The action of running water as a modeling agent in changing the earth's surface has long been recognized in geology. It must be expected that in time all reservoirs ultimately will be filled with sediments, whether the time involved is 100 or 10,000 years. A survey of many of the reservoirs within the United States made by the Soil Conservation Service, and reported by Carl B. Brown,[117] indicates that generally only one half of the nation's reservoirs have a life of more than 100 years. In the case of Lake Mead and Elephant Butte reservoirs, the quantities are more impressive due to the size of the reservoirs and the extent of the drainage areas involved. If the economic development based on the irrigation of land in the arid western states were to be terminated within a none too distant span of time, measured in terms of the anticipated economic life of the West, the future of this area would indeed be dark. However, the problem is not quite so serious as it might appear, and it is believed that by proper control and conservation methods the production of irrigation water can be extended into an almost indefinite future time.

Production of Sediment by Erosion.—All streams erode and thus transport great quantities of weathered rock fragments and deposit them elsewhere along their courses. This is a natural geologic process. The most that man can hope to do is to control the process with a view of maintaining normal erosion at a minimum, and not by his works and activities to accelerate the process. Under natural conditions, eroded debris transported by streams is deposited into lakes, dry basins, or the ocean. When man creates a reservoir by interposing a dam in a stream channel, he at once creates a trap for the collection of water and wind-borne sediments. Streams loosen material along their banks by the impact of the water against relatively weak rocks, soil, and rock mantle. The heavier particles are rolled or bumped along the stream bed, while the lighter ones are swept along by the eddies and currents of the stream and are carried suspended for long distances until deposited in the relatively still water of the reservoir. Abrasion of the stream bed by the larger particles, carried along with the flowing water as part of the bed load, increases the total sediment carried by the stream. The particles themselves are reduced in size by collision with each other and with the bedrock. Thus, the erosive effect of the sediment is cumulative, increasing as the flow proceeds downstream until a saturation of the sediment load is reached.

The transporting capacity of the stream, or the size of particles that can be carried, depends on the velocity of the water at a given point along its course.

---

[117] "The Control of Reservoir Silting," by Carl B. Brown, *Miscellaneous Publications No. 521*, U. S. D. A., 1943, p. 20.

In general, the maximum size of a particle that can be picked up from a position of rest by streams at a flood stage depends on the square of the velocity; but, once in motion, the transporting power of the stream on particles varies with the sixth power of the velocity. The rate of abrasion also varies as the square of the velocity, as a general rule. Thus, the movement of sediment is greatly increased when the stream is at flood stage and moving at its maximum velocity. On major streams and large tributaries having flat slopes, the sediment carried into the main channel by steep tributaries will be dropped near the junction of the two streams, resulting in aggradation of the main channel. A sedimentation of downstream reservoirs in such cases is caused by a reworking of the sediments carried into the stream channel. Because of the difference between the abrasive and transporting power of a stream, it is difficult to move all the deposited material once aggradation of the channel has started, as in the case of the Rio Grande. However, when the slope of the main channel is steep, the sediment carried into it by the tributaries will be carried on by the velocity of the current, and the dynamic action of the water will cause excessive bank and bed erosion by abrasive action. These two classifications of sediment transportation require different treatment in their control.

The picking up of material from the stream bed depends on the drag, which varies with the depth of the water and the slope of the stream bed. Hence, it may be inferred that the usefulness of a reservoir as a silt trap is not terminated with the filling of its water-storage space with debris. The increased width of the aggraded channel decreases the average depth of water, and thereby reduces the drag. Furthermore, if the size of the particles of sediment is such that the gradient of the stream is reduced below its original slope after the filling of the reservoir, the drag is further diminished. This points to the conclusion that the building of several reservoirs on a watershed, such as is suggested by the author as a possible development on the Colorado River, should have a progressive effect in diminishing the rate of erosion. From this, it may be concluded that the life of the reservoirs built to reduce the rate of sedimentation of Lake Mead may extend the life of the total reservoir system for a very appreciable period of time beyond that estimated by the author.

The effect of aggradation in reducing the sediment deposits can be compared from the records given in the paper for Elephant Butte Reservoir and Lake Mead. The author has estimated an annual sediment deposit from the Colorado River of 198,000 acre-ft from a drainage area of 167,800 sq miles above the Boulder Dam. This is equal to an annual sediment deposit of 118 acre-ft per hundred square miles of drainage area. The record of silt deposition in Elephant Butte Reservoir during a period of 25.75 years shows a total deposit of 442,900 acre-ft from 25,923 sq miles of drainage area. This is equal to an annual sediment deposit of 66 acre ft per hundred square miles of drainage area. These two adjacent drainage areas, having rock formations of a similar character and climatic conditions practically equivalent, show a large difference in the rate of reservoir sedimentation. The reason for the lower rate of deposition in Elephant Butte Reservoir has been explained by the author. He states (see heading, "Probable Useful Life"): "Deposits in the valley above the reservoir have been enormous so that a substantial portion of the water-borne sediments is arrested before it reaches the reservoir." It is further stated that the aggradation of the lower part of the valley above San Marcial, N. Mex., started prior to the construction of Elephant Butte Reservoir. The Soil Conservation Service has estimated that the deposits on the valley floor between Santa Fe Creek and San Marcial have averaged 12,000 acre-ft per yr. Assuming that the rate of aggradation of the valley has been uniform during the period from January 1, 1915, to September 30, 1940, while sediment was being deposited in Elephant Butte Reservoir, a total of 310,000 acre-ft of sediment must be added to the deposits in the reservoir to bring the gross erosion from the drainage area to a total of 753,000 acre-ft. This is equal to an annual sediment deposition of 113 acre-ft per hundred square miles of drainage area, or approximately the same as that estimated by the author for the Colorado River.

At many places along the inner gorge of the Grand Canyon of the Colorado, the walls are so steep that blocks of rock falling from the cliffs tumble into the water to be slowly swept downstream and ground up. Even where rocks do not fall directly into the river, either in the Grand Canyon or along the precipitous walls of other canyon sections of the main river or its tributaries, they fall on talus slopes extending to the river's edge. These slopes are gradually eroded and the material ground up and moved downstream by the waters of the Colorado. The building of dams for the storage of sediment along the river and its main tributaries would not stop the movement of sediment from the smaller tributaries into the main channels; but it would have the effect of keeping material originating in the main canyons in place and prevent its movement downstream. Hence, it is very probable that the construction above Boulder Dam of storage for sediments on the Colorado River will result in an aggradation of the bed of the river canyon between these various dam sites so that the movement of sediment originating in the canyon will be greatly reduced, with the result that the life of Lake Mead may be increased at to least twice the author's estimate.

In addition to the stream channel erosion, there is also sheet and gully erosion from those portions of the land surface carrying water only during rainstorms. The principal damage to the surface of the ground in arid regions due to erosion comes from unusually heavy falls of rain, or from the sudden melting of snow and ice caused by a rapid rise of temperature. Then, very little water sinks below the ground or is evaporated, and large quantities flow over the surface of the ground in a sheet flow. The velocity of the flow depends upon the quantity of water and the steepness of the slope. Since the vegetation is too sparse and scattered to break the force of the flood, the erosion damage depends upon the resistance of the materials over which the sheetflood travels. Weak sedimentary rocks and unconsolidated alluvium, especially if the latter is fine-textured and of little coherence, are quickly eroded by sheetfloods. Since large areas of the watersheds of the Colorado and Rio Grande are of this type of material, the potentiality for sheet and gully erosion is very high.

The sediment from these sources may be carried into streams, into dry valley bottoms, or it may be deposited over gently sloping areas adjacent to the steep slopes from which the material originated. Sheet flow rapidly collects into rills or furrows which will soon enlarge into gullies entrenched as narrow V-shaped cuts on steep slopes or which broaden out with flat bottoms on flatter grades. Roads may be converted into gullies by flash floods resulting from summer thundershowers. In many instances, excessive grazing of the native grasses and the succession of dry seasons since 1925, with the consequent damage of plant cover, are responsible for accelerated erosion following the return of normal rainfall.

In a recent survey of western range lands, more than 80% of the entire range areas, or some 728 million acres, was found to exhibit evidence of more rapid erosion than in the past. Overgrazing and drought have wrought pronounced changes in the range cover. On extensive areas, the better range grasses have been displaced by inferior nonforage plants. The encroaching plants are also of inferior soil-holding species, and the total vegetation cover is usually much less dense. A survey made by the Soil Conservation Service on the basis of grazing capacities revealed that on the average about one half of the range lands have been depleted, the extent of the damage varying from nothing in some regions to full destruction in other areas.

If the natural cover on the range lands is restored so that sheet erosion is reduced to a minimum, the channel erosion is likewise automatically reduced. As previously pointed out, the abrasive effect of sediment is cumulative after it reaches the stream channel. Hence, if water originating from the range lands enters the streams in a fairly clear condition, the erosion of the stream channels themselves is greatly reduced.

Deposition of Sediments in Reservoirs.—The value assigned for the specific weight of the deposits may result in a large variation in the estimated space occupied by sediment reaching a reservoir. Elephant Butte Reservoir affords a unique opportunity for comparison of measurements of inflowing sediments, measured for many years at San Marcial, to the surveys of the volume occupied by the sediments deposited in the reservoir. After making some well-considered adjustments to the records of samples of suspended sediments, the author determined that the average specific weight of deposits in Elephant Butte Reservoir is 65.3 lb per acre-ft. There is no reason to question the result of these computations as applied to the present deposits in Elephant Butte Reservoir; but a question does arise whether these results can be applied to sediment deposits in other reservoirs. Tests of dried sediments made by various observers have shown that the weight varies from 30 lb to 110 lb per cu ft. The lightest specific weight applies to fine clay that has not been exposed to air, whereas the heaviest weight is applicable only to delta deposits consisting of fine sand and gravel that have been dried out in the air and well compacted. The specific weights usually adopted for reservoir deposits range from 55 lb to 90 lb per cu ft. Even with this range, which does not represent the extremes, the volume of space occupied by sediments in a reservoir can be increased by 60%, if a specific weight of 55 lb per cu ft should be applicable rather than the higher value of 90 lb per cu ft. Furthermore, it seems reasonable to assume, particularly in the case of deep reservoirs such as Lake Mead and Elephant Butte reservoirs, that compaction of the lower deposits by the overlying beds will result in a gradual increase in the average specific weight of the materials. The weight per unit volume that may be stored within the reservoirs may ultimately be appreciably larger than would be found during the early stages of the deposition.

Even after the reservoir has been completely filled with sediments, there is still available space for the storage of water within the void spaces of the deposits. Assuming the higher values for the specific weight, there would probably be at least 50% voids remaining in the deposits which would be filled with water. The specific retention of the deposits would prevent the recovery of all this water, but it might be safely assumed that, with sand and gravel, 50% could be recovered by drainage, or 25% of the original capacity of the reservoir. The proposed construction of the five upstream reservoirs for storage of sediment to prolong the life of Lake Mead would create a total of 49 million acre-ft of storage on the lower Colorado River. In addition, the ultimate construction of the Glen Canyon Reservoir would furnish 60 million acre-ft of additional storage, bringing the total available storage capacity to approximately 110 million acre-ft. With all this storage filled with sediment, if it could be assumed that 25% of the volume would still be available from interstitial storage between the voids of the deposits after allowance for specific retention, there would remain a total available storage capacity on the Colorado River of 27,500,000 acre-ft, or a volume practically equivalent to the initial water storage in Lake Mead. Additional reservoir sites are available on the Rio Grande River; by a suitable program of reservoir construction on that river, it would be possible, ultimately, to provide sufficient underground storage equivalent to the initial storage capacity in the Elephant Butte Reservoir.

The author's statement of the ultimate deposition of sediment in reservoirs above the spillway level excludes many possibilities. The slope taken by the sediment deposit along the stream profile depends entirely on the grading of the materials carried with the water. If these are predominantly of fine sizes, the deposition will not extend very far upstream from the flow line of the reservoir, particularly if the volume of inflow is relatively large. If coarse material constitutes a large proportion of the load, there will be a tendency for the stream to build up its new bed very nearly parallel to the original stream gradient. Under these circumstances, with favorable gradient, the deposits may extend many miles upstream from the reservoir flow line; and in such instances the silt-storage capacity will greatly exceed the water-storage capacity. In some cases, with the proper configuration of the reservoir, a pond may be left permanently above the dam that will remain clear of sediment deposition. In other instances, sediment may be deposited in the reservoir to the maximum level of flood flow over the spillway, through which the low flows of the stream will cut a narrow channel on a gradient starting with the elevation of the spillway lip. Thus, it cannot be assured that much of the 2,500,000 acre-ft of storage above the crest gates at Boulder Dam will ultimately remain to serve as regulating storage for a river-run power plant. The foregoing conclusions were reached by the writer from a study of deposits in a number of reservoirs and erosion control structures; but an exhaustive study of the profile and cross sections of sediment deposits in and above completely filled reservoirs is highly desirable and will yield much more information on this phenomenon.

The availability of some small part of the water storage may exist for a considerable period of time beyond that indicated by the assumption of a linear rate of storage loss. This conclusion is reached, since the "trap efficiency" of a reservoir decreases as the total storage available in relation to the size of the drainage area decreases. Probably a more accurate relation of the "trap efficiency" of a reservoir could be reached by relating it to the mean annual runoff of the basin. In any event, the results in delaying the final sedimentation of a reservoir are appreciable. However, as the author states, the value of the reservoir for storage purposes would be seriously impaired after one half of the initial storage had been exhausted. Thus the extension of the time for the final filling of the reservoir with silt is of minor importance, as the "trap efficiency" of a reservoir is not materially impaired until approximately three fourths of the capacity is occupied by sediments.

Measures of Prolonging the Life of Reservoirs.—Even if underground storage can be made available after the complete sedimentation of existing reservoirs, it is highly desirable to adopt economically feasible means for prolonging their useful life for the storage of water due to the great investment involved. Under this heading, the author has considered as possible measurements: (*a*) Land management on the watershed, (*b*) control of density currents, (*c*) upstream storage for sediment and for other purposes, and (*d*) removal of sediments.

(*a*) Land Management.—Land management of watersheds must contemplate more than merely the conservation of soil and water. The conservation of soils and their more effective use must be planned so that food, forage, and timber may be produced continuously. Conservation is an aid in flood and erosion control and in drought alleviation for the purpose of protecting people and the works of man from damage and destruction. Extensive changes in farming and tillage practices, although of value, are insufficient to check destructive runoff and to control, fully, the erosion that occurs in desert regions. Reliance must be placed mainly on structural works. In cases where the benefits of erosion control to the general public exceed those accruing to the owner of the land, the use of public funds may be justified in meeting the cost of erosion and flood control measures.

The author states that the adoption of all practical methods of land management on the Colorado watershed, regardless of the expense involved, would not reduce the annual sediment load carried into Lake Mead by as much as 10%. The writer agrees that land-management practices would not reduce the soil erosion from the range land by more than 10% of the present total silt volume carried by the Colorado and the Rio Grande rivers; but, because of the principles underlying channel erosion and abrasion, it is the writer's opinion that by control at the source the total volume of sediment would be reduced by many times the 10% reduction resulting from the control of sheet and gully erosion. If the water reaching the stream channel from the fields and ranges is reasonably free from silt, the abrasive action in the main stream is greatly reduced, with the result that the total silt load farther downstream is diminished to an extent far in excess of the quantity of silt retained by the upstream erosion control measures. Obviously, once the sediment has reached the main river channel through sheet and gully erosion, the reduction of further erosion in the stream channel must depend to a large degree on structural works.

The types of erosion-control measures can be classified as vegetative and structural. Under vegetative control may be listed the following:

(1) Replanting of deforested areas and other places where shrubs and grass will thrive;

(2) Removal from cultivation of grass or marginal and mediocre lands subject to excessive erosion;

(3) Ploughing and cultivating along contours of land instead of up and down slopes;

(4) Terracing and furrowing hillside slopes along contours and planting of rows of strip crops; and

(5) Planting of willows or other suitable vegetation along eroded gullies and stream banks;

Under the heading of structural erosion-control measures may be listed the following:

(6) Dams or drops in gullies or stream channels to reduce the velocity of floods and initiate deposits behind them that ultimately reduce the stream gradient and afford support to the channel banks;

(7) Building spreader ridges or dikes which will divide flood waters and prevent their concentration in depressions with the ultimate formation of gullies; and

(8) Placing dikes, jetties, revetments, or tetrahedrons along streams to control stream meandering and bank erosion.

Sheet and gully erosion can be controlled by vegetative methods, whereas stream channel erosion lends itself in most cases most effectively to structural control. However, stream channel erosion on most watersheds greatly exceeds sheet and gully erosion. From what has been stated previously, this does not infer that vegetative control can be neglected; but these methods lie in the field of forestry and agronomy, whereas structural control is in the engineering province. Once the sediments have reached the stream channel, the control of erosion is primarily an engineering problem.

(*b*) Density Currents.—The control of sedimentation of reservoirs through the discharge of silt-laden waters through outlet valves is predicated upon the assumption that an appreciable part of the sediment is of sufficient fineness to remain in suspension during the time of its travel from the upper end of the reservoir to the discharge outlets. In the Pardee Reservoir on the Mokelumne River in California, where the discharge of fine sediments through sluice valves is reasonably effective, it is estimated that only 10% of the total sediment load has been disposed of by this means.[118] However, the removal of these fine sediments is important if, after complete sedimentation, the reservoir is to be used as a source of ground-water storage. The fine sediments are usually deposited near the dam and might seriously affect the drainage toward the outlets near the dam of the more permeable coarse materials at the head of the reservoir. If this drainage were seriously impaired by fine sediments, it might become necessary to install wells in the coarse deposits and to pump the discharge over the spillway of the dam. In some reservoirs, the proportion of coarse deposits may be so small that the specific yield would be much below the average of 25% previously assumed. In this phase of the subject, future research would point the way to the best solution. The wasting of a large proportion of the water yield of the stream, when heavily silt laden to avoid the deposition of fine sediment in the reservoir, may be indicated.

---

[118] *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1097.

In Lake Mead, most of the sediments originating on the Colorado drainage area above Lees Ferry are so heavy that they form delta deposits at the head of the reservoir. Frequently, no turbid waters were discharged through the outlets during the deposition of such sediments, particularly during the snow runoff season with a preponderance of coarse materials in the stream. On the other hand, summer flood inflows resulting from thunderstorms originating on the Little Colorado, Virgin, and Muddy rivers carrying heavy loads of fine silt, were observed to pass through the outlets.[119]

Further study of density currents in reservoirs may lead to techniques that will increase the percentage of sediment that can be discharged through gates and valves set at properly determined operating levels. The writer is fully in accord with the author as to the need for exhaustive studies along these lines.

(*c*) Upstream Storage of Sediments.—The benefit of upstream storage of sediments has already been discussed by the writer and appears to be a very effective means of prolonging the life of the main reservoir, not only by providing additional storage for sediments, but also by reducing the bank erosion in the stream channel.

(*d*) Removal of Sediments.—As stated by the author, there appears to be no practical method to remove sediments once they have been deposited in the reservoir. Even if it were feasible to remove the reservoir from operation and to allow the stream to wash the collected sediments through a large discharge tunnel, it would be necessary to assist the stream by hydraulicking the deposits into the main channel. Past experience has indicated that normally an attempt to remove sediments by the action of the stream will result in the cutting of a narrow channel through the alluvial material leaving the major part of the sediments undisturbed. Furthermore, assuming that removal of sediments from a reservoir by this means is feasible, the discharging of huge quantities of debris into the river below a dam would impose tremendous problems in maintaining channel capacity so that overflow of valley lands downstream would not result.

Conclusion.—The future of reservoirs is not so dark as painted by Mr. Stevens, but the writer is in accord with his conclusion that extensive research and consequent improvements are necessary to provide an ultimate solution to the problems. Many of these have been only barely touched upon to permit the confining of the discussion within reasonable limits. Mr. Stevens has pointed the way to a proper approach to the problem of reservoir sedimentation; namely, (1) analysis of suspended sediment records to locate the most active sources of erosion and then (2) outline of a program for controlling the erosion both at its source and in the stream channel.

J. C. Stevens,[120] Past-President, Am. Soc. C. E.—The object of writing this paper was not so much to present factual data as to "rivet" attention on a problem that affects every one—a problem that must be faced and solved if western civilization is to endure. Twenty-four readers submitted discussions that have covered nearly every phase of the subject. Most of the discussers accept the paper in the spirit in which it was intended and agree in the main with the conclusions. Space will permit rejoinders to only a few of the discussions.

[120] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

Consumptive Use.—Messrs. Bondurant and Bliss take exception to the statement about the Rio Grande Compact precluding any increase in consumptive use of water. That preclusion is implied in the compact, although not definitely stated. Only in low runoff periods does unwarranted consumptive use become critical. Elephant Butte Reservoir now evaporates nearly 100,000 acre-ft of water per yr—enough to irrigate 25,000 acres of land. Even after this reservoir is filled with silt and its usefulness for storage entirely gone, the evaporation from its swampy surface will not diminish—it may even increase. Texas, therefore, may look with deep concern upon any plan to build another reservoir with holdover capacity in the Upper Rio Grande basin without compensating importation of water from the Colorado River basin. Elephant Butte will continue to take its toll of needed water indefinitely.

Land Management.—A number of discussers have "raised their eyebrows" at the writer's statements that even the best land management program that man can maintain will not make important reductions in the sediments carried by the streams; that in the Colorado River basin such management could not reduce the sediments more than 10%; and that land management of range land for sustained livestock feed, and of forest lands for sustained lumber yields, will automatically take care of the erosion-prevention feature. Emphasis should be placed on feed for livestock and on lumber yield; and any expenditures beyond such requirements can have no economical justification. The discussion on this phase of the subject has only confirmed the writer in the foregoing views.

Mr. Leopold has cited the work of Messrs. Kirk Bryan and G. M. Post[37] on the Rio Puerco. There is no doubt of the extent of erosion in recent years on this and other southwestern streams. The question is: What caused it? There is abundant geological evidence that these streams have passed through recurring cycles of erosion and sedimentation. Fig. 8 presented by Mr. Leopold shows a photograph of an ancient channel of the Rio Puerco.

A most illuminating story of these recurring cycles has been told by Mr. Bryan:[121]

> "Most of the minor streams of the Southwest are mere wet weather water courses. Muddy floods accompany and follow rain, but throughout the remainder of the year, the stream beds are dry. These ephemeral streams flow in valleys floored with alluvium from twenty to one hundred feet thick. The alluvium has been accumulated by the building up of the grade of the streams which, before the year 1880, ran in discontinuous shallow channels and during floods spread widely over the valley floors. After 1880 and continuing to the present, stream after stream has cut a deep channel, or arroyo, twenty to fifty feet deep into its valley floor or flood-plain. The mud excavated from these channels or arroyos is carried into the main rivers, and as the arroyos are widened by each successive flood, more mud is carried down. Because on the main streams, the Colorado, the Gila, and the Rio Grande, great reservoirs have been built, the increased load of mud will, within a few generations of men, fill the reservoirs and render them

---

[121] "Erosion in the Valleys of the Southwest," by Kirk Bryan, *The New Mexico Quarterly*, November, 1940, pp. 228–229.

valueless for storage. This is the great 'arroyo problem.' How and at whose expense are these reservoirs to be protected?

"The western migration of cattle and cattle men began in the late seventies, and at the same time bands of sheep migrated from New Mexico. Both the cattle and sheep businesses were well developed by 1880. As the cutting of arroyos was begun at this time, some hold that the stock business is the malefactor. The claim is made that the reduction of the native vegetation, by the use or misuse of the grazing, has increased the flood run-off, and thus caused the cutting of arroyos. There is no question that our hesitant land policy, or lack of policy, has encouraged the misuse of grazing land and that overgrazing has resulted in many localities. Nor can one question the general coincidence in time between the cutting of arroyos and the development of the stock business. However, geologic studies of the valleys of the Southwest have demonstrated that the present arroyos had predecessors cut and filled up again before the coming of white men and the introduction of his domestic animals. Investigations of many stream valleys have been made, and the results are brought together in the accompanying table [see Table 19].

TABLE 19.—EROSION AND SEDIMENTATION IN THE FLOOD PLAINS OF SOUTHWESTERN VALLEYS

Alternate process	Evidence on the ground	Comment
Erosion.........	The existing arroyo	Cut from flood plains since 1880 and still being eroded.
Sedimentation...	Late channel fill	Contains, in places, potsherds and other human relics; began to be deposited from about 1300 to 1400.
Erosion.........	Ancient arroyo	Similar in size to existing arroyo; in places, known to have been cut in the period from 1100 to 1400.
Sedimentation...	Intermediate fill	Of Puebloan or earlier date; may be twofold.
Erosion.........	Earliest arroyo	Much larger than later arroyos; associated with strong wind action.
Sedimentation...	Early fill (Neville, Jeddito, and other formations)	Cemented and weathered; in some localities, contains extinct animals; absent in some valleys.

"There have been at least three periods of deposition of alluvium, and three periods of arroyo cutting of which the present arroyo is one. The dates at which these events took place have been determined mostly by interpretation of the relics of man found in the alluvium through the generous cooperation of many archaeologists. In this field the two sciences merge and the broken pieces of Pueblo pottery and other relics of man become fossils recording geologic events. The chronology of Southwestern Pueblo cultures is now in a highly developed state, so that types of pottery are correlated with the tree ring chronology invented by Douglass, and dates on the absolute time scale are possible. The third period of deposition which was brought to a close by the present arroyo cutting is quite well established as to date in these widely scattered areas and apparently occurred between 1200 and 1400 A. D. The period of arroyo cutting next previous is also fairly well established and occurred between 1100 and 1300 A. D.

* * *

"So far as the cause of the arroyo cutting which began after the year 1880 is concerned, the dates set forth in the table are conclusive that arroyos similar to and even larger than the recent arroyos were cut in past time. As these ancient episodes of erosion antedate the introduction of grazing animals, they must be independent of that cause. Each interval of erosion apparently occurred synchronously over the Southwest.

* * *

> "If, therefore, previous to 1880 A. D., alluvium was deposited under moister climates than the present and arroyos were cut under drier conditions, it seems reasonable to believe that the present arroyo is essentially climatic in origin. The introduction of grazing animals handled by optimistic owners may have reduced the already impoverished vegetation, and precipitated the event. Overgrazing thus becomes merely the trigger pull which timed the arroyo cutting in the thirty years following 1880."

In another paper,[122] Mr. Bryan correlates the rise and decline of Indian Pueblo culture with these periodic erosion and sedimentation cycles, and gives the following conclusions:

> "That such a cycle of erosion took place in prehistoric time and was succeeded by a period of alluviation that continued down to about 1880 is supported by an increasing body of fact. A buried channel representing such a cycle of erosion and alluviation has been found at Chaco Canyon and at other localities, notably on Rio Galisteo.[123] The channel formed and filled at about the end of the Great Pueblo period. The collection of data on this episode is still going on, but it appears that an adequate physical cause for the decline in Pueblo culture from its peak and the shifts in population at about that time is in sight. Such an explanation rests on the postulate that flood-water farming was the principal support of the prehistoric people."

If, therefore, the Pueblo indians lived mainly by floodwater farming their source of water disappeared when a cycle of arroyo cutting set in and they had to move to other localities.

Mr. Bryan's conclusion that the cause of these cycles is climatic seems to have some substantiation in Fig. 4 showing the levels of Great Salt Lake in Utah. The peak of 1865–1880 coincides with the end of the sedimentation period, mentioned by Mr. Bryan, and the subsequent rapid decline in levels with the erosion period. Man's activities loom large and important on the political horizon but in the cosmic sense they are quite puny and futile.

Lake Mead.—The validity of the estimates of the useful life of Lake Mead depends on a number of factors fully recognized and treated in some of the discussions:

1. "Blowing up" a 17-yr record of sediment inflow to a period of from two hundred to three hundred years;

2. Adjusting the record for unmeasured bed load and for contributions from drainage areas not included above the sediment measuring stations;

3. Appraising the climatology of the years of record as a "yardstick" of the entire period;

4. Determining the space occupied by the sediments; and

5. Deciding the accuracy of sediment flow determinations.

Mr. Brown argues that the period of record is not adequate as an index of the long period. By extending the record at Grand Canyon back to 1897, making a 45-yr record, he shows a mean annual sediment flow at Grand Canyon of nearly 252,000,000 tons as against the 200,000,000 tons reported in Table 7—an increase of 25% in sedimentation with an approximately corresponding reduction in useful life. Mr. Fox has estimated the sediment flow into the Gulf of California at 1,000,000 acre-ft per yr.

---

[122] "Flood-Water Farming," by Kirk Bryan, *The Geographic Review*, July, 1929, p. 444.

[123] "Recent Deposits of Chaco Canyon, New Mexico, in Relation to the Life of the Prehistoric Peoples of Pueblo Bonito" (abstract), by Kirk Bryan, *Journal*, Washington Academy of Science, Vol. 16, 1926, pp. 75–76.

Messrs. Howard and Crawford and Benedict have shown the inaccuracies inherent in sediment sampling during past years. A new and more accurate approach to this problem is being initiated from which it is expected data will be obtained to correct the old records. Mr. Howard has also added 3 years to the sediment record in the Colorado River basin which were not available to the writer at the time the paper was being prepared. Thus, the sediment flow at Grand Canyon is reduced from 200,000,000 to 191,000,000 tons per yr; and that at Lees Ferry, from 186,000,000 to 155,000,000 tons per yr. This region is still in a low runoff period.

Mr. Bell has presented very pertinent data on the space occupied by sediments. His conclusions are that the Elephant Butte sediments should have a greater specific weight than those of Lake Mead; that this difference will disappear with the passage of time; and that the value of 65 lb per cu ft is too high for Lake Mead now but may be about right in 2075. The effect of these changes would be to lengthen the estimated life of Elephant Butte Reservoir and to shorten that of Lake Mead.

The writer is not aware of the news article published in 1916, mentioned by Edward Gerald Smith, in which a life for Elephant Butte Reservoir of 233 years was predicted; but he is certain that the late W. W. Follett, M. Am. Soc. C. E., used a specific weight of 53 lb per cu ft in his calculations.[111] Using 53 lb instead of the 92.34 lb given in the article cited, the 233-yr life reduces to 134 years which is nearer the estimated life of 158 years given by the writer.

Conclusions.—The writer can only repeat from the last paragraph of his paper that:

> "The available data are pitifully meager, and must be greatly enlarged before any constructive program for relief can be developed."

Regardless of the technical aspects of the problem and of the accuracy of the basic data and the estimates of useful lives of the reservoirs deduced therefrom one must agree with Professor Berkey that:

> "Although the principles involved in the paper * * * are well known, it is not certain that the implications are fully appreciated by many even in responsible relation to them."

Professor Berkey adds:

> "For the first time, after reading this paper, the long-range significance of the suffocating effect produced by accumulating silt in all these reservoirs was borne down on the writer."

Through the Hydraulics Division, the Society has appointed a Joint Committee on Sedimentation in Reservoirs on which not only the Hydraulics Division but the Irrigation, Power, Sanitary, and Waterways divisions have representation. The declared objective of this committee is "to study and report on problems connected with the depositing of sediment in reservoirs, its prevention and reduction." A well-rounded program of research sponsored by, and divided among, federal, state, and private agencies must now be formulated to obtain essential basic data before effective plans for ameliorating the silt menace can be formulated.

Chapter XIII.—Retroactive Adjustment of the Depreciation Reserve... 1398

PRINCIPLES OF DEPRECIATION

FINAL REPORT OF THE SPECIAL COMMITTEE AUTHORIZED BY THE BOARD OF DIRECTION TO ANALYZE AND DISCUSS THE 1943 REPORT OF THE NATIONAL ASSOCIATION OF RAILROAD AND UTILITIES COMMISSIONERS' COMMITTEE ON DEPRECIATION

I.—Introduction

The Special Committee of the Society on Depreciation respectfully submits this, its final report on the subject of "Depreciation," for the purpose of expanding the discussion of important phases of the subject which could only be suggested, and the committee's opinion stated, in the Progress Report submitted[1] in April, 1944. The limited time then available to the committee made it impossible to secure records of past experience of any of the different utilities which have built up reserves for "depreciation" under regulated accounting, or for the members of the committee to discuss thoroughly the many different and complex phases of the subject so as to be in accord on an extended discussion of this most important subject.

The Report of the Committee on Depreciation of the National Association of Railroad and Utilities Commissioners (hereinafter referred to as the NARUC committee) is devoted primarily to a discussion of methods to be used in a revision of the Accounting Classification to be required. By far the largest part of that report is devoted to the purely accounting phase of the subject and to detailed discussions of various methods—straight-line, sinking fund, compound interest, and other methods, problems that belong primarily to the Accounting Profession. There are many things in that report with which the Society's committee is in agreement. The Society's committee in this, as in the Progress Report, has limited its discussion to the fundamental differences of opinion which have developed from a study of the NARUC committee's report.

That report, when analyzed, recommends that annual depreciation expense be calculated by the straight-line method of distribution, using as a basis for the distribution the average lives of groups or units of property. Also, it recommends that the straight-line method be used for the computation of the depreciation reserve and that such reserve, when so computed, shall measure the actual depreciation in the property.

---

[1] *Proceedings*, Am. Soc. C. E., June, 1944, p. 887.

Even when the most complete and accurate data on average life are available, the straight-line method of distribution is still open to the objection that it assumes that a unit of service rendered today and one to be rendered some years in the future are of equal value, which obviously they are not.

The Society's committee, while fully recognizing the usefulness of the straight-line method in accounting for unregulated industrial property and possibly for certain utility properties, does not believe that its use is proper in the case of the great majority of utility properties; or that the reserve thus computed represents the "actual depreciation"; or that the depreciation reserve accumulated under regulated accounting should be "corrected" or readjusted to make it conform to the amount computed by the "straight-line" method by transfers of capital.

Each property, large or small, offers its own distinct problems of regulation and accounting. Its own management and engineering and accounting officials best know its problems and its needs, and, subject to the approval of the Regulatory Commission having jurisdiction, should be able to estimate the requirements of the property as to proper charges to operating expenses for "depreciation" and proper limits to reserve balances in a far more satisfactory manner than if compelled to use an arbitrary formula which not only deprives the management of control of this important matter, but places restriction on the exercise of informed judgment by the Commission in matters of regulation.

The Society's committee considers that the accounting plan adopted for the creation of reserves for retirement or "depreciation" in any particular case, whether "straight-line" or one of the interest methods, is immaterial, so long as it is founded upon sound economic and legal principles and creates adequate but not excessive reserves. It is the committee's opinion that for most utility properties the results of the application of one of the interest methods, preferably the present worth method, most nearly parallel the depreciation requirements.

The best proof of the results that follow by the use of any method is found in the statistics of properties which have used that method for a long period of years. Regulated accounting has been in operation for a quarter of a century and more statistics are becoming available. The committee has used certain of these statistics to give point to the argument which it presents in support of its views.

The Society's committee believes it proper to state here that all of its members are advocates of the regulation of public utilities; that they fully recognize the great amount of good that has resulted from this form of regulation. They believe that this regulation should be for the benefit not only of the patrons of the utility—the consumers—but also for stockholders and security holders as well; to insure fair and reasonable rates which will permit the utility to maintain its plant, adequately compensate its employees, furnish reliable service, permit a fair return to investors, and maintain the integrity of the investment. The management of a Public Service Corporation has three responsibilities—(1) to furnish the best of service to its patrons at the lowest rates consistent with, (2) the payment of good salaries and wages together with old-age retirement allowances to skilled employees many of whom devote a lifetime to the service, and (3) a return to the stockholders sufficient to permit the Corporation to attract new capital when needed for expansion.

II.—DEFINITIONS

Among the reasons why the general subject which has come to be called "depreciation" is so confusing and difficult of understanding are: (1) the use of the word depreciation to refer to the amount of physical deterioration or loss of service value to be found and deducted in valuations for the establishment of a rate or taxation base; (2) the use of the same word to refer to an accounting reserve created to provide for the retirement of plant through charges to operating expenses; (3) the frequent use of the word, sometimes expressed as "annual depreciation," to describe the amount of money annually charged to operating expenses and credited to the reserve; (4) the frequent use of the word to describe the credit balance in the reserve, sometimes using the term accrued depreciation for the same purpose; (5) the fact that in the voluminous literature of the subject published in the period, 1912 to 1925, and later, many attempts were made to coin terms to express certain distinctions, such as "physical depreciation" and "functional depreciation," which have come into general use and are well understood; and a number of others used to express some particular shade of meaning which the author was trying to express, and which have not come into general use.

In Chapter II of the NARUC report the nature of depreciation is discussed at length and the present-day concepts are outlined in considerable detail. A number of the definitions current in the literature and in the regulations of various public agencies are presented. It is quite apparent that the term "depreciation" is employed in all of the quoted definitions in a qualitative sense, which is correct because the term means literally the state of being of less worth. However, in valuation and accounting, the objective is quantitative and the long custom of employing the term in both a qualitative and quantitative sense has been in part responsible for the misunderstandings that characterize discussion of the subject.

The Society's committee in its meetings and discussions of the subject has found this confusion of terms to be the cause of much misunderstanding. In order to attempt to make clear to readers of this report the exact meaning attached by the Society's committee to the words used, certain definitions, with comments on each one, are given. It believes that there should be an attempt, on the part of leaders of the engineering and accounting professions, and regulatory bodies as represented by the NARUC, to clarify the subject by the adoption of an approved terminology.

1. Depreciation.—

"Broadly speaking depreciation is the loss, not restored by current maintenance, which is due to all the factors causing the ultimate retirement of the property. These factors embrace wear and tear, decay, inadequacy and obsolescence. Annual depreciation is the loss which takes place in a year."

Comments: The above is accepted as the best and most authoritative short definition. It is that of Mr. Chief Justice Hughes in the Lindheimer Case (292 U. S. 151–167). It clearly and definitely refers to the engineering concept—depreciation which is deductible in finding a rate base. It is shorter than the definition in the present NARUC Uniform System of Accounts which reads as follows:

> " 'Depreciation,' as applied to depreciable telephone plant, means loss in service value not restored by current maintenance, incurred in connection with the consumption or prospective retirement of telephone plant in the course of service from causes which are known to be in current operation, against which the company is not protected by insurance * * *. Among the causes to be given consideration are wear and tear, decay, action of the elements, * * * changes in demand and requirements of public authorities * * *."

The definitions of the Interstate Commerce Commission (177 I.C.C. 351–422), 1931; the Federal Communications Commission (Uniform System of Accounts, Telephone Co., p. 4), 1934; the Federal Power Commission (Uniform System of Accounts, p. 5); are practically identical with that of the NARUC. All of them use the term "service value" and all of them exclude all property protected by insurance. These omissions mark the major difference between these definitions and that of Chief Justice Hughes. The definitions of the commissions specify utility property. That of the Chief Justice is a good definition of depreciation of any property, regulated or otherwise. The Chief Justice, instead of using the term "service value," uses the expression "loss * * * due to all factors causing ultimate retirement," a much broader definition.

The definitions of depreciation used by the regulatory commissions have been in use for ten years or more and have controlled in matters of utility regulation. The Society's committee sees no particular objection to any of them, but would call attention to the fact that accounting for the adjustment of insured losses can be handled through the retirement reserve, as well as otherwise, and therefore places no emphasis on that omission from its adopted definition, which is clear cut and otherwise all inclusive.

The NARUC committee recommends the abandonment of all of them and after five pages of argument in its report recommends a new definition which would substitute expiration of "service life or utility of property" for "loss not restored by maintenance" in Chief Justice Hughes' definition, or "loss in service value not restored by current maintenance" in others.

2. Amortization.—

The liquidation or extinguishment of the investment in a property by means of a series of partial payments is prorated to extend over the period during which the property will exist, or over the period during which it is anticipated that benefit will be realized.

Comments: The NARUC committee on page xiv limits amortization to recouping the "cost of intangibles, such as patents, copyrights, leaseholds, etc." Depreciation and Amortization are not synonymous. The definition of Encyclopedia Britannica is as follows: "Amortization is the liquidation or extinguishment of an asset by means of a series of partial payments prorated to extend over the period during which the assets will exist." Amortization is in effect a return to the investors of money expended for wasting assets or for physical plant which is reaching the end of its useful life with no prospect of renewal. This is illustrated by the practice of writing off the investment in coal mining property, oil or natural gas property and the physical plant connected therewith as the coal, oil, or gas supply is depleted. Such utilities as pipe lines for natural gas or oil should create reserves for amortization. In past years, railroads in the lumbering districts built hundreds of miles of branch lines, which were torn up after the lumbering operations were finished. Reserves for amortization of the entire investment, every element of cost, would have been proper, but in many if not most cases were not established.

The Society's committee believes that amortization reserves should be entirely separate from reserves for the retirement of units of property on a continuing utility such as a water works or telephone property. In continuing properties the funds represented by the reserves are not returned to the investor. The object of the reserve is to maintain the integrity of the original investment.

The effect of the forced adoption of the straight-line method in the manner recommended by the NARUC committee is to provide for amortization of an unlimited life property rather than to provide a reserve for depreciation or retirement.

3. Annual Depreciation.—As included in the recommended definition of depreciation, annual depreciation is the loss that takes place in a year. The Society's committee believes that long custom has established this term to apply to the estimated annual charge to operating expenses which is credited to the reserve.

Comments: In the body of this report there is a full discussion of the difficulties involved in the exact determination of the amount of depreciation occurring in any one year. One of the fundamental differences between the NARUC report and that of the Society's committee is that the NARUC committee determines annual allowances for depreciation and assumes that the accrued depreciation follows, whereas the Society's committee believes that accrued depreciation should be determined and from accrued depreciation an annual allowance can be set up.

4. Accrued Depreciation is the total depreciation that has taken place in a unit of property or an entire existing property from the date when it was first placed in service up to the date of inquiry.

Comments: This term, accrued depreciation, is understood to be synonomous with "actual" depreciation as used by the NARUC committee. Retirements that have actually been made are not reflected in accrued depreciation.

5. Reserve for Depreciation or Retirements (hereinafter referred to as "The Reserve").—The accounting reserve is established by a series of annual charges to operating expenses and credits to a reserve, against which the cost of units of property, less net salvage, are charged upon retirement from service for any cause. The object of the reserve is to maintain the integrity of the investment in plant "so that the original investment remains as it was in the beginning."

Comments: The only reason for the reserve that has been approved by a long line of United States Supreme Court decisions is to restore to the property through this accounting device the full cost, less net salvage, of all units of plant, during the lifetime of the units. The accounting profession in the early history of this accounting device used the term "depreciation reserve" and through the years developed the theory that it should cover all theoretical expired service value or service life of all units, so that the credit balance at the end of any year would include all of the theoretical loss of value of all units in service, many of which would not be retired for many years or decades.

6. *The Credit Balance in the Reserve* is the amount of the book figure after all credits have been added and all retirements and other debits deducted.

Comments: The credit balance in the reserve should be large enough not only to cover all loss in service value presently known but also a reasonable amount to cover sudden retirements caused by storms and other unforeseen casualties.

The Society's committee considers it highly improper to call this credit balance "Accrued Depreciation," a term which should be applied only to total actual impairment to service value—a physical fact.

III.—PRINCIPAL CONCLUSIONS

The Society's committee, as a result of the study of actual statistics of regulated accounting for so-called "depreciation" over a period of thirty years, and of a review of the U. S. Supreme Court opinions bearing on questions of valuation and depreciation from the early years of this century, has reached certain conclusions, some of which are indicated in the text itself.

1. The summary that is included in the NARUC report states, "In summary statements it is obviously not possible to capture all the refinements of meaning or all the particular qualifications set forth in the main text. Therefore these statements are to be taken as condensed expressions of the ideas and principles that are developed more fully in the report." The report should have either chapter summaries or a general summary of conclusions to which the committee is unequivocally committed.

2. Depreciation is factual and quantitative, capable of reasonably accurate determination by an engineering study of plant and records.

3. The NARUC committee report discusses the application of the straight-line method with judgment in the determination of lives of property units, or groups of units, from mortality tables. The facts are that on large proportions of public utility property there are no reliable mortality data and on many properties of considerable magnitude there may be no mortality statistics at all. The Society's committee believes that the application of general data regarding mortality and the adoption of average lives for various units of utility property are to be strongly condemned. Such a use of any method cannot lead to other than inaccurate and inequitable results.

4. The straight-line method advocated by NARUC committee assumes that a unit of service to be rendered today and one to be rendered some day in the future are of equal value, which obviously they are not. The only theoretically correct method of distributing the depreciation of a unit of property over its

service life is on the basis of a method by which the time value of money is recognized.

5. The Society's committee is unable to see how allowances for depreciation expense can be made to the owners unless it is known with reasonable accuracy at all times just how much of the usefulness of the property has been consumed. It is believed that the NARUC committee should reconsider the statements of approved practice which it recommends to bring them in line with the fundamental purpose of depreciation accountancy, the clear implications of a long line of court decisions, and the plain common sense view that the allowance of depreciation expense is only the method of compensating the owners for property consumed and should in no wise be amortization of principal.

6. The cost of plant and equipment worn out or consumed in producing goods or rendering services is part of the cost of goods or service and should be included in the selling price of the products during the lifetime of the various units of the plant and equipment.

7. Reserves should be created and maintained to offset depreciation. This creation of reserves was first approved in the Knoxville Water Works Case (212 U. S. 1), in which the scope of the reserve was limited to "maintaining the integrity of the investment"; restoring to the property through charges to operating expenses the dollars which represented the cost of equipment retired from service. That principle has been recognized and approved in numerous cases since that time.

8. The Society's committee is of the opinion that, in establishing regulations for the accounting of public utility properties in the various utilities, it would be most unwise to attempt to apply any one formula or rule for universal application in accounting for depreciation. There are such wide differences in the factors causing depreciation in the properties of the different utility industries that the use of any accounting method will revert to estimates, and deal with many uncertainties. In any industry the great differences between small and large plants, or between static and rapidly growing ones, call for individual treatment. The present classification of the NARUC leaves latitude for the exercise of judgment by the various commissions and by the management of the corporations and permits the commissions to base their approval on records of past experience, as has been emphasized in a number of U. S. Supreme Court opinions. The change proposed by the NARUC committee substitutes a particular formula in the application of which adequate data are frequently lacking, and which is complicated by the question of salvage at some remote future date, and takes away in very large measure the opportunity for the exercise of sound judgment based on experience of the commission and the management.

9. The use of straight-line depreciation for thirty or forty years by two great utility industries has been discussed in this report at some length and actual data of its results have been shown. Analysis of these data has convinced the Society's committee that the enforced application of the straight-line method to the majority of public utility properties is not in the public interest.

10. The tables and charts in this report show very definitely that the telephone and railroad utilities, using the straight-line method, have built up credit

balances in the reserve that are vastly in excess of their requirements and are approximately double those of other utilities which have operated under the present NARUC accounting classification.

11. The Society's committee believes that, in cases where adequate mortality data are available, it is possible for an engineer, experienced in design, construction and operation of properties similar to those being studied, to combine the use of such data with his examination of property, and, by the application of one of the interest methods, preferably the present worth method, arrive at proper figures for annual allowances, which will result in reserves that are in fairly close relationship to actual requirements. It is also believed that the application of the same process will give reasonably close estimates of accrued depreciation, but that the major increment in such determination must be the exercise of judgment. The use of mortality statistics largely incidental should not be controlling.

12. The "reserves" in general do not have money or securities in them; they reflect money that has been charged to operating expenses and expended for new plant or other corporate uses. None of this has gone to the stockholders direct. Where reserves are excessive over and above needs for retirement and where the excess has been expended for new plant, the value of their equity has been increased. Analysis of these reserves as made in the pages of this report indicates that in the past the reserves have made very substantial contributions to the capital additions.

13. The reserves, to the extent that they exceed the needs for depreciation, reflect dollars that have been advanced by ratepayers on which the corporation has paid no interest, but which have been expended for new plant. The saving of interest to the corporations through the use of the money collected for depreciation, which otherwise would have been financed by issues of stocks and bonds, is in some cases very large.

The Society's committee believes that this condition resulting from the use of the straight-line method calls for some modified plan of reserve accounting that will prevent such occurrences in the future.

14. Equity requires that the part of the credit balance in the reserve, which is in excess of current requirements, should bear interest.

15. The Society's committee is wholly in disagreement with the conclusion of the NARUC committee that the credit balance in the reserve represents "actual" depreciation and should be deducted in a valuation for rate making. This is incorrect except in those very rare instances where the credit balance in the reserve and the actual requirements are in balance and where a depreciated rate base is appropriate. The NARUC recommendation disregards the purpose for which reserve accounting was established and approved by the Courts, namely, to keep the investment intact and to restore to the corporation the cost of all property retired from service from any cause.

16. In the Progress Report the Society's committee stated[1] its conclusions in reference to the proposed retroactive adjustment of existing retirement reserves to bring the current reserve up to the so-called "depreciation reserve" computed on the straight-line basis through charges to surplus or a special section of the income account. Those conclusions are here repeated:

> "* * * The Society's committee feels that in view of the fact that practically all utilities have been subject to governmental regulation over a period of two to four decades and the reserves currently carried on the books of the utilities have been accumulated, credited and charged in compliance with the regulation of such bodies, the adjustment of the current reserve upward so as to equal those computed on the straight-line basis by withdrawal from surplus or otherwise is not only generally financially impracticable but is also ethically unjust.
>
> "Present reserves should, and usually do, reflect rates charged and collected from consumers. To arbitrarily increase the reserves at this late date by withdrawal from surplus is to require the utility rather than its consumers to make good the cost of property used up in their service. This procedure is in conflict with the basic principle of depreciation as well as plain justice.
>
> "The reserve requirements should be measured by the actual needs of the utility and not by an arbitrary straight-line determination which in the case of many of the best utilities in the United States would require reserves substantially double those which a long background of experience under regulation has determined as adequate."

17. The Society's committee is of the opinion, as stated in its preliminary report, "that the actual depreciation should control the size of the reserve, rather than that the reserve should determine the actual accrued depreciation."

18. That method of accounting for depreciation and for the establishment of retirement reserves to provide for future retirements is best which most closely harmonizes with the facts found for each individual property.

19. Uniformity of treatment and administrative convenience in dealing with depreciation are desirable when equitable; but neither uniformity nor administrative convenience should control over the facts of a particular situation. The NARUC report under discussion would make incorrect theories, rigid uniformity, and administrative convenience controlling. Actual depreciation existing in the physical property is a fact. It is the kind of fact that can be determined with reasonable accuracy only by study of the property by qualified, trained engineers or operators with engineering training who follow approved methods.

20. The state regulatory commissions in the United States must be credited with contributing greatly to the abolition of serious evils that once beset the utility industry. The decisions of the commissions have generally been sound and wise. The commissions have had freedom to exercise their own judgment, rather than being bound by arbitrary rules and regulations. The Society's committee believes that accounting regulations which have left much to the wisdom and discretion of the commissions in the matter of depreciation is abundantly proven by the results.

21. Generally speaking, the Society committee's views regarding the proper procedure in determining annual depreciation allowances are as follows:

1. The preparation of an engineering determination of accrued depreciation.
2. The determination of an annual depreciation allowance which had it been in effect during the life of the property would have provided for all retirements and left a credit balance in the reserve approximately equal to the actual depreciation.

IV.—Historical Development of the Conception of Depreciation

A. Valuation in the Nineteenth Century.—

Valuations which were made to determine the price to be paid for property, when the issue was the purchase of a water works by a municipality on the expiration of the franchise; a valuation to establish a basis for taxation on the *ad valorem* method, as was the case in the Michigan valuation of railroads, or to determine a rate base as was true in other states, were the pioneer undertakings in what has come to be a large and important field of engineering practice. In all of them the early work was along practically the same general lines.

The engineers secured from all available sources data as to the units which composed the property—the inventory; they found the actual cost if data were available; they estimated what it would cost to build an identical property at the time of the investigation, thus establishing the cost of reproduction at then prevailing prices; from which was deducted accrued depreciation to arrive at a figure designated as "Cost of Reproduction Less Depreciation."

While this report deals with the problem of depreciation, a brief review of the history of valuation, of which the determination of depreciation is an important element, is essential to an understanding of the origin of some of the theories now prevailing.

There are very few references to the subject of depreciation in the literature prior to 1900. A few old reports are to be found in the libraries, none of which gives any details, but all of which indicate that the subject of depreciation in the sense of loss of value was recognized.

One paragraph in the annual report of John T. Clark, State Engineer of New York, for the year 1855, is worth quoting:

> "It is contended by many skillful managers that if the works and rolling stock are kept in thorough repair, they are in as good condition at the end of each year as they were at the end of the preceding year, and therefore that there can be no depreciation. The difficulty lies in determining the fact whether the repairs have been kept up in this thorough manner."

This indicates that in the very early days of the railroad industry the managers advanced exactly the same arguments that were used in hearings before the Interstate Commerce Commission seventy years later.

In the "Nebraska Rate Cases" which reached the U. S. Supreme Court as the famous Smyth vs. Ames (169 U.S. 466, decided March 7, 1898), there was much testimony as to the cost of building the roads at that date, 1894–1895, and the state based its testimony as to value on the cost of duplication theory at the period of the very lowest price levels recorded since the Civil War. In the often quoted "rule" laid down by the Court in Smyth vs. Ames there is no mention of depreciation. After naming various matters for consideration, the Court added a sentence: "We do not say that there may not be other matters to be regarded in estimating the value of the property." Depreciation has developed as the most important of those "other matters."

In 1897 the first paper on the subject of valuation in *Transactions* of the American Society of Civil Engineers, by the late Wynkoop Kiersted, M. Am.

Soc. C. E., entitled "Valuation of Water-Works Property"[2] discussed Measures of Value. Four members discussed the paper. The author and the four who discussed agreed that "cost of duplication less depreciation" was entitled to the greatest weight.

There are brief references to the accounting for loss of value by the establishment of "sinking funds" by the late Emil Kuichling,[3] M. Am. Soc. C. E., and by the late Alex Dow, Hon. M. Am. Soc. C. E., in 1898 in a paper presented to the National Electric Light Association which give recognition to the practice of private industry in accounting and to the need of some provision by the utilities to care for depreciation, but no general use of reserves was made by the railroads or early utilities. The reason for this was undoubtedly the opinion of the Supreme Court in the earliest recorded attempt to create reserves for replacement.

The Kansas Pacific Case (United States vs. Kansas Pacific Railway Co., 99 U.S. 455, decided October, 1878) dealt with the subject of "depreciation" reserves. The Auditor of the railroad undertook to establish a reserve for the replacement of rails, assuming a 20-yr life, and contended that it was proper to reserve from earnings each year an amount representing loss of life chargeable that year.

The Court said:

> "First. 'Depreciation account or expense not charged up.' This is explained to be the amount necessary to put the road in proper repair, but which was not actually expended for the purpose. We are clearly of the opinion that it is not a proper charge. Only such expenditures as are actually made can with any propriety be claimed as a deduction from earnings."

That opinion clearly disapproved the creation of reserves and was the controlling case for the rest of the century. There was at the end of the century no regulation of accounting of any utility. The Interstate Commerce Commission had been created in 1887, but was not given authority over accounting until 1907; and not until after the first decade of this century were other utilities than the carriers brought under regulation.

Valuation of properties for sale, control of security issues, rates and taxation commenced in a small way in the 1890's. The acquisition of water works plants by municipalities on the expiration of franchises accounted for most of it. A few valuations of railroads under the Texas "Stock and Bond Law" were completed before 1900. The Michigan Railroad Appraisal, begun in 1900, was the first state-wide appraisal in the United States. It was the first to develop rules and uniform methods, and to adopt cost of reproduction less depreciation as the measure of a taxation base. Depreciation was considered as a condition below the maximum service value at which property could be maintained and was based on inspection and the personal opinion of the senior engineers, all experienced railroad men.

This work was followed by state-wide valuations in Wisconsin, Minnesota, Washington, and several other states prior to the beginning of the Federal Valuation of Railroads in 1913. In all of the states the problem dealt with depreciation—a condition of plant to be found and deducted from value. None of them dealt with problems of reserves or of accounting for the purpose of recovering the cost of worn out or retired property through charges to operating expenses. The first extensive consideration of that subject was by the Bell Telephone Utility, discussed at length later in this report.

B. The Period of the State Valuations.—

The Texas valuations under the Stock and Bond Law recognized the existence of depreciation, but made no estimate or deduction for depreciation, assuming that the property was maintained in normal operating condition and that reasonableness of security issues was the chief problem to be solved.[4] Existing depreciation became a major consideration of the State Railroad Valuations, 1900 to 1912. The Michigan, Wisconsin, and Minnesota valuations were completed or under way when the Interstate Commerce Commission was first given authority to regulate railroad accounting in 1907. Depreciation was determined by the senior engineers by inspection and represented the personal judgment of experienced railroad men as to the extent of falling below a maximum condition of operating efficiency. A handbook issued by the Master Car Builders Association containing rules for determination of depreciation was used as to all cars.

Measured by standards of valuation practice of later decades, these early valuations were primitive. In most of them the total figure of depreciation was a composite of the personal judgment of many engineers. The Washington State Appraisal was unique in that the field determination of depreciation was done away with. The description of the method used in Washington is quoted from the first extensive paper on the subject of railroad valuation published[5] and is as follows:

> "A percentage of depreciation was not placed in the field, but was determined by 'mortality tables,' or by ascertaining the probable years of structure life, then determining from the age of the particular structure under consideration its percentage of depreciation, a method by no means new."

This is what is now called the "straight-line" method, a term not used in this 167-page paper. It is of further interest to note that all that is contained in the paper on the subject of depreciation are the foregoing paragraph, half a dozen scattered sentences, and the following statements:[6]

> "(*d*) *Depreciation.*—Thus far, this discussion has not dealt at length with the subject of depreciation, and it is not considered essential to the purposes of this paper that it be done. The State appraisals have raised a question as to the propriety of using mortality or life tables as compared with personal inspection and the placing of a percentage based on individual judgment. * * * It is certainly desirable to secure the opinion of the man who inspects a bridge, or building, or locomotive, as to its physical condition. It may be desirable to use the check secured by the fact that the age of the building is known and also the average life of structures of its class."

[6] *Ibid.*, p. 141

These references to this old paper presented in January, 1911, are quoted to direct attention to the fact that the problems now under discussion are not new problems, but have been recognized for many decades. That paper was discussed by twenty-five prominent engineers and economists and constitutes a symposium on the subject just before the beginning of the Federal Valuation. One more quotation from the discussion is of interest. It has been noted that the Washington State Appraisal used "life tables," that is to say, the straight-line method, in finding "depreciation." That appraisal was made under the direction of Halbert P. Gillette, M. Am. Soc. C. E. In his discussion[7] Mr. Gillette said:

> "Of almost as great moment as the item of development expense is the question of depreciation. The author [referring to the author of the paper under discussion], in common with most engineers, holds that depreciation should be deducted. This is a consequence of regarding a public service plant as if it were a machine bought in a second-hand store. A public service plant is a device which is intended to perform a given service forever. It is true that its parts are subject to wear, and must be renewed from time to time; but the plant as a whole is everlasting, or practically so. Managers of public service corporations, perceiving this fundamental truth, have rarely established sinking funds for the redemption of any considerable part of the plant. In a great railway system the renewal of a freight car is not a proportionately larger item of expense than is the renewal of a tooth in a steam shovel bucket owned by a contractor. This fact, coupled with the permanence of the railway plant as a whole, has led railway owners to make no provision for a return of the money lost in depreciation. Railway ties in a large railway system inevitably reach a condition such that their average age is exactly half the life of the average tie. Shall a sinking fund be provided for ties? If not, where does logic place a line of demarcation? When does an element of the railway plant attain a condition of sufficient importance to warrant 'writing off' some of its value from the capital account? The facts are that railway managers have not 'written off' anything worthy of mention for depreciation, and, in the writer's opinion, they have been perfectly logical. * * * In other words, if depreciation is to be deducted from the cost of reproduction, it must be added to the development expense ascertained from the accounting records; so that, in the final analysis, depreciation should be ignored entirely in any appraisal of a public service corporation where the object is either rate-making or purchase of the corporation by the public. One qualification to this statement is needed, however, and that is that the depreciation shall not have gone far enough to result in an average age of plant less than half the life of the plant—that being the ultimate normal operating condition."

It is of special interest to note from the above quotation that the only man who used the straight-line method for estimating depreciation in a state valuation of railroads opposed its deduction from value.

The foregoing discussion is designed to throw light on the views of the profession prior to the beginning of the Federal Valuation of Railroads.

C. The Period of the Federal Valuations.—

A Committee was appointed by the American Society of Civil Engineers in September, 1911, to Formulate Principles and Methods for the Valuation of

---

[7] *Transactions*, Am. Soc. C. E., Vol. LXXII (June, 1911), pp. 278–279.

Railroad Property and Other Public Utilities. It submitted a Progress Report in January, 1914. The Final Report was completed in the autumn of 1916 and submitted at the Annual Meeting, January 17, 1917,[8] a few weeks before the United States declared war on Germany. As a consequence of war only four members of the Society discussed this very significant report.

The Federal Valuation of Railroads was provided for in 1912; the Board of Valuation Engineers of the Interstate Commerce Commission was created and organized in 1913. The Texas Midland Opinion of the Interstate Commerce Commission (75 I.C.C. pp. 1–48) fully outlined the methods, rules, and theories as used in the primary valuations of this Commission.

This great undertaking was pushed through to the completion of the primary valuation in the middle 1920's; railroad records were made, such as had never existed before; the most elaborate and accurate studies of costs were completed dealing with prices of the period 1910–1914, which are admittedly as accurate as it is possible to make them, and valuations priced as of date June 30, 1914, were completed for all carriers. Depreciation was deducted on the age-life or straight-line method, the percentages of deduction varying on different carriers but for most of them ranging from 18% to 25%, some running as high as 30% or more.

The only case bearing on the Primary Valuation which reached the Supreme Court was the Los Angeles and Salt Lake Case in which the Court held that the valuation was merely the gathering of data for the files of the Commission which might be used some day in litigation, but the collection of which did not injure the carrier.

The "recapture valuations" which commenced in the middle 1920's made use of the Primary Valuation in the St. Louis and O'Fallon Case (279 U.S. 461). There the Court held that the use of 1914 prices in valuations of 1920 to 1922 and later was improper, and that weight must be given to the price levels of the years of valuation. The Bureau then adopted new methods to translate the primary valuations into the terms of values as of later years. The methods used were radically different from those of the primary valuation.

Many recapture valuations were completed, but no case reached the Supreme Court before the repeal of the recapture provision of the Transportation Act in 1933. The Federal Valuation of Railroads practically ended with that repeal, leaving as its most valuable result the record of the Primary Valuation.

D. Accrued Depreciation Is a Determinable Fact.—

The vast majority of public utility properties must be considered as having an indefinite, continuing life, a life that will last as long as there will be a demand for the service being rendered; therefore there is no necessity for amortizing the entire investment. Each property is a composite of many separate, and different, kinds of units, each having terminable life of varying length, each unit being made up of a large number of items which must be kept in a maximum condition of service efficiency and which must be replaced when it ceases to function in order that the unit be always in maximum service condition. Repair and replacement of items of property is distinctly maintenance, a straight operating expense. The unit of property, when retired, is written off the fixed capital. The claim of the railroads throughout the entire period of valuation was that the maximum or 100% condition of the unit was not "new" as claimed by the Bureau of Valuation, but maximum condition of service efficiency, with its component items in all stages of life from newly installed to imminent replacement. The Bureau of Valuation formula assumed that such items of the track or road units as ties, or of telephone units as poles, were 100% when newly installed and zero when replaced, thus reducing value of these millions of items to around 50%.

---

[8] *Transactions*, Am. Soc. C. E., Vol. LXXXI (December, 1917), pp. 1311–1620.

A study of the Primary Valuation reports discloses not only very high percentages deducted from value but some interesting discrepancies due to the assumptions of "life" and the failure to draw a clear line between units, such as major sections of "road" or "track," composed of the items of grading, ballast, ties, rails, etc. As a result carriers with a large investment in right of way and grading show very much less depreciation than those in level territory with little grading.

One of the "best" carriers in the country, with approximately only 10% deduction for "depreciation," was found to be the Bingham and Garfield Railroad, an ore-carrying road a few miles long running from the Great Copper Mines in Bingham Canyon, Utah, to the Smelter on Great Salt Lake. This is a mountain road with very heavy cuts and fills which "do not depreciate" and with heavy steel bridges and trestles of long life.

If there is a better example in America of a single purpose road, with a life limited to the life of the mine, and with a real need for creating reserves for amortization of the entire property, it is hard to imagine. Yet less than half of the "depreciation" was found here than for such carriers as its only connection—the Union Pacific, or the New York Central, Norfolk and Western, Chesapeake and Ohio and other heavy duty highly maintained properties.

The assumption that such land as railroad, power, telephone and other rights of way, and grading, do not "depreciate" is hard to sustain. There are several thousand miles of abandoned right of way and grading of railroads that have been torn up. It is hard to imagine anything more worthless. The grade of a railroad is an element or item of the track or road unit, such as a main-line division or branch line, which calls for constant maintenance to overcome erosion, repair washouts, and similar expense.

Accrued depreciation, deductible in a valuation on any property, is only in part evident on inspection. The full amount of it is a matter of estimate based on studies of past maintenance, study of the history of the property, determination of the amounts of money that should be spent to restore the plant to full condition of operating efficiency, and thorough study of the obsolescent units to determine whether there is justification for their imminent retirement. Engineering valuation has been carried on for nearly half a century. Theories and methods have been developed and have been in constant use for all of that time that are at wide variance with those used by the Interstate Commerce Commission's Bureau of Valuation. They have not been based upon the age-life straight-line estimates. They have been approved by the Courts as later quotations in this report will indicate.

The railroad contention was that accrued or deductible depreciation in any utility property at any time is an existing condition below the maximum service condition which can and should be continually maintained, a physical fact bearing little relation if any to the theoretical elapsed life of the property. Its only relation to any reserve that may be established for the retirement of the units of property or for the amortization of the whole property in an expiring plant is that it should have been provided for, and that the reserve should be enough larger to fully provide for coming retirements.

This form of depreciation has been recognized by the engineering profession, by the owners of utility property, and by the Courts. There is no need here to quote from the many opinions, beginning with that in the Knoxville Water Case (212 U.S. 1). The Society's committee fully recognizes the fact that existing depreciation must be found and deducted in valuation. It believes that it is a matter of fact, not of theory. It cannot be determined with mathematical accuracy by formula, but is subject to determination within reasonably close limits by men experienced in the design, construction, and operation of utility properties. It is basically an engineering determination. It includes not only inspection of the plant, but detailed examination of conditions not evident to the eye. It calls for studies of past and probable future growth, types of plant and equipment, their functional features, and all matters that would affect their probable future usefulness. Such a study establishes a factual basis for appropriate financial and accounting procedure.

The Society's committee contends that accrued depreciation can only be ascertained accurately by this method.

V.—Historical Development of Accounting Reserve for Retirement or Depreciation

The two subjects, accrued or deductible depreciation in valuation, and accounting reserves for retirement of plant, which are both generally spoken of as "depreciation," are of vital importance in regulation both to the utilities and to the public. They are not well enough understood by engineers and accountants by whom the amounts of money involved must be determined, by the managements of the corporations or officials of the Regulatory Commissions in charge, or by the patrons of the utilities.

Practically all of the discussions of "depreciation" in papers in technical publications or society proceedings or in books by accounting authorities present the academic theories of the authors without using illustrative material drawn from the records of actual experience of the public utilities and railroads, all of which have been under regulation of accounting for twenty-five or thirty years or more. In the following discussion of accounting reserves the Society's committee has chosen its illustrative material from the voluminous public records of data of existing corporations, records actually made during the 30-yr period of regulated accounting.

The subject known as retirement or "depreciation accounting" deals with vast sums of money charged to operating expenses and credited to reserves which have been miscalled "reserves for accrued depreciation." The only purpose for which these reserves have been approved by the Supreme Court is to reimburse the corporations for the cost of property that has been retired from service or is being consumed in service and will be retired. These reserves were originally called Reserves for Retirement by the National Association of Railroad and Utilities Commissioners—a correct statement of what they really are.

The last data available to the Society's committee drawn from reports of regulatory commissions indicate that in 1942 the credit balances in these corporation reserves were well in excess of eight billion dollars after charging all previous retirements of plant to them. These figures include the credit balances of the major telephone, electric, gas, and railway equipment reserves. This vast sum of money is stated at this point in the discussion in order to emphasize the fact that the subject is of major financial importance not only to the corporations but to the patrons who furnish the money through payment of rates for service and to the commissions charged with regulation. The reserves should be ample for the purpose of "maintaining the integrity of the investment," a term frequently used in opinions of the U. S. Supreme Court, but as has also been made clear from those opinions, they must not be excessive.

The two subjects which are called "depreciation" have been referred to. There must be a clear distinction in any discussion of the subject between (1) accrued depreciation, loss of service value, which must be found and deducted in valuation for the determination of a rate base, a fact which can be determined with reasonable accuracy by inspection of physical plant and study of maintenance records; and (2) the accounting provision for a return to the company of the cost of property retired and for maintaining a reasonable reserve balance to provide for future retirements of property on which depreciation is now operative, and for casualties of flood, storm, or other disaster. The word "depreciation" has been used to describe this reserve and also to describe the annual charge to operating expense, thus using the one word to describe three different things, two of them having little real connection with true depreciation, which is loss of service value.

Origin of Reserve Accounting.—

For more than a hundred years there has been recognition of the sound principle that the owners of any manufacturing, mercantile, or utility business selling goods or services to the public are entitled to charge, as an essential part of the cost of production, all of the legitimate costs of management, all operating expenses including the cost of maintenance and repairs to the plant, and the original cost of all major units of plant and equipment worn out in service and retired. This latter item can best be spread with reasonable uniformity during the useful life of major units by means of yearly accruals to a reserve.

The earliest references to the methods adopted for spreading the cost of plant and equipment over its service life found by the Society's committee dealt with "sinking fund" and "annuities" for marine boilers and hulls in the period, 1810 to 1815.

Between 1845 and 1855 there was considerable discussion of the subject of replacement of railway plant and equipment in England, Holland, and United

States. In 1850 a volume entitled "Railway Economy" by Dionysius Lardner, published by Harper and Brothers in New York, contained the statement:

> "Estimating as nearly as possible the major limit of the cost of relaying, at the end of twenty years, the amount of an annuity (to use a term well understood) must be calculated which at the termination of twenty years would be equal to the cost of laying the rails; and an equivalent sum must be taken annually from revenue and invested at compound interest to meet the exigency."

This volume contains the earliest extensive discussion of the subjects of depreciation and of accounting for the cost of retirement of utility property found by the Society's committee.

Recognition by the Courts of the Necessity for Retirement Reserves.—

Not until 1909 did the Courts recognize the character of depreciation and provide, not only for the deduction of accrued depreciation, but also for making provision for maintenance of the integrity of the investment. In Knoxville vs. Knoxville Water Company (212 U.S. 1), Mr. Justice Moody said, on January 4, 1909:

> "Before coming to the question of profit at all, the Company is entitled to earn a sufficient sum annually to provide, not only for current repairs, but for making good the depreciation and replacing the parts of the property when they come to the end of their life. The Company is not bound to see its property gradually waste, without making provision out of earnings for its replacement. It is entitled to see that from earnings the value of the property invested is kept unimpaired, so that at the end of any given term of years the original investment remains as it was in the beginning. It is not only the right of the Company to make such a provision, but it is its duty to its bond and stockholders, and, in case of a public service corporation at least its plain duty to the public."

In the following month, February, 1909 (in R. R. Com. of Louisiana vs. Cumberland Tel. and Tel. Co., 212 U.S. 414), the Supreme Court said:

> "That it was right to raise more money for depreciation than was actually disbursed for the particular year there can be no doubt, for a reserve is necessary in any business of the kind, and so it might accumulate, but to raise more than enough money for the purpose and place the balance to the credit of capital upon which to pay dividends cannot be proper treatment."

These two cases are quoted because the opinions were handed down before the public utilities came under general regulation and only two years after the first classification of Railroad Accounts was issued by the Interstate Commerce Commission. Thus, right at the beginning of regulated accounting in the United States, there was clear recognition by the U. S. Supreme Court of the propriety of the creation of reserves to maintain the integrity of the investment by restoration to the corporation of the cost of all units of property worn out and equally clear warning against the accumulation of excessive reserves.

On May 21, 1934, Columbus Gas and Fuel Company vs. Public Utility Commission (292 U.S. 398), the opinion was handed down by Mr. Justice Cardozo. This case, and a companion case (Dayton Power & Light Co. vs. P.

U. Commission 292 U.S. 290), decided on April 30, 1934, involved large allowances for depletion in natural gas fields. The Court said:

> "To withhold from a public utility the privilege of including a depletion allowance among its operating expenses, while confining it to a return of 6½% upon the value of its wasting assets, is to take its property away without due process of law, at least where the waste is inevitable and rapid. * * * Plainly the State must either surrender the power to limit the return or else to concede to the business a compensating privilege to keep its capital intact. * * * It is idle to argue that a company using up its capital in the operations of the year will have received the same return as one that at the end of the years has its capital intact and interest besides."

These cases, and three telephone cases, later quoted in this discussion (the New York Telephone Case, 271 U.S. 23, April, 1926; Smith vs. Illinois Bell Telephone Co., 282 U.S. 133, December; 1930, and Lindheimer vs. Illinois Bell Telephone Co., 292 U.S. 151, April, 1934), are among the many cases which sustain the proposition that the cost of retiring units of property no longer useful in the manufacture of goods or the rendering of public service is part of the cost of service and is properly chargeable to operating expenses and thus paid for by the consumer of the goods or services. The creation of reserves for this purpose and the attempt to spread the cost over the life of the units of property with some reasonable degree of uniformity is fully sustained by a long line of U. S. Supreme Court opinions.

Accounting for Retirement.—

As already stated, the creation of reserves to collect the cost of retirement of units of plant during the life of these units has been in use for over a century. It obviously had its beginning in the accounting of manufacturing, mercantile and marine property, and other privately owned property.

Apparently during the nineteenth century some form of interest method was in quite general if not universal use. The early references which the Society's committee has found all speak of "sinking funds" or "annuities." In 1897 Mr. Kuichling[3] said "As the gradual formation of a fund by a series of annual payments is generally understood only in a vague manner outside of financial circles, a few words on the subject may be permitted." In that same decade the published papers of Mr. Dow make it evident that the electric power industry, then in its infancy, recognized the need of reserves but had no definite plans for their creation. Mr. Dow was an advocate of reserves as early as 1895.

VI.—THE STRAIGHT-LINE METHOD

The straight-line method was defined, or described, by the late Joseph B. Eastman, on November 2, 1926 (118 I.C.C. 353), as follows:

> "First of all the total depreciation expense is determined by estimating the service value of the property in question. This requires not only a ledger value corresponding as nearly as may be to original cost, but also an estimate of net salvage value at the time of prospective retirement and a similar estimate of service life. Finally the annual depreciation charge is determined by dividing the estimated service value by the estimated service life. The purpose of this method of determining depreciation charges is to spread the entire expense evenly over the property in question."

The accounting profession recognizes the straight-line method as a simple method of spreading the cost of a unit of property over the estimated life of that unit by collecting each year an equal part of the estimated cost less estimated salvage without the use of any interest accrual. In the case of a machine shop, printing office, or other privately owned plant, where the cost of all machines is known, where the sole object is to charge enough for the product to cover the cost of wearing out of the machines which make it, and where "conservatism" (that is, possibly excessive charges to depreciation) is not legally forbidden, the plan undoubtedly has great merit. It is evident that small isolated municipally owned utilities can make good use of reserves collected by this method and undoubtedly there are some special instances of privately owned utility properties which could use the straight-line method to advantage and without serious grounds for criticism.

The "Comments of the Committee of the American Institute of Accountants on the NARUC Committee Report" said of the straight-line method:

> "This Institute has for many years been engaged in a campaign in which it has sought to stress equally strongly the indispensability of accounts and the inescapable limitations on their significance. Straight-line depreciation is a crude process of allocation based on working hypotheses that must be constantly reviewed, and on incomplete and in some cases irrelevant statistics which must be constantly supplemented. To apply to such raw material highly refined mathematical processes would be to create an even more delusive suggestion of certitude than that to which Mr. Justice Jackson referred."

The reference to Mr. Justice Jackson in the above quotation relates to his dissenting opinion in the Hope Natural Gas Case which is in part as follows:

> "To make a fetish of mere accounting is to shield from examination the deeper causes, forces, movement and conditions which should govern rates. Even as a recording of current transactions, bookkeeping is hardly an exact science. As a representation of the condition and trend of a business, it uses symbols of certainty to express values that actually are in constant flux. * * * However our quest for certitude is so ardent that we pay an irrational reverence to a technique which uses symbols of certainty, even though experience again and again warns that they are delusive."

Mr. Justice Brandeis, who had an exceptionally clear understanding of accounting problems, in his dissenting opinion in United Railways and Electric Company vs. West (280 U.S. 234, 276–277, January, 1930), discussed the subject of accounting reserves in part as follows:

> "For an annual depreciation charge is not a measure of the actual consumption of plant during the year. No such measure has yet been invented. There is no regularity in the development of depreciation. It does not proceed in accordance with any mathematical law. There is nothing in business experience, or in the training of experts, which enables man to say to what extent service life will be impaired by the operations of a single year, or of a series of years less than the service life.[13]"

Footnote 13 of the opinion reads as follows:

> "Depreciation of physical units used in connection with public utilities, or, indeed, with any other industries, does not proceed in accordance with

> any mathematical law. * * * There is no regularity in the development of the increasing need for repairs; there is no regularity in the progress of depreciation; but, in order to devise a reasonable plan for laying aside allowances from year to year to make good the depreciation as it accrues, and to provide for the accumulation of a sum equivalent to the cost less salvage of a unit by the time it is retired, some theory of depreciation progress must be assumed on which such allowances may be based. 81 Am. Soc. Civil Eng. Transactions (1917) 1311–1462–3."

This quotation by Mr. Justice Brandeis is from the report of the Society's Committee on Valuation hereinbefore mentioned,[8] of which the late Frederic P. Stearns, Past-President, Am. Soc. C. E., was Chairman. This long dissenting opinion of Mr. Justice Brandeis, supplemented by that of Mr. Justice Stone who agreed on the subject of depreciation, constitutes one of the most complete legal discussions on the subject extant. Only a few more sentences of this opinion of Justice Brandeis need be quoted:

> "The main purpose of this charge (to operating expenses for 'depreciation') is that irrespective of the rate of depreciation there shall be produced, through annual contributions, by the end of the service life of the depreciable plant, an amount equal to the total net expense of its retirement. To that end it is necessary only that some reasonable plan of distribution be adopted. Since it is impossible to ascertain what percentage of the service life is consumed in any year it is either assumed that depreciation proceeds at some average rate * * * or the annual charge is fixed without any regard to the rate of depreciation. * * * It is a bookkeeping device introduced in the exercise of practical judgment to serve three purposes. It preserves the integrity of the investment. * * * It serves to distribute equitably throughout the several years of service life the only expense of plant retirement which is capable of reasonable ascertainment—the known cost less the estimated salvage value. And it enables those interested * * * to ascertain as nearly as possible the actual financial results of the years operations."

Every time $1,000 is charged to operating expenses for "depreciation" and credited to the "reserve," $1,000 is held back from net revenue, from the stockholders, and left as cash for the management to spend for new plant or for other legitimate corporate uses. There are a number of corporations which invest part of the money in securities until needed for construction but the general practice on expanding properties is to invest it in new plant. All retirements, less salvage, are charged to the reserve. The resulting credit balance is a bookkeeping entry representing all prior charges to operating expense, less all retirement. It is usually not maintained as a cash reserve. It is never available to the investor except in case of partial or complete liquidation of the property.

The expenditures for new plant to the extent of past retirements assist in fulfilling the function of "maintaining the integrity of the investment." It is new property replacing retired units of property and to that extent the method should not be a matter of controversy. That, however, does not relate to the credit balance in the reserve as upon the retirement of plant the resulting charge reduces the credit balance. Property previously retired is not represented in the credit balance of the reserve which is available for unmatured depreciation.

Some form of a reserve is essential to provide for future retirements. There can be no legitimate objection to a reserve, or surplus, of reasonable size to provide for future retirements, some of which can be foreseen with reasonable certainty a few years in advance, and some of which are the result of flood, sleet and ice storms, lightning or other disasters which frequently take a heavy toll of railroad, power, telegraph and telephone property. Such reserves have been approved again and again by the U. S. Supreme Court, but the Courts have been interested in the size of the reserve rather than the method of accrual. The Courts' warnings against excessive reserves, the obviously excessive nature of "straight-line" accumulations, and the fact that in many litigated cases accrued depreciation has been found to be much less than the straight-line reserve, all point to much lower provisions for retirement than have been used in the past by many corporations. The U. S. Supreme Court's decisions in a number of cases refer to experience as the proper guide to the establishment of reserves.

It is very clear, in the light of many U. S. Supreme Court decisions, that there is no legal justification for making provision for anything more than reserves sufficient to reimburse the corporation for the cost of all plant retired for any reason and for maintaining a balance sufficient to provide for depreciation in progress but not yet reflected in retirements. Any theory or any method of accounting that builds up reserves in excess of a reasonable balance or surplus for that purpose is almost certain to lead to controversy and litigation.

It is also true that, at the present time, the law is clear that credit balances that have been accumulated in the past under regulated accounting belong to the company. That fact, however, does not justify continuing charges to operating expenses at rates that are in excess of the actual provable requirements.

In the New York Telephone Case (271 U.S. 23–32), in 1926, the Court said:

> "It may be assumed * * * that in prior years the company charged excessive amounts to depreciation expense and so created in the reserve account balances greater than required adequately to maintain the property. * * * The revenue paid by the customers for service belongs to the company. The amount, if any, remaining after paying taxes and operating expenses, including the expense of depreciation, is the company's compensation for the use of its property * * * customers pay for service, not for the property used to render it. * * * Property paid for out of moneys received for service belongs to the Company, just as does that purchased out of proceeds of its bonds and stock. * * *"

This case was approvingly quoted by Chief Justice Hughes in Smith vs. Illinois Bell Telephone Company (282 U.S. 133–158) in December, 1930:

> "While it has been held by this court that property paid for out of moneys received for past services belongs to the company, and that the property represented by the credit balance in the reserve for depreciation cannot be used for imposition of a confiscatory rate (citing 271 U.S. 23) it is evident that past experience is an indication of the company's requirement for the future. The recognition of the Ownership of the property represented in the reserve does not make it necessary to allow similar accumulations to go on if they are excessive."

It is significant that the court suggests a change in the annual allowance as contrasted to the NARUC Retroactive Adjustment of the reserve.

The inevitable conclusion to be reached from a study of the opinions of the

U. S. Supreme Court is that any method that is shown by experience to provide a sufficient reserve is legal. "Some average rate * * * or the annual charge is fixed without any regard to the rate of depreciation" would satisfy Mr. Justice Brandeis' requirement. All of the opinions limit the amount of money to be raised to the amount of the retirements, to "maintaining the integrity of the investment." The capital of the corporation must be furnished by stock and bondholders—not by ratepayers. Capital consumed by the wearing out of plant in furnishing service is to be restored to the property by the consumers through charges to operating expenses. It must again be emphasized that this is in no sense a return of money to the investors whose money built the plant. It is money that is to remain in the plant to restore the loss in service value caused by depreciation.

The essential difference between the thoughts expressed by the two committees is that the report of the NARUC committee says in substance that the reserve, when properly computed, is the best measure of accrued depreciation, whereas the Society's committee states that the accrued depreciation is factual in nature and that the amount of such accrued depreciation should be included in the amount of the reserve. No member of the Society's committee would take exception to the use of the reserve when properly computed as a measure of accrued depreciation, but the NARUC committee goes further and recommends (Conclusion 26) "The straight-line method is generally recommended for public utility accounting and financial purposes and also for the computation of both depreciation expenses [annual allowances] and accrued depreciation for purposes of rate making." Such a method, in the opinion of the Society's committee, is not a proper one, if the reserve is to be used as a measure of accrued depreciation. Objection is taken to the use of a reserve as a measure of accrued depreciation, unless the reserve is in reasonable conformity with the actual depreciation.

Accrued depreciation, which manifestly involves many variables, should be determined on its own merits, and the reserve accumulated to cover it, and adjusted to it, by means of changes in the annual allowances. It would seem that such a plan would be the only means available for checking the propriety of the annual allowances. The basic thing sought is the determination of actual depreciation, and the provision of a reserve that is at least equal in amount to it, which reserve is accumulated through annual allowances for depreciation. To fix the accrued depreciation by the reserve set up by allowances, determined by any method, is fixing an item factual in nature, and possible of determination within reasonable limits, by an item that should be subject to frequent changes as conditions change. The object of the reserve is to provide for the actual depreciation and not to have the actual depreciation (a factual matter which cannot be changed) equal to the reserve. It is axiomatic that accrued depreciation which automatically integrates all the time variables can be more accurately estimated than the annual allowance. It therefore should be the starting point.

The NARUC committee recommends that the actual depreciation should be determined by application of the straight-line method, which entails the assumption of probable average useful lives for the different units or groups of units involved, and that the loss in service value would occur in equal annual amounts. The facts are that most adherents to the straight-line theory, of necessity, use tables or probable useful lives prepared by different authorities, mostly general in nature, and having no connection with the property being studied. The term, "of necessity," was used above as very few properties have mortality statistics that can be considered more than roughly indicative, and usually those that have such data do not have them for anything other than mass property. Most mortality statistics relating to mass property are derived from dollar ages, the only ages readily available, rather than property ages. With widely fluctuating prices over the years, the difference may be very substantial. It is probable that no public utility property can ever have mortality statistics on any large percentage of its plant account. Such statistics are of little conclusive value unless they are in the nature of mass data. No property will have mass data on retirements of such items as buildings, boilers, turbines, water purification plants, pumping equipment, and the like. It is probable that the average utility plant, with the possible exception of water works and gas properties having a majority of their investment in pipe lines, would never be able to have conclusive mass data on more than a small percentage of its property.

Even when mortality statistics are available, they cover, generally speaking, units that are not the same as those upon which the amount of accrued depreciation is being determined. Also they cover units retired during a different period and under different conditions. They also cover premature retirements due to casualty, such as storms, fire, automobile collisions and the like. It would seem illogical to say, for instance, that a new pole line had accrued depreciation existing at the start of its use, due to the fact that it might be wrecked by storm during the first year of its life. Saying it another way, the service value of the pole line at any one time would be less because some day the line might be wrecked by storm. That is exactly what takes place when age-life methods are used with useful life figures based upon mortality statistics that include such casualties.

There are many reasons why mortality statistics covering units of property in public utility systems should be used with care, as a basis of determining useful lives for use in age-life calculations. The main reason is that such statistics do not now, and probably never will, show any consistency of "dispersal pattern." The NARUC report likens mortality statistics obtained from utility retirement records to vital statistics upon which life insurance premiums are based, and states that such mortality statistics can be used as a safe means of useful lives for utility property. Vital statistics used by life insurance companies do show a fairly constant "dispersal pattern," but even those statistics are not infallible. This fallibility was recognized by Mr. Justice Brandeis in his dissenting opinion in Pacific Gas and Electric Company vs. San Francisco and in which Justice Holmes concurred, as follows:

> "A depreciation charge resembles a life insurance premium. The depreciation reserve, to which it is credited, supplies insurance for the plant against its inevitable decadence, as the life insurance reserve supplies the fund to meet the agreed value of the lost human life. To determine what

> the amount of the annual life insurance premium should be is a much simpler task than to determine the proper depreciation charge. * * * Moreover, for human lives, mortality tables have been constructed which embody the results of large experience and long study. By their use the required premium may be fixed with an approximation to accuracy. But, despite the relative simplicity of the problem, it was found that the variables leave so wide a margin for error that premiums fixed in accordance with mortality tables work serious injustice either to the insurer or to the insured. Although the purpose was to charge only the appropriate premium, the transaction resulted sometimes in bankruptcy of the insurer; sometimes in his securing profits which seemed extortionate; and rarely, in his receiving only the intended fair compensation for the service rendered. Because every attempt to approximate more nearly the amount of required premium proved futile, justice was sought by another route. Ultimately, strictly mutual insurance was adopted. * * *"

Even though it were possible to forecast accurately the life of a property or unit, the parallel between insurance and straight-line depreciation of utility property ends there, for insurance premiums are based on interest accumulating annual payments while straight-line depreciation neglects the interest factor.

It is apparent that very little conclusive mortality data exist so far as utility property is concerned, and that many of the available data are not properly usable as the basis of useful lives for a determination of accrued depreciation, although they may be valuable in its determination. This means that the selection of useful lives for use in age-life methods must be largely a matter of judgment.

One great difficulty in making the straight-line method seem practical to those experienced in the operation of utility property is the fact that, when it is applied to most properties, it results in many absurdities. There will usually be a number of items, actually in use, that should not be operating if the application of the straight-line method using customary useful life figures is accepted as gospel. The usual useful life placed on power plant buildings is 50 years. To illustrate by an actual case, a building from which, at the time it was 50 years old, the old equipment was removed, a new turbine installed, the building given minor repairs, from every known standpoint could be said to have as much value as a new building starting on a new life cycle. If the usual application of the straight-line method had been applied, this building would have been entirely written off about the time it received its new lease on life. The result of such accounting would have been that the ratepayers contributed the entire cost of building through annual allowances for depreciation, during what appears to be perhaps half its useful life. There are other examples, such as turbines that are topped, meters and transformers that are rebuilt, etc., which make the accurate estimating of useful lives very difficult.

When applied to most utility properties, the application of the straight-line method of determining accrued depreciation produces reserves that are so greatly in excess of the actual depreciation that the answer is manifestly wrong. The fault probably lies partly in the improper determination of useful lives in the particular property being studied, and is principally due to the fact that in actual practice depreciation does not take place in a straight line. The use of any age-life method of computing accrued depreciation, whether straight line, sinking fund, or present worth, is subject to the same inaccuracies so far as selection of useful lives is concerned. It is believed, however, that the interest methods more closely parallel the accrual of actual depreciation.

Perhaps the strongest argument against the use of any mathematically theoretical method of computing accrued depreciation is the fact that actual retirements in seasoned utility properties indicate the complete lack of a sound basis for them. The straight-line method is used quite extensively in industrial properties, and properly so in most cases, as the useful lives of the units making up a large part of the investment are short and amortization as well as depreciation is involved. In the case of utility properties, the reverse is true, as a majority of the units involved have relatively long lives, the property as a whole is continuing, amortization is not a factor in most cases, and equity to the consumers requires that the depreciation reserve be accumulated only as fast as the property is consumed in their service.

It is believed that the statement in the NARUC report to the effect that the use of the straight-line method of figuring both annual allowances for depreciation and accrued depreciation is in the ascendancy expresses a wish rather than a fact. It is true that certain governmental regulatory agencies favor such a plan, but it is certain that, in the field of the public utilities, there is no such ascendancy for determining accrued depreciation. In fact, as depreciation accounting becomes better understood, quite the reverse is true.

As stated previously, the Society's committee takes the stand that accrued depreciation is factual in nature and that accounting should fit the fact rather than let some uniform accounting rule determine what the facts are. This committee further states that, while accrued depreciation is a fact, its determination cannot be made by any mathematical formula or calculation, but must be based upon the consideration of all conditions existing, by someone thoroughly familiar with the design, construction, and operation of the property involved.

VII.—The Straight-Line Method was Developed by the Bell Telephone Companies

The earliest extended discussion in the present century of accounting reserves is to be found in the Annual Reports of the American Telephone and Telegraph Company. These were all signed by Theodore N. Vail, President.

Beginning with the report of 1907, under the captions, Maintenance and Reconstruction, it is pointed out that from 1903 to 1907 about $150,000,000 was spent on maintenance and reconstruction on plant which in 1907 had a value a little under $500,000,000.

In 1908 the report shows an expenditure of about $40,000,000 for these purposes, discusses "Permanency of Plant," and, under the caption "Depreciation," reports that studies were made during the year "to determine the actual rate of depreciation that should be provided for."

Beginning on page 5 of the report of 1910, under the caption "Depreciation," there is a long discussion on the subject of reserves from which the following quotations are taken:

> "The question of depreciation has been considered very critically and analytically during the past year, by commissions and other bodies, in connection with studies on the rate question. While a depreciation reserve was generally favored, there seemed to be a disposition to apply experience and theories, gleaned from other lines of business, to the telephone business.

* * *

> "The present policy of the Bell System is to provide against every probable contingency and to base the amount and extent of such provision on past experience—not on future expectations.

* * *

> "All of this has been made possible through the unremitting study and research of the staff of the Engineering and Experimental Departments of the Company, who by close attention, observation and study, anticipate and provide for all such contingencies and conditions as can possibly be anticipated or provided for in advance."

The next four or five paragraphs discuss the rapid development of the industry. Mr. Vail cited the need for improved construction in advance of hand-to-mouth needs of the day and referred to work then in progress which was estimated to cost $180,000,000, which, if it were to be built piecemeal, the portion then urgently needed would cost $112,000,000 at the time, but the whole job which was then under construction would total $250,000,000. Thus immediate construction of the whole job resulted in an estimated saving of $70,000,000. The subject is then closed with the following paragraph:

> "The capital for this advance construction must be provided by and at the cost of the present, as was the advance construction of the past provided by and at the cost of the past. To the extent that advance construction reduces the cost of necessary plant and anticipates reconstruction and replacement, to that extent the capital charge to be borne by present and future is reduced and to that extent it immediately puts the depreciation reserve to its intended use. The criticism that any excess of reserve is at the cost of the present for the benefit of the future is true, but only to the extent that it may be found eventually in excess of actual retirements. In any case it would be no more than might rightly be considered on insurance against obsolescence which cannot be foreseen."

In the 1911 Annual Report of the American Telephone and Telegraph Company, on pages 5 to 11, Mr. Vail went to the extreme in his argument for reserves created by charges to operating expenses. Space is available in this discussion for only one quotation of the many which the Society committee would like to use in presenting the argument made at that time for straight-line reserves.

> "There are however, in the conduct of business many conditions and possibilities which can not be met out of current net revenue and should not be met out of capital, but which if not provided for in some way would put all industrial companies on a speculative basis.
>
> "There is that obsolescence which comes from revolutionary improvements necessitating wholesale replacement of obsolete apparatus or plant, such as the replacement of overhead systems by underground systems, or such as took place when the present method of operating was introduced. There are those fluctuations in net revenue caused by business depression which cannot be overcome by immediate reduction of fixed charges, overhead expense or operating costs. There is that constant tendency to increase in

> wages and cost of material, that tendency to increase in operating expenses and capital charges caused by constant demand for increased efficiency of service, that demand for extensions, productive and unproductive, and that call for improvements in plant, equipment and apparatus. There is that increase in costs of operating in greater ratio than the increase in business, peculiar to some branches of the telephone service.
>
> "These and many other possibilities always confronting industrial and public service undertakings must be provided for. They are not the subject of capital expenditures, and can only be provided for by an accumulating surplus and reserves invested in productive plant or securities. If these are not provided for, trouble if not disaster or destruction is inevitable."

In the report for the year 1913, on page 10, is the following paragraph:

> "All of the present surplus and reserves aggregating $174,000,000 is invested in tangible and productive property the revenue from which enables the companies to maintain their efficiency, without paying capital charges on this amount."

The previously quoted paragraph from the Louisiana Telephone Case in 1909 seems to indicate that the Telephone Companies had reserves as early as that which were large enough to create the impression that this form of accounting (straight line) was creating excessive accumulations of money which were being invested in new plant.

The studies made by the Bell Telephone officials in the earlier years, 1905 to 1909, resulted in the development of the Accounting Classification of the Bell Telephone Company about 1909 or 1910. The classifications of the New York Public Service Commission and of the Interstate Commerce Commission issued in 1911 or 1912 were practically verbatim copies of the Telephone Company Classification with some slight rearrangement of paragraphs.

The Company has what are probably the most complete records of the life history of property retired over a long period to be found in any utility. Life estimates are based on these studies. Equally fine are the studies of retirements, salvage, cost of removal, etc. The many reports to state and federal commissions, exhibits in the many litigated cases of record, and other published statistics of the telephone utility, make available a great volume of statistical data. There are probably no more complete and accurate records extant than those of the Bell Telephone Companies.

VIII.—The Experience of the Telephone Utility with Accounting by the Straight-Line Method

In view of the great mass of statistical information available to the state and federal regulatory commissions and other governmental agencies it is a matter of considerable surprise that the NARUC committee in its study, extending over four years, did not investigate the actual results of the accounting methods in use by the telephone, railroad and electric utilities instead of setting up hypothetical computations.

The data drawn from various unimpeachable sources as to the actual experience over a long period of years furnish the best proof of the results of any particular method of accounting. Whether the results are adequate for the purpose or excessive, whether the hidden benefits, such as saving of interest to a corporation by the use of money represented by the credit balance in the reserve is substantial or not, can only be determined by an analysis of the record.

The Society's committee has made a partial study of the Bell telephone records available to its members. In order to obviate the use of many tables, and avoid great masses of dollar figures running into hundreds of millions or billions of dollars; and to reduce the figures to terms that will permit comparison of the results secured by the use of different accounting methods by different utilities, the tables showing charges to operating expenses, retirements, and growth of credit balances are generally stated in terms of percentage of fixed capital or depreciable plant. To indicate the magnitude of the amounts of money involved, the summaries of the conclusions of the committee are stated in dollar figures.

The telephone utility had its first beginnings in the late 1870's or early 1880's. During the last decade of the past century and the first decade of this one was the period of promotion when scores or hundreds of local telephone companies were organized in many cities and small areas; when such long-distance lines as existed were almost wholly in the hands of the Bell System and were in the process of expansion and development of equipment, and when many of the smaller companies and local systems were being absorbed by the Bell and other large companies.

During the next three decades the process of consolidation of companies, retirement of duplicate plant and of old and obsolete properties, and of invention and development went on. The annual reports of the Federal Communications Commission show that in 1930 there were 136 reporting corporations, whereas in 1938 there were only 73. In 1938 the Commission reported for these 73 companies the values listed as Item 1, Table 1. For the same year, Item 2 gives the statistics of the Bell System, which would indicate, for all other properties, the values given as Item 3, Table 1. The total credit balance in Item 2 is 27.84% of the total plant investment, or 30.1% of the depreciable plant. Obviously either the small properties have been unable to build up the reserves as rapidly as the Bell System or they began reserve accounting at a later date.

TABLE 1.—DEPRECIATION RESERVE DATA FOR 1938; REPORTS OF THE FEDERAL COMMUNICATIONS COMMISSION

No.	Description	Total investment in plant (dollars)	Depreciation Reserve	
			Dollars	Percentage of total
1	73 telephone companies	4,783,082,000	1,316,368,000	27.52
2	Bell Telephone System	4,489,078,000	1,249,563,000	27.84
3	All other properties	294,004,000	66,805,000	22.72

The statistics of the one system which has 93.85% of the total telephone investment in the country furnish an excellent illustration of the operation of the straight-line method.

From the early annual reports of the American Telephone and Telegraph Corporation we find that in 1907 the total investment in plant was a little under

$500,000,000. On December 31, 1913, this had increased to $820,885,000 of which 90% was classified as depreciable. The investment in plant steadily increased until it reached $4,183,236,000 in 1931 and for four years was practically stationary or slightly lower. In 1935 it was $4,187,790,000 since which it steadily increased to $5,387,790,000 on December 31, 1943.

During the period from December 31, 1913, to December 31, 1943, the credit balance in the depreciation reserve increased from $107,081,000 to $1,713,175,000. Thus it will be noted that while plant investment increased 556⅓% during the 30-yr period the credit balance in the reserve increased 1500%.

A careful study of the growth of the credit balance reveals the fact that, while its growth, in terms of percentage of depreciable plant, was negligible between 1917 when it was 20.55% of plant value, and 1933, when it stood at 22.63%, the lowest intermediate figure being 20.39%, the highest 25.39%, in terms of percentage of depreciable property the credit balance has increased, in dollars, every year since 1933 and at the end of 1943 stood at 34.34%, or more than one third of depreciable plant.

When the increase of the credit balance in dollars is considered, however, it is to be noted that there has been an increase every year in the terms of tens to hundreds of millions of dollars.

Col. 1, Table 2, shows the growth, in dollars, of the depreciation reserve as above analyzed, and Col. 2 shows the dollars of increase in each year. The total increase in the credit balance was $1,605,994,000 in the 30-yr period of which $914,923,000 came in the 11-yr period from December 31, 1932, to December 31, 1943, during which the investment in depreciable plant increased $1,138,467,000. Thus the money reflected by the increased credit balance in the reserve would have been sufficient to pay for more than 80% of the plant growth.

If Table 2 be again referred to it will be noted that from 1913 to 1926 the annual charges to operating expenses for "depreciation" (Col. 4) were in excess of the total retirements (Col. 5) in all years except one, while from 1927 to 1943 total retirements were substantially above the annual "depreciation" charge in all but the years 1935 and 1943. This fact apparently furnishes justification for the substantial percentages charged to operating expenses, but on the other hand is in conflict with the rapid growth of the credit balance. This calls for analysis.

Study of the statistics shows that plant retired over the entire period cost $4,184,461,000 while total charges to operating expenses amounted to $3,833,435,000, or $351,026,000 less than total retirements, whereas as already noted the credit balance increased more than one billion six hundred million dollars. This directs attention to salvage. The straight-line formula calls for an estimate of life of property and for an estimate of salvage. On actual retirement cost of retired property less net salvage is charged to the credit balance. Data for the analysis of the actual salvage of this more than four billion dollars worth of retired property are not available to the Society's committee, nor are they essential. Accounting accuracy has been almost a religion with the telephone staff for a third of a century and the results of that accounting may be accepted as correct. The point which the Society's committee desires to bring out is the extreme difficulty which will be encountered when an attempt is made to check salvage records kept under the straight-line method, or to order changes in that method, on a great far-flung property with an investment of hundeds of millions of dollars and with an accounting system less complete than that of the Bell Telephone Companies.

TABLE 2.—TELEPHONE RESERVE ACCOUNTING, ALL COMPANIES FORMING THE BELL SYSTEM

(Percentages in Terms of Depreciable Plant)

Year	Credit balance in depreciation reserve (thousands of dollars) (1)	Annual increase in credit balance (thousands of dollars) (2)	Credit balance in percentage of depreciable plant (3)	Charge to operating expense for depreciation (percentage of depreciable plant) (4)	Total retirements (percentage of depreciable plant) (5)
1913	107,181	....	14.55	5.01	5.10
14	122,338	15,157	15.58	5.15	5.07
15	142,307	19,969	17.38	5.38	4.60
16	168,044	25,737	19.25	5.63	4.55
17	201,090	33,046	20.55	5.35	4.26
1918	235,395	34,305	22.32	4.96	3.70
19	276,304	40,909	24.52	5.64	3.80
20	303,076	26,772	24.91	5.37	3.59
21	343,331	40,255	25.06	5.14	3.60
22	387,148	43,817	25.39	5.23	4.00
1923	434,129	46,981	24.78	4.97	4.06
24	476,374	42,245	23.07	4.87	4.37
25	519,023	42,649	22.33	5.01	4.80
26	564,541	45,518	21.86	4.98	4.93
27	584,762	20,221	20.93	5.05	5.51
1928	634,030	49,268	20.90	5.03	5.72
29	681,611	47,581	20.39	4.88	6.15
30	720,690	39,079	19.68	4.92	6.63
31	768,817	48,127	20.14	4.96	6.42
32	798,252	29,435	20.73	4.63	6.69
1933	876,373	78,121	22.63	4.34	4.96
34	950,628	74,255	24.46	3.87	4.22
35	1,042,011	91,383	26.65	4.31	4.20
36	1,124,809	82,798	28.38	4.06	4.30
37	1,195,269	70,460	29.43	3.98	4.66
1938	1,249,563	54,294	30.10	3.79	4.50
39	1,300,660	51,097	30.72	3.78	4.97
40	1,357,091	56,431	31.04	3.74	5.08
41	1,440,224	93,133	31.12	3.74	4.73
42	1,556,095	115,871	31.85	3.82	4.11
1943	1,713,175	157,080	34.34	3.95	2.86

Table 3 is derived from a table introduced by the New York Telephone Company and marked for identification in connection with the cross examination of a nationally known authority on accounting at Albany, N. Y., April 15, 1930. It is a summary of gross retirements of that company for the period 1910–1929 inclusive, sales excluded, showing the average percentage that each class of property is of total property retired during that 20-yr period together with the portion of original cost recoverable through salvage for each of these classes of property.

This 20-yr average percentage of net salvage on the retirement of nearly 193 million dollars does not, however, furnish any clue to the average annual net salvage from retirements during the 20-yr period. During these years the lowest percentage was 24.62%, the highest 59.02%. The average percentages for five years were less than 40% and five above 50%. This discussion of actual salvage experience is introduced to make it perfectly clear that the estimates of the "life" of plant or of "salvage" are not the simple matters that are indicated by the advocates of the straight-line method when the accounting deals with property of hundreds of millions of dollars.

TABLE 3.—TOTALS OF PLANT OF VARIOUS KINDS WITH NET SALVAGE THEREFROM RETIRED DURING PERIOD 1910–1929, INCLUSIVE

Acct. No.	Portion of property	Original cost, sales excluded	NET SALVAGE; SALES EXCLUDED	
			Dollars	Percentage of original cost
(1)	(2)	(3)	(4)	(5)
207	Rights of way	932,166	11,433	1.2
212	Buildings	6,253,816	1,020,156	16.3
221	Central office (C.O.) telephone equipment	31,717,472	4,416,055	13.9
222	Other equipment of central office	3,453,943	1,647,833	47.7
231	Station apparatus	54,691,545	40,384,344	73.8
234	Private branch exchange (P.B.X.) switchboards	31,473,557	21,313,744	67.7
234	Booths and special fittings	3,815,608	3,091,958	81.0
241	Exchange pole lines	8,935,427	1,909,547[a]	21.4[a]
242	Exchange aerial cable	7,858,225	1,547,781	19.7
251	Toll pole lines	4,390,289	176,142[a]	4.0[a]
252	Toll aerial cable	726,134	345,036	47.5
253	Toll aerial wire	3,073,548	1,285,938	41.8
244–14	Exchange underground (U.G.) conduit main	302,179	8,655[a]	2.9[a]
244–24	Exchange underground conduit subsidiary	123,459	4,673	3.8
245–15	Exchange underground cable main	9,543,735	5,477,389	57.4
245–25	Exchange underground cable subsidiary	7,289,682	165,782	2.3
246	Exchange submarine cable	270,556	52,672	19.5
254	Toll underground conduit	13,591	5,385	39.6
255	Toll underground cable	2,992,005	1,866,188	62.4
256	Toll submarine cable	329,493	105,750	32.1
261	Office furniture and fixtures	2,186,961	610,185	27.9
262	General shop equipment	67,734	29,492	43.5
263	General store equipment	206,897	74,400	36.0
264	General stable and garage equipment	3,547,095	563,462	15.9
265	General tools and implements	7,818,702	4,646,990	59.4
268	Interest during construction	920,730	....	....
274	Miscellaneous construction expense[b]	....	....	....
	Grand total	192,934,549	86,572,304	44.87

[a] Negative net salvage; that is, cost of removing exceeds gross salvage. [b] In view of special character of this small class of property, and of meager amount of available actual experience data relative thereto, quantities for this item have been omitted.

Table 3 brings out clearly the high percentages of salvage of telephone properties under the accounting plan of the telephone companies, higher probably than percentages to be found in any other utility industry due to the use, after restoration of many items of plant. This exhibit clearly shows the difficulty of the checking of accounts by people not familiar with these great properties.

Interest on the Credit Balance.—The credit balance in the reserve for retirement or so-called "depreciation" reflects money which has been collected from the ratepayers. Any excess over the total amount of retirements is usually invested in property additions. Mr. Vail stated in the 1913 American Telephone and Telegraph Company report that "all the present surplus and reserves is invested in * * * property * * * without paying capital charges on this amount." At that time the credit balance was well in excess of 107 million dollars and saving of interest was in terms of millions of dollars per year whatever rate be used for the computation. If simple interest be computed on all the credit balances over the 30-yr period shown in Table 2, Col. 1, it will be found to be the equivalent of one year's interest on more than twenty-one billion dollars. No matter what rate of interest be used the resultant saving to the corporation of interest on money used for legitimate corporate uses, such as construction of new plant, is found to amount to hundreds of millions of dollars.

Apparently this question of interest saved to the owning corporation by the use of money reflected by the credit balance has not been made an issue in any of the telephone cases involving rates and valuation in the past, although it was suggested by the company in the Lindheimer Case "that an adjustment might be made by giving credit in favor of the telephone users in an amount equal to 3½% upon the difference between the depreciation reserve and the amount deducted from the valuation for existing depreciation." No matter what method is adopted in accounting the fact is inescapable that the credit balance in the reserve reflects money that has been advanced by ratepayers through charges to operating expenses in excess of needs; that its use in construction of plant obviates the securing of capital on which interest or dividends would be paid; and that excessive reserves not only constitute what Prof. H. W. Hatfield in his books on accounting terms "hidden surplus" in themselves, but secure to the corporation a substantial return in the form of saving of interest. This subject is again referred to later in this report. No emphasis is placed on this important matter in the NARUC report.

Early in this discussion of the straight-line reserves of the telephone company attention was directed to the increase of the credit balance in terms of percentage of fixed capital. From December 31, 1930, to December 31, 1940, during which time the credit balance increased from 19.68% of depreciable plant to 31.04%, the increase of the credit balance amounted to $636,131,000. In that same period the total investment in plant showed an increase of $706,437,000. Thus it appears that during these years of depression when all American business was seriously affected, the equivalent of 90% of all the money for extension of plant was derived from operating expenses through the depreciation reserve.

The Bell telephone industry developed the straight-line method in its accounting before railroad accounting came under regulation and before any regulation of other utilities. It fully and frankly discussed its system of accounting in its annual reports, pointing out matters that were open to criticism. The method has done all that Mr. Vail predicted for it and the results probably exceed any early expectations of the officers.

The company has defended its position in many lawsuits. It has been sustained in the perfectly sound position that money collected through rates belongs to the company and that property which reflects reserves created by money paid for rates, under commission approval, also belongs to the company. The Smith and Lindheimer cases, however, have held that excessive contributions to reserves should not be permitted to continue and the Lindheimer Case places the burden of proof on the company to show that they are not excessive. As the law has been established by the opinions of the Court, the reserves are higher than needed for retirement and a reasonable balance to care for coming retirements. In the past they have served to build up an industry that has completely revolutionized the business and social communication system of the world, and through thorough research in this and other fields has perfected instrumentalities of service worth far more to the nation than any excess that has been paid by the patrons of the service.

The Bell Telephone Utility initiated and perfected its system of accounting just as the Congress approved public regulation of Railroad Accounting. As case after case involving utility rates and accounting practice has been decided by the Supreme Court a body of law has been built up which definitely limits the objectives of reserve accounting, and makes it very clear that the method used by the telephone and railroad utilities results in charges to operating expenses and the accumulation of reserve balances that are substantially in excess of permissible amounts.

IX.—The Experience of the Railroads with Accounting by the Straight-Line Method

The railroads of the United States have been under the regulation of the Interstate Commerce Commission since 1887, but the authority of the Commission was not extended to the regulation of Accounting until 1907. At that time the late Dr. Henry C. Adams was "In charge of statistics and accounts" for the Commission. Professor Adams had been statistician for the Commission from its organization and was familiar with conditions on the carriers. He was associated as a consultant on the Michigan Valuations of Railroads in 1900 and 1903. He was much concerned at the very large deductions for depreciation which were made by this and other later State Valuations on a number of decadent little railroads and on the then dying lumber roads and branch lines of the large systems into the timber areas of the states of Michigan, Wisconsin, and Minnesota. The introduction of depreciation of equipment as an operating expense account in the first classification was largely due to Dr. Adams' concern regarding the failure of many companies to make any provision in accounting for recouping capital losses due to retirement of road and equipment. Many of the larger roads made a practice of charging replacements, including many large additions or betterments, to operating expenses. The regulation of accounting resulted in the abolition of many very serious evils. The weaker roads, however, were unable to set aside reserves to maintain value even though the state valuations disclosed serious amounts of actual depreciation or loss of service value.

Depreciation of equipment was provided for in the first classification of accounts. The second classification in 1914 provided for depreciation of way and structures, but owing to the strenuous opposition of the carriers the creation of reserves was made mandatory for equipment and optional for way and structures. In the third classification of 1936 depreciation for way and structures was again left optional with the carrier.

The straight-line method is specified in railroad accounting. On pages 88 and 89 of the 1936 classification the following excerpts are to be found:

> "These charges for currently accruing depreciation shall be computed at such percentage rate of the ledger value of the equipment that the service value may be distributed under the straight-line method in equal annual charges to operating expenses and other accounts during the estimated service life of the equipment.
>
> * * *
>
> "(e) The carrier shall keep such records of equipment retirements as will reflect the service lives and value of salvage of each class of equipment; shall maintain in convenient and accessible form engineering and other data bearing on prospective service lives; and shall be prepared at any time upon direction of this commission to compute and submit for its approval, new percentage rates to take the place of those based on service lives or value of salvage found to be inaccurate."

The annual statistical reports of the Interstate Commerce Commission are among the most complete of all government statistics and furnish a wonderful record of railroad statistics and accounts for more than half a century but unfortunately do not permit a complete analysis of the accounting for depreciation until very recent years. Prior to 1934 the summaries for all class 1 carriers do not separate, on the balance sheet, either investment or depreciation, as between road and structures and equipment. As many carriers do not charge depreciation to operating expenses for road and structures at all, and those that do make only very limited charges, the resulting percentage that the credit balance is of the investment furnishes no clue to the effect of the required straight-line accounting for equipment.

Table 4, derived from the Commission's Table 155, "Development of Steam Railways—1890–1942," shows the total investment in road and equipment for all United States railroads and total reserves for depreciation. This shows the fairly rapid growth of investment in railroads from 1911 to 1930 and the complete lack of growth from 1930 to 1942, the latter year showing less total investment than 1930. During these years the growth of the total credit balance from 1.35% in 1911 to 13.78% in 1942 gives no indication of the effect of the straight-line method adopted in accounting for equipment and the resulting percentages of credit balance to investment place the total reserves in the class of those of the electric companies, but do not represent the effect of any "method."

An analysis of the 1942 statistics shows that of a total of $3,232,242,347 in the credit balance of reserves of class I carriers only $171,249,504, or 5.3% of this total, was accrued for way and structures, and $3,060,992,843, or 94.7%, was accrued for depreciation of equipment.

Not until 1934 did the statistics of the Interstate Commerce Commission show in the summarized balance sheets for all class I carriers the separation of the investment on the asset side and of the reserve for depreciation on the liability side as between way and structures, and equipment. To make this separation and prepare a table showing the growth of the reserve for equipment would be a difficult task which the Society's committee would not be justified in undertaking, if it were possible to do so.

In 1926, in the consideration of Docket 15100, the Interstate Commerce

Commission had a study made of the depreciation of equipment from the reports of carriers which made the separation between road and equipment in their returns. This was a smaller group than that analyzed in Table 4, having 81.3% of the investment and 81.1% of the amount of money in the credit balance. This study furnishes a basis for showing the rate of growth of the credit balance from 1914 to 1923 (118 I.C.C. p. 335). The Interstate Commerce Commission statistics give the data for all class I carriers from 1934 to 1942.

1919	19,300,121	1,009,322	5.23
1920	19,849,320	1,081,342	5.44
1921	20,329,224	1,237,030	6.08
1922	20,580,001	1,335,453	6.50
1923	21,372,858	1,408,461	6.59
1924	22,182,267	1,547,969	6.98
1925	23,217,209	1,681,291	7.24
1926	23,880,740	1,811,002	7.58
1927	24,453,871	1,946,798	7.96
1928	24,875,984	2,043,976	8.22
1929	25,465,036	2,169,736	8.52
1930	26,051,000	2,360,767	9.06
1931	26,094,899	2,520,738	9.66
1932	26,086,991	2,632,922	10.09
1933	25,901,962	2,707,942	10.45
1934	25,681,608	2,764,726	10.75
1935	25,500,465	2,771,404	10.86
1936	25,432,388	2,809,063	11.45
1937	25,636,082	2,950,848	11.53
1938	25,595,739	3,044,972	11.89
1939	25,538,157	3,102,779	12.18
1940	25,646,014	3,095,237	12.10
1941	25,668,984	3,240,145	12.62
1942	25,838,351	3,561,570	13.78

From these sources Tables 5 and 6 have been prepared. The missing years 1924 to 1933, inclusive, in Table 5, would undoubtedly show a much more rapid increase in the credit balance after 1929 as from that date to 1936 the investment in equipment was practically stationary.

Analysis of Table 5 shows that investment in railway equipment has increased more than one billion dollars from 1936 to 1942 while during the same period the credit balance increased $686,197,000, or enough to pay for two thirds of the increase.

Some advocates of the straight-line method contend that as a result of its use the reserve will ultimately reach 50% of the investment and remain substantially stationary. Table 5 shows that this condition has nearly been reached with railway equipment. The statistics of the Interstate Commerce Commission, if thorough analysis were to be made, would hardly sustain the contention that the 49.03% credit balance in 1942 represents the physical condition of the equipment at that time. It is noted from Table 155 in the Interstate Commerce Commission statistics that in every year since 1911 there has been an increase in tractive power of locomotives and in capacity of freight cars, the present-day locomotive having 86% more power and the freight car

[a] Roads that report depreciation of equipment. [b] Years 1914 to 1923, inclusive, from 118 I.C.C. pp. 334 and 335. Years 1934 to 1942, inclusive, from Annual Statistics of Railroads, Interstate Commerce Commission.

TABLE 6.—CREDITS AND DEBITS; EQUIPMENT RESERVES FOR DEPRECIATION
(From I.C.C. Annual Statistical Reports)

Year	Total credits to reserve	Percentage of investment	Total debits to reserve	Percentage of investment
1938	$199,893,533	3.63	$ 98,250,949	1.80
1939	183,451,275	3.35	126,829,566	2.31
1940	187,680,918	3.34	111,802,662	1.99
1941	197,276,722	3.36	81,658,354	1.39
1942	262,501,070	4.20	60,022,716	0.96

37% greater capacity. The old all-wooden cars have largely disappeared and steel or steel under frame cars have taken their place. It is further noted that the highest average traffic densities on all class I carriers between 1910 and 1940 were in the years 1926 to 1929, the highest being 1,732,295 ton miles per mile of road in 1926. Densities of 1,950,166 in 1941 and 2,638,067 in 1942 do not indicate a physical condition of equipment corresponding to the percentage shown for the reserve balance.

Examination of individual reports of carriers shows great differences in the percentages of the reserve for "depreciation" in the road accounts, ranging from nothing at all to 4% or 5%, but in the required accounting for equipment all of them show high percentages ranging from 45% to 49% and in a few cases of small roads with a limited amount of equipment the reserve exceeds 50%.

The most noticeable result of an analysis of these "straight-line" reserves is that, in periods of depression or other economic disturbance, the charges to operating expenses greatly exceed the retirements and actual accrued depreciation which would be deducted in valuation, and result in credit balances which reflect the collection of money from this source sufficient to defray a very large part of the cost of new construction. That is not the purpose for which depreciation reserves are set up.

To illustrate: (1) The reports of the Federal Communications Commission show that, from 1930 to 1938, the credit balance in the "depreciation" reserves of class A telephone companies increased $554,022,000, or 72.6%, while in the same period the total investment in plant of these companies increased $565,372,000 or 13.4%. In other words, the increase in the reserves provided more than 97% of the money needed for plant extension during this period of economic depression. (2) The reports of the Interstate Commerce Commission show that from 1930 to 1942, a period four years longer, the railroad plant account for all class I carriers decreased $212,650,000, or 0.81%, while the credit balance increased $1,200,803,000 or 50.8%. During the period there were many changes and great improvements in the equipment of the railroads of the nation.

The Society's committee points out these facts as they are reported by the commissions for the purpose of showing the results of straight-line accounting. Undoubtedly the money reflected in the reserve balances of the railroads went far to put them in condition to handle the greatest traffic in their history in the years immediately following this 11-yr period. However, financing plant additions is not the purpose for which depreciation charges are made.

The statistics that have been cited as to the two great industries, one of which may be said to have originated the straight-line method as a means of creating reserves for retirement, the other of which was compelled by the Interstate Commerce Commission to use it, are presented to substantiate this committee's belief that the straight-line method accrues substantially more than is a proper reserve for retirement of plant, and that it is not a simple but a very involved method which has been, and is, difficult and costly for commissions to regulate.

X.—The Experience of Industries Which do not Use Straight-Line Method

Water Works.—

The Committee on Depreciation of the American Water Works Association (A.W.W.A.), in a study of 181 privately owned water works properties, reports for the year 1943 the following figures:

Total depreciable property	$282,082,402
Retirement reserves	38,092,121 (13.4%)
Annual depreciation allowance	2,820,540 (1.0%)

Similar figures for 107 municipally owned water works are reported in the August 1944 Journal of the A.W.W.A. as follows: Total depreciable property $1,047,000,000, depreciation reserves equal to 27% of depreciable property and annual depreciation allowances of 1.77%. Publicly owned utilities commonly accrue excessive reserves as a deterrent to the diversion of profits to other channels and to provide funds required for new construction without the necessity of bond issues.

Gas Companies.—

The Committee on Depreciation of the American Gas Association has recently made a study of 72 privately owned properties.

The committee's study reveals the following facts:

Total plant accounts	$6,650,836,000
Retirement reserves exclusive of depletion	1,018,701,000 (15.3% of plant cost)

The Committee of the American Gas Association states that "The essential purpose of a retirement reserve is to provide a reserve adequate for the retirement of major units of property, not taken care of by maintenance, and to equalize large retirement losses over periods of years." This is an excellent statement of what is actually being done by most of the properties which do not use the straight-line method.

Natural Gas, Pipe Lines, Etc.—

The Society's committee has made no study of the practice of these utilities in the matter of reserves for depreciation or amortization. Gas reserves and in some cases the pipe lines from them are wasting assets. The problem with them is amortization rather than depreciation so far as the wasting assets are concerned.

The Electric Power Utility.—

The Electric Power Utility has used for many years the classification of the NARUC and, since 1937, the almost exactly similar classification of the Federal Power Commission. The NARUC Classification reads as follows:

> "Each utility shall record as at the end of each month the estimated amount of depreciation or amortization and depletion accrued during that month on utility plant subject to charges for depreciation, amortization and depletion."

The Federal Power Commission classification differs only by one word; the word "utility" plant is changed to read "electric" plant; and, on page 89, the classification provides for six subdivisions: Steam, Hydro and Internal Combustion Plants, and Transmission, Distribution, and General Plant.

This leaves the estimating of a proper and reasonable charge to the management of each company, without any restrictions as to the method of making

1940	2,358,328	57,745	2.45	33,805	1.43	400,555	16.98
1941	2,430,894	62,059	2.55	35,023	1.44	430,500	17.70
1942	2,493,766	66,052	2.65	25,253	1.01	472,953	18.97
1943	2,493,233	66,584	2.67	20,837	0.84	499,732	20.04

the estimate, but subject to the approval of the commission in control. This is a wise provision as there are great differences in the requirements of different companies in any industry, and also between industries. This provision is primarily a matter for determination by the management subject to the orders of the regulatory body. There now exist records under regulated accounting of from 25 to 30 years of actual retirements, salvage and other matters upon which most companies can base their estimates of their annual requirements which will maintain an adequate reserve. Since the year 1937 estimates have been subdivided as prescribed by the Federal Power Commission.

[a] During this period, book value increased from approximately $50,000,000 to approximately $289,000,000, or 477%. The major part of this growth, 330%, to $215,000,000, was from 1918 to 1931; hence the more rapid growth of the reserve from 1931 to 1942. The 1937 cost was $247,200,000. Credit balances were as follows:

Year Balance
1918 = $ 1,050,000
1931 = 11,158,500
1937 = 21,679,000
1942 = 31,501,000

The Financial Record of the Electric Utility Industry 1937–1942, issued in December, 1943, by the Federal Power Commission, to the industry as a whole, gives the data presented in Table 7.

It will be noted from Table 7 that while the book cost was increasing 7.2% the credit balance increased 54.2%, again reflecting the rapid increase in the reserve balance in periods of slow growth of plant.

In order to get comparable figures with those of the straight-line method as used by the telephone industry for the whole period 1918 to 1942, the Society's committee has used the percentage figures developed in a study by the Edison Electric Institute of seventeen companies with a plant total of $2,493,233,000,

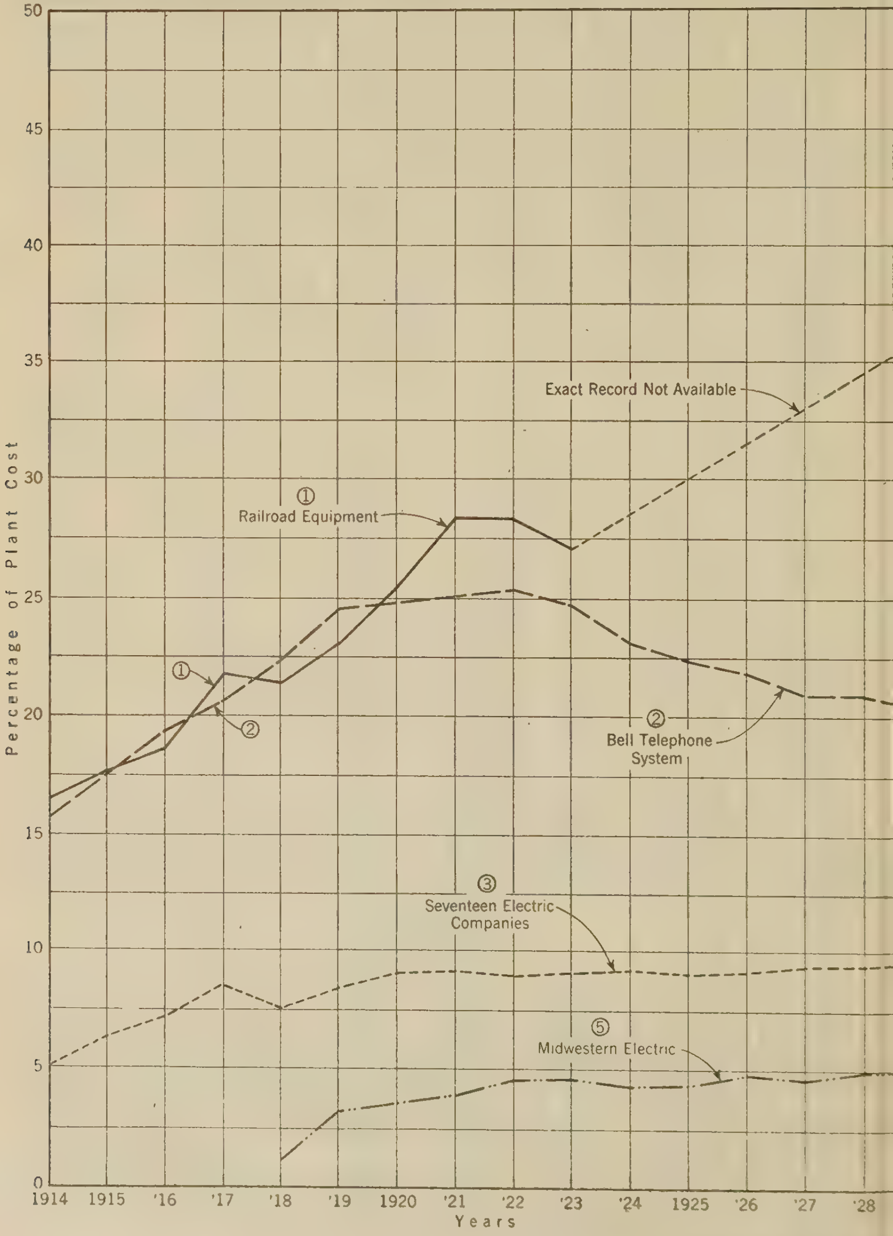

Fig. 1.—Growth of Credit Bala

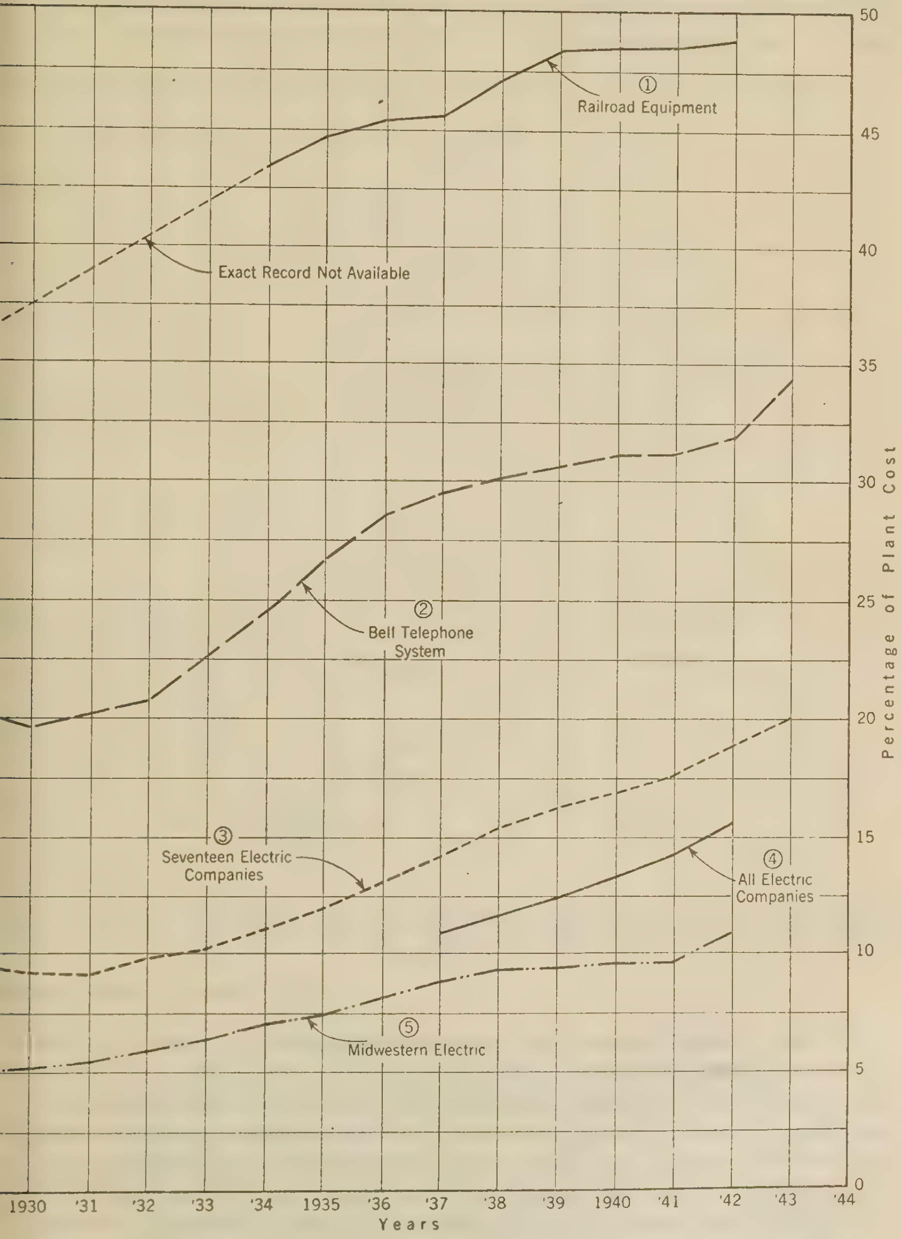
and also a study of a state-wide midwestern electric utility in the $300,000,000 class. These figures appear in Tables 8 and 9.

Table 8 shows the consolidated figures, in dollars and percentages of plant cost, the credits to the reserve (which in all cases are principally made up of



RESERVES FOR RETIREMENT

charges to operating expense for depreciation); debits to the reserve (net retirements); and credit balance in the reserve. It will be noted that in every year of the period credits exceeded debits in both dollars and percentage of total value of plant; consequently the credit balance in the reserve steadily increased from \$9,364,000, or 4.25% of the book value of plant in 1913, to \$499,732,000, or 20.04% of the immensely larger value of the plant thirty years later.

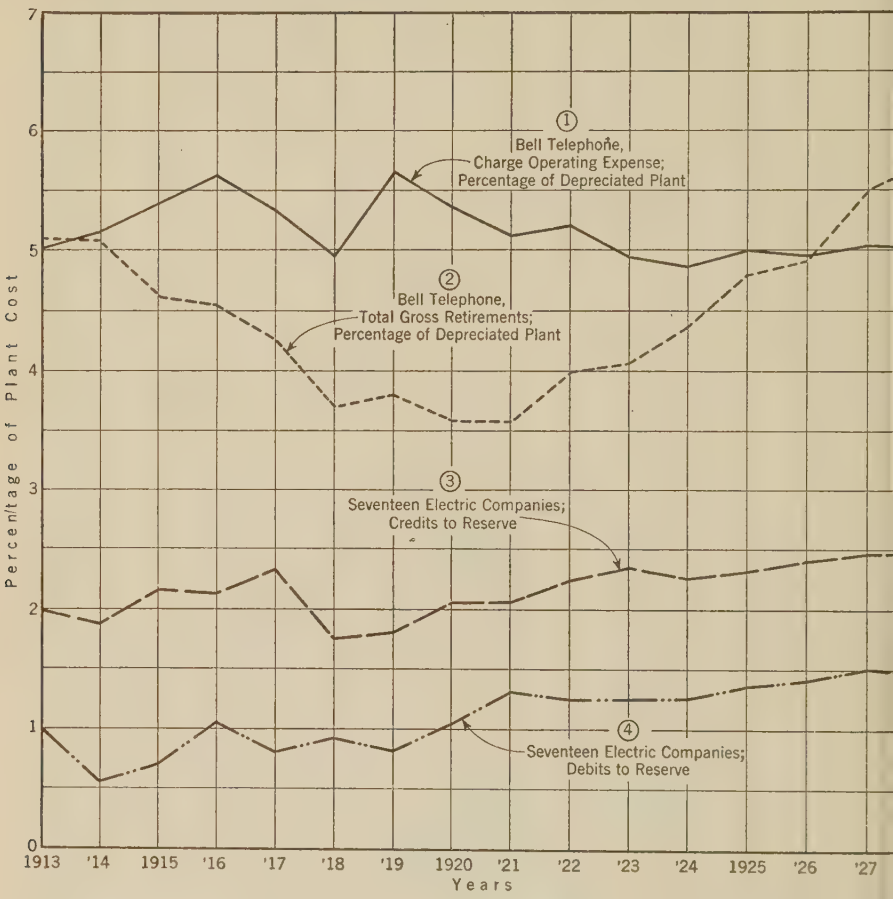


FIG. 2.—CREDITS AND DEBITS TO RES

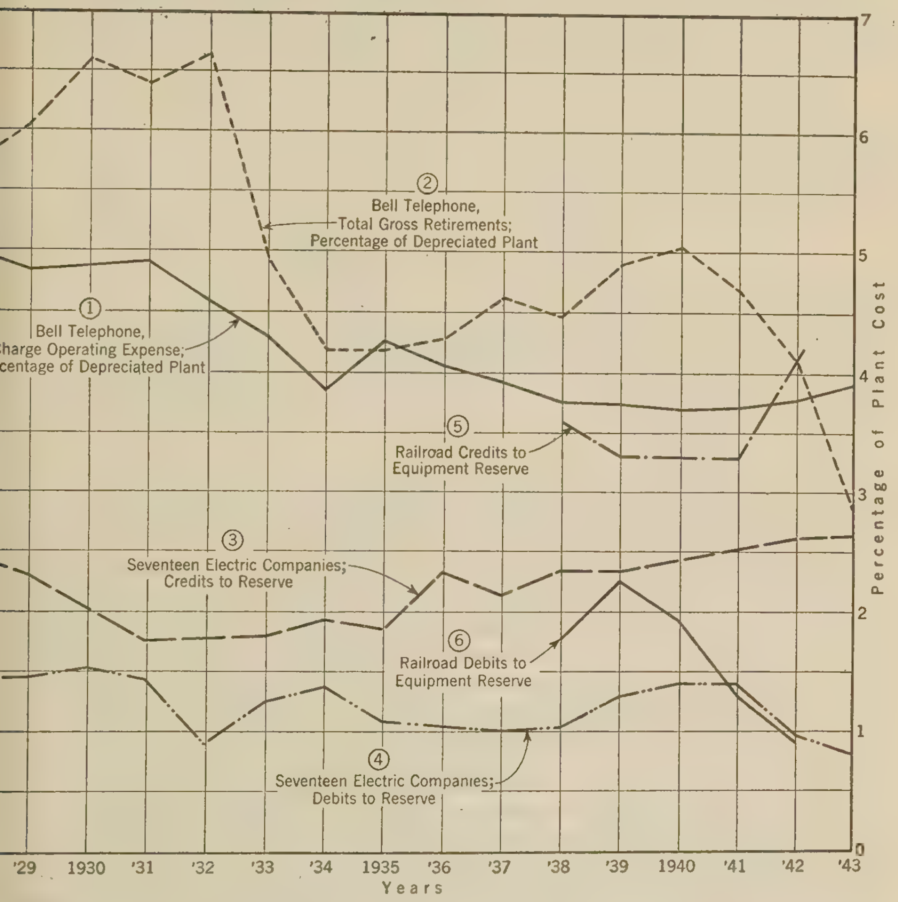
In view of such a showing, or the similar showing of the data of the midwestern single plant (Table 9), or the Federal Power Commission data for five years covering the whole industry (Table 7), the Society's committee cannot agree that, speaking of the industry as a whole, there is any necessity for more ample reserves; that there is any possible justification for recomputing retroactively on the straight-line method; or that there is any justification for the deduction for "depreciation" of any amount computed on a straight-line basis.

It is believed that these records may be accepted as fairly typical of the results in the power industry of the method provided for in the present accounting classification. When the results from this far from complete study of existing records of the telephone and railroad equipment reserves treated by the use of the straight-line method and those of the Electric Corporation reserves, built up under the present NARUC accounting requirements, are compared in Figs. 1 and 2, it is perfectly evident that the straight-line method as used by the Telephone Utility and for railroad equipment results in credit balances very greatly in excess of those where judgment based on experience is the guide.



ERMS OF PERCENTAGE OF PLANT COST

These studies indicate that, as an average, the utilities covered maintain adequate balances in the reserve, although some individual companies may have balances which are either too large or too small. When a method has been in use for 25 or 30 years and in not one year of the period have retirements and other debits to the reserve been sufficient to reduce the dollars in the credit balance—but on the other hand the credit balance has steadily grown year after year, and unless it can be shown that the reserve is less than the amount of actual accrued depreciation—it cannot be said that the company is not making adequate provision "to keep the investment intact."

Careful Analysis of Statistics Necessary.—

The committee is fully convinced that Retirement Accounting, as now used by the electric, gas and water works industries, is in general providing credit balances in the reserves that are ample. Table 10 has been prepared to summarize and compare some of the figures already given.

TABLE 10.—SUMMARY AND COMPARISON OF DATA

Year	Utility	Investment in plant	Credit Balance in Reserve		Method of computing depreciation
			Dollars	Percentage of investment	
1943	Telephone...........	4,990,000,000	1,713,175,000	34.34	Straight line
1941	Railroad (equipment).	5,752,904,000	2,467,735,000	42.9	Straight line
1943	Gas	6,650,836,000	1,018,701,000	15.3	Other than straight line
1942	Electric.............	14,848,000,000	2,306,000,000	15.5	Other than straight line
1943	Water works (private).	....	....	13.4	Other than straight line
1943	Water works (public) .	....	....	27.0	Predominantly straight line

The total amount of money that has been collected from ratepayers over and above past retirements that have been charged to "depreciation," now probably well in excess of eight billion dollars, for all these groups of utilities, directs attention to the magnitude and importance of this form of accounting. Only the railroads, the largest in investment of all the utilities (and which in general apply it only on equipment), and many of the publicly owned water works use the straight-line formula. These figures are doubtless somewhat in excess of the total amount needed for retirement reserves. It must be clearly understood, however, that a very large part of these balances are proper and fulfill the purpose for which they were created and approved by the Courts.

The Society's committee does not condemn the straight-line formula or contend that it should not be used in accounting. It does, however, believe that on large, far-flung utilities it results in the accumulation of credit balances that are substantially above any needed requirement, and that, due to the fact that its accumulations have no relation to actual depreciation, and that the use of it tends to cause managements to consider the reserve a mere matter of formula and not to give this important subject sufficient attention, its use should not be required.

Those who advocate the use of the straight-line method usually adopt average lives in its application rather than those derived from a special study of the mortality of units on the particular property, and without any check of the results of its application in the relationship between the size of the reserve and the actual depreciation in the property. This may and often does result in wide variation from the truth, and in gross inequity.

XI.—RECONSIDERATION OF "DEPRECIATION" IS ESSENTIAL NOW

There is unquestionably a present need for a full and complete discussion of the subject of accounting methods for creating reserves for plant retirement which is the maximum permissible size of those reserves, and for the final determination of the relationship of such reserves, actual depreciation, and the amount to be deducted in the determination of a rate base.

In connection with his discussion of Dockets 14700 and 15100 which dealt with proposed changes in telephone and railroad accounting, Mr. Eastman said, in November, 1926 (118 I.C.C. on p. 356):

> "It is essential to bear in mind, however, that there is an inseparable connection between the straight-line method and the principle that accrued depreciation represented by the depreciation reserve must be deducted in ascertaining the rate base value. If any other principle should hereafter be adopted by the courts a reconsideration of the entire question of depreciation would at once become necessary."

It is quite probable that this statement of eighteen years ago was prompted by the opinion of the Supreme Court in the New Jersey Telephone Case (271 U.S. 23) decided earlier in that year, which held squarely that the property which was represented by the reserve belonged to the company, just as much so as if it had been acquired through the sale of stocks and bonds. Obviously the doctrine stated by the Court in that case and later reaffirmed by Chief Justice Hughes in Smith vs. Illinois Bell Telephone Company (282 U.S. 133) is in direct contradiction of the theory stated by Commissioner Eastman in the statement just quoted. These Supreme Court opinions clearly prohibit the deduction of reserves which have been built up under regulated accounting. The subsequent opinion in the Lindheimer Case (292 U.S. 151), handed down in 1934 by Chief Justice Hughes, discussed the straight-line method at length. A study of this long opinion, which was a unanimous opinion of the Court, expanded somewhat in a concurring opinion of Mr. Justice Butler, makes it very clear that it is in no sense an approval of the straight-line method.

The Society's committee believes that the evident meaning of the Court is not to be found in any single paragraph and therefore includes a rather extended quotation from this most important opinion:

> "Broadly speaking, depreciation is the loss, not restored by current maintenance, which is due to all the factors causing the ultimate retirement of the property. These factors embrace wear and tear, decay, inadequacy and obsolescence. Annual depreciation is the loss that takes place in a year. In determining reasonable rates for supplying public service, it is proper to include in the operating expenses, that is in the cost of producing the service, an allowance for the consumption of capital in order to maintain the integrity of the investment in the service rendered. The amount necessary to be provided annually for this purpose is the subject of estimate and computation. In this instance, the Company has used the 'straight-line' method of computation, a method approved by the Interstate Commerce Commission. 177 I.C.C. pp. 408, 413. By this method the annual depreciation charge is obtained by dividing the estimated service value by the number of years of estimated service life. The method is designed to spread evenly over the service life of the property the loss which is realized when the property is ultimately retired from service.

"As the allowances for depreciation, credited to the depreciation reserve account, are charged to operating expenses, the depreciation reserve invested in the property thus represents, at a given time, the amount of the investment which has been made out of the proceeds of telephone rates for the ostensible purpose of replacing capital consumed. If the predictions of service life were entirely accurate and retirements were made when and as these predictions were precisely fulfilled, the depreciation reserve would represent the consumption of capital, on a cost basis, according to the method which spreads that loss over the respective service periods. But if the amounts charged to operating expenses and credited to the account for depreciation reserve are excessive, to that extent subscribers for the telephone service are required to provide, in effect, capital contributions, not to make good losses incurred by the utility in the service rendered and thus to keep its investment unimpaired, but to secure additional plant and equipment upon which the utility expects a return.

* * *

"The calculations are mathematical but the predictions underlying them are essentially matters of opinion. They proceed from studies of the 'behavior of large groups' of items. These studies are beset with a host of perplexing problems. Their determination involves the examination of many variable elements and opportunities for excessive allowances, even under a correct system of accounting, are always present. The necessity of checking the results is not questioned. The predictions must meet the controlling test of experience.

* * *

"In this instance, the evidence of expert computations of the amounts required for annual allowances does not stand alone. In striking contrast is the proof of the actual condition of the plant as maintained—proof which the Company strongly emphasizes as complete and indisputable in its sharp criticism of the amount of accrued depreciation found by the District Court in valuing the property. The Company insists that 'the existing depreciation in the property physical and functional, does not exceed 9 per cent in the years 1923 to 1928 and 8 per cent thereafter.' The existing depreciation as thus asserted by the Company, and the amounts it shows as the depreciation reserve allocated to the intrastate business in Chicago (taking in each case the average amounts per year) are as follows:

Years	Existing depreciation	Depreciation reserve
1923	$11,992,000	$26,797,000
1924	12,865,000	29,316,000
1925	13,775,000	32,155,000
1926	14,621,000	35,572,000
1927	15,360,000	39,352,000
1928	16,241,000	42,769,000
1929	15,300,000	44,515,000
1930	15,863,000	45,829,000
1931	15,828,000	48,362,000

* * *

"Giving full weight to these considerations, we are not persuaded that they are adequate to explain the great disparity which the evidence reveals. As the Company's Counsel says: 'The reserve balance and the actual depreciation at any time can be compared only after examining the property to ascertain its condition; the depreciation, physical and functional, thus found can be measured in dollars and the amount compared with the reserve.' Here we are dealing not simply with a particular year but with a period of many years—a fairly long range of experience—and with careful

> and detailed examinations made both at the beginning and near the end of that period. The showing of the condition of the property, and of the way in which it has been maintained, put the matter in a strong light."
>
> * * *
>
> "This condition, kept at a nearly constant level, directs attention to the amounts expended for current maintenance. In the process of current maintenance, 'new parts' are 'installed to replace old parts' in units of property not retired. Such 'substitutions or 'repair'' are separate from the amounts which figure in the depreciation reserve. The distinction between expenses for current maintenance and depreciation is theoretically clear. Depreciation is defined as the expense occasioned by the using up of physical property employed as fixed capita; current maintenance, as the expense occasioned in keeping the physical property in the condition required for continued use during its service life. But it is evident that the distinction is a difficult one to observe in practice with scientific precision, and that outlays for maintenance charged to current expenses may involve many substitutions of new for old parts which tend to keep down the accrued depreciation."
>
> * * *
>
> "In the light of the evidence as to the expenditures for current maintenance and the proved condition of the property—in the face of the disparity between the actual extent of depreciation, as ascertained according to the comprehensive standards used by the Company's witnesses, and the amount of the depreciation reserve—it cannot be said that the Company has established that the reserve merely represents the consumption of capital in the service rendered. Rather it appears that the depreciation reserve to a large extent represents provision for capital additions, over and above the amount required to cover capital consumption. This excess in the balance of the reserve account has been built up by excessive annual allowances for depreciation charged to operating expenses.
>
> "* * * The point is as to the necessity for the annual charges for depreciation, as made or claimed by the Company, in order to avoid confiscation through the rates in suit. On that point the Company has the burden of proof. We find that this burden has not been sustained. Nor is the result changed by figuring the allowances at the somewhat reduced amounts fixed by the court below.
>
> "We find this point to be a critical one. The questionable amounts annually charged to operating expenses for depreciation are large enough to destroy any basis for holding that it has been convincingly shown that the reduction in income through the rates in suit would produce confiscation."

The Supreme Court reversed the Court below, dissolved the injunction, ordered a refunding of the amounts charged by the Company in excess of the rates in suit, and dismissed the bill of complaint.

As the Society's committee interprets this opinion it squarely holds that the straight-line reserves were excessive; that the straight-line method is "beset with a host of perplexing problems * * * and opportunities for excessive allowances * * * are always present"; that "the predictions must meet the controlling test of experience"; that the engineering determination of actual depreciation in the case was most convincing.

In a concurring opinion Mr. Justice Butler said:

> "The Company's properties constitute a complex and highly developed instrumentality containing many classes of items that require renewal from time to time. But, taken as a whole, the plant must be deemed to be permanent. It never was intended to be new in all its parts. It would be impossible to make it so. Expenditures in an attempt to accomplish that

> would be wasteful. Amounts sufficient to create a reserve balance that is the same percentage of total cost of depreciable items as their age is of their total service life cannot be accepted as legitimate additions to operating expenses. In the absence of proof definitely establishing what annual deductions from revenues were necessary for adequate maintenance of the property, the company is not entitled to have the rate order set aside as confiscatory."

The Society's committee is unable to read into the opinion in the Lindheimer Case, or any of the preceding cases back to 1909, any suggestion or inference that a reserve designed to return to the company, through charges to operating expenses, the money to make good losses due to retirement, or even to cover the theoretical consumption of capital, is to be deducted from value. The Lindheimer opinion of Chief Justice Hughes, and the concurring opinion of Mr. Justice Butler, emphasize the fact that the straight-line method results in reserves grossly exceeding actual depreciation.

To what extent the opinion of the Hope Natural Gas Case, decided January 4, 1944, will affect utility regulation or prescribed accounting remains to be seen. That case dealt primarily with the extent of authority of the Commission under the Natural Gas Act, where a 40-yr old company was being brought under regulation for the first time. The facts of the case as stated in Mr. Justice Douglas' opinion clearly appear to justify the conclusions of the Commission, which found the "actual legitimate cost" of the property to be approximately \$52,000,000 and deducted as depreciation \$22,328,000, or 43%, in the process of determining a rate base. The company had accumulated a credit balance in the reserve of about \$46,000,000, and in the presentation of its own case deducted about \$30,000,000 as depreciation, apparently based on a present value computation. It should be noted that these figures involve both depletion of Natural Gas facilities a wasting resource (an amortization problem) as well as depreciation of physical property, two distinctly separate things.

Mr. Justice Douglas said:

> "In determining the amount of accrued depletion and depreciation the Commission, following Lindheimer v. Illinois Bell Tel. Co. 292 U. S. 151, * * * based its computation on 'actual legitimate cost.' It found that Hope during the years when its business was not under regulation did not observe 'sound depreciation and depletion practices' but 'actually accumulated an excessive reserve of about \$46,000,000.' * * * One member of the Commission thought that the entire amount of the reserve should be deducted from 'actual legitimate cost' in determining the rate base. The majority of the Commission concluded, however, that where, as here, a business is brought under regulation for the first time and where incorrect depreciation and depletion practices have prevailed, the deduction of the reserve requirement (actual existing depreciation and depletion) rather than the excessive reserve should be made so as to lay a sound basis for future regulation and control of rates."

It is very clear on a study of this case that it is wholly unlike any that would be likely to occur where a property had been under regulation for a quarter of a century.

The deduction was an amount less than half of the credit balance in the reserve, less in dollars than the depreciation estimated by the Company, and certainly affords no precedent for the deduction of a credit balance established under regulated accounting. It does however emphasize in a most positive manner the warning of the Lindheimer and other cases against excessive reserves.

"To keep the investment unimpaired" is not to provide a reserve to be deducted from value in a rate base. That would be just plain confiscation. But any reserve that accumulates more than enough to provide for return to the company cost of plant that has been and is to be retired is taking from the consumers money to be invested in capital which should be furnished by stockholders or through the issue of bonds. It is very difficult to understand why the NARUC committee in its report recommends the straight-line method which results in the accumulation of vast and obviously excessive reserves at the expense of the consumers.

Referring once more to Commissioner Eastman's statement at the beginning of this section of the report, it seems to be evident that the adoption of the straight-line method was, in his mind, inseparably connected with the deduction of the accumulated credit balances in the "Depreciation" reserve as accrued depreciation in ascertaining a rate base value. He called for a reconsideration of the "entire question of depreciation" if the Court decided otherwise. In the same month in which Mr. Eastman wrote the statement quoted, which was probably prompted by the opinion in the New York Telephone Case (271 U.S. 23), John W. McCardle et al. vs. Indianapolis Water Company (272 U.S. 400) was decided, the opinion being handed down by Mr. Justice Butler on November 23, 1926. In this opinion are the following statements:

> "There is deducted approximately 25% of estimated cost new to cover accrued depreciation. The deduction was not based on an inspection of the property. It was the result of a straight-line calculation based on age and the estimated or assumed useful life of the perishable elements. The Commission's report indicates that property is well planned, well maintained and efficient."

* * *

> "The testimony of competent valuation engineers who examined the property and made estimates in respect of its condition is to be preferred to mere calculations based on averages and assumed probabilities. The deduction made in the City's estimate cannot be approved. Pacific Gas Co. v. San Francisco, 265 U.S. 403–406; Standard Oil Co. v. Southern Pacific, Supra 159; Landon v. Court of Industrial Relations, 269 Fed. 433–445; City of Winona v. Wisconsin Minnesota Light and Power Co. 276 Fed., 996–1004; New York Telephone Co. v. Prendergast, 300 Fed., 822, 826; Southern Bell Tel. & Tel. Co. vs. Railroad Commission, 5 Fed. 2nd 77–95."

This opinion makes it perfectly evident that there was a long line of precedent approving the deduction of observed depreciation as found on an engineering study of property. That case apparently should have caused abandonment of the belief that the straight-line computation of accounting reserves for retirement was a proper figure for accrued depreciation to be deducted in a rate procedure.

In the eighteen years that have elapsed since then the concept has been clung to by some of the men in regulatory bodies. Ten years ago Mr. Chief Justice Hughes made clear the fact that the purpose of reserve accounting is to maintain the integrity of the investment, not to destroy it, and discussed the straight-line method at length, pointing out its weaknesses, comparing the credit balance in the reserve with the accrued depreciation found by engineering inspection and definitely approving the inspection method.

In spite of his apparently definite opinion in the Lindheimer Case, which was approvingly cited in the Hope Natural Gas Case in 1944 (subsequent to the NARUC committee's report), we find, on page XIX of the NARUC committee's report, in No. 40, the following statement: "In fixing public utility rates adequate depreciation expense should be allowed accordingly to the service life basis and, in principle, the reserve requirement determined on the same basis should be deducted in determining the rate base."

With this principle the Society's committee is in complete disagreement for the reasons stated at length in this section of this report.

XII.—THE ENGINEERING DETERMINATION OF ACCRUED DEPRECIATION

The engineering determination of accrued depreciation referred to and recommended in the Progress Report of the Society's committee[1] is a determination made by competent and reliable individuals, who, after a study of the property involved, determine what the actual effect of depreciation has been up to some specific date. Such a determination includes the consideration of many factual data, upon which an opinion as to the amount of accrued depreciation is finally based. As stated in the progress report, this method has in the past been referred to as the "Observation" method, and the results styled as "Observed Depreciation." Opponents of this method have capitalized on the word observed, and have tried to belittle it by inferring that the determination was made by simply observing or looking over the property. Such may have been and probably was the case in some instances. However, there have been undoubtedly just as many instances where the straight-line method has been used, where the only basis was a life table in some textbook applied wholly without consideration of the property whose depreciation was being determined.

A proper engineering determination of accrued depreciation includes the consideration of all data available in regard to the unit of property, and is the sort of determination made by most responsible and experienced men engaged in valuation work.

The process of making an engineering determination of accrued depreciation varies somewhat from property to property and among engineers who are experienced in appraisal work. Essentially, it includes the following steps, not necessarily in this chronological order.

The books and records of the property are examined with the assistance of employees of the company charged with the responsibility of keeping records, and who are familiar with them. From these records there is prepared a list of property units, or groups of like units, and, if available, the dates when they were installed, their cost new, installed, ready for service, including appropriate overhead costs (engineering, general, and interest lost during construction) and the expenses for maintenance and repairs during the period from installation to date.

The engineer then makes an inspection of the units, accompanied by such assistants as may be required, examining each unit of property, observing its conditions during operation, determining its operation behavior from inquiry from operators, and ascertaining what repairs may be imminent, and any other factors bearing upon the character and extent of deferred maintenance. In many cases machines are partially dismantled to permit examination of working parts. In the case of static property, such as pipe, wire, poles, transformers and the like, the examination includes a notation of corrosion, decay, abnormal characteristics developed during service, etc.

Included in the study is an analysis of past and probable future growth of the system and the city as affecting the relationship of the size of unit and adaptability for continued future service. The character of the community is studied with respect to its type; that is, whether residential or industrial, etc., and any indication of impending changes in the character of the load. Load curves of the system are also helpful in the consideration of the adaptability of the unit in question, to serve with other units, the size of which also may have a bearing upon the probable place of the particular unit in the future operating schedule.

It will also be of assistance if mortality statistics for the property are assembled from the records of retirements whenever records permit. These data may be arranged in the form of curves or diagrams. Other pertinent mortality data are examined and where applicable to the local conditions are assembled in the form of mortality curves if sufficient applicable data are available to permit doing so. A study of type mortality curves and the selection of those adapted to the local conditions and the units of property will be helpful in interpreting such data as may be otherwise available and will assist in arriving at a final judgment as to future service by the unit.

It will frequently, perhaps usually, be found that no pertinent mortality data are available on the particular property or type of unit being studied and the experienced engineer should be very careful to use only such types of mortality curves as he feels certain are applicable.

From such a study it is practicable for the engineer to reach a conclusion as to the probable future usefulness of the unit. In the light of all the data relative to the unit, its operations, capacity for future service, probable future usefulness, the consideration of whatever mortality statistics may be applicable, and the use of any mortality curves applicable to the particular unit, the engineer can then arrive at the percentage condition of the property and the total accrued depreciation which is the ultimate end desired.

The Society's committee believes that an engineering determination of accrued depreciation, made as outlined above, is the only way the actual effect of depreciation can be obtained, and that accounting practice should be so planned that a reserve for depreciation sufficient to meet the requirements indicated by such a determination will result. This belief is in marked contrast to that expressed in the recommendations of the NARUC committee, that annual allowances for depreciation should be calculated by the straight-line method and that the reserve created by such allowances becomes the measure of actual depreciation.

It is believed that if those connected with public utility regulation would accept the fact that the effect of depreciation on utility property has been, is now, and probably always will be subject to many variables, differing in each property, and that it cannot be determined by any theoretical uniform system of accounting a lot of the fog that has been thrown around the subject would burn off. It is proper to use theoretical methods in the accounting for annual allowances, and to create a reserve on that basis, but such a reserve would seldom, if ever, constitute a fair measure of accrued depreciation. The annual allowances should be adjusted to meet the requirements by periodic determinations of what the accrued depreciation actually is. The statement of Mr. Justice Jackson in the Hope Natural Gas Case is well worth repeating—it expresses the danger in strict adherence to fixed accounting conventions as follows:

> "To make a fetish of mere accounting is to shield from examination the deeper causes, forces, movements, and conditions which should govern rates. Even as a recording of current transactions, bookkeeping is hardly an exact science. As a representation of the conditions and trend of a business, it uses symbols of certainty to express values that actually are in constant flux. It may be said that in commercial or investment banking or any business extending credit success depends on knowing what not to believe in accounting. Few concerns go into bankruptcy or reorganization whose books do not show them solvent and often even profitable. If one cannot rely on accountancy accurately to disclose past or current conditions of a business, the fallacy of using it as a sole guide to future price policy ought to be apparent. However, our quest for certitude is so ardent that we pay an irrational reverence to a technique which uses symbols of certainty, even though experience again and again warns that they are delusive."

XIII.—Retroactive Adjustment of the Depreciation Reserve

The NARUC Committee on Depreciation in its report recommends that "The reserve should be deducted * * * in arriving at the rate base for the reserve alone measures actual depreciation." The NARUC Depreciation Committee also recommends that, where the depreciation reserve as computed by the straight-line method materially exceeds the reserve currently in the property, an adjustment shall be made in the amount necessary to bring the current reserve up to that computed on the straight-line basis; this adjustment to be made through charge to surplus or special section of the income account.

Before proceeding to discuss these recommendations it is well to review the fundamental concept of depreciation. Depreciation is an operating cost. Even the NARUC committee recognizes this in their statement: "Depreciation results in a cost of service." Mr. Justice Moody, in the Knoxville water case, stated it admirably as follows:

> "Before coming to the question of profit at all, the company is entitled to earn a sufficient sum annually to provide, not only for current repairs, but for making good the depreciation and replacing the parts of the property when they come to the end of their life. * * * The Company is entitled to see that from earnings the value of the property invested is kept unimpaired, so that at the end of any given term of years the original investment remains as it was in the beginning."

It is apparent from this excerpt from the Knoxville decision which has been the primary judicial basis for depreciation allowances for nearly forty years, that the investor is entitled to see that the value of the property is kept unimpaired. How can the value be kept unimpaired if, as the NARUC committee now recommends where the credit balance in the depreciation reserve is less than the amount computed on a straight-line, age-life basis, the difference be withdrawn from surplus or capital? If that subtraction is made, as recommended by the NARUC committee, the capital is directly impaired. By that method an unearned operating expense becomes a deduction from capital.

The unfairness of this recommendation is further shown when it is recalled that practically all utilities have now been under supervision of public regulatory bodies for the past twenty to forty years. During that period their depreciation allowances have either been determined or approved by these regulatory bodies. To now arbitrarily require capital adjustments to bring the results of public regulatory policies up to the measurements of straight-line age-life depreciation, and to reflect this adjustment in the valuation or rate base cannot, in the opinion of the Society's committee, be viewed in any other way than the taking of property without the process of law.

In the Columbus Gas and Fuel Company vs. Public Utilities Commission of Ohio case decided May 21, 1934, in an opinion delivered by Mr. Justice Cardozo, the following statement appears:

> "To withhold from a public utility the privilege of including a depletion allowance among its operating expenses, while confining it to a return of 6½% upon the value of its wasting assets, is to take its property away from it without due process of law, at least where the waste is inevitable and rapid * * *. Plainly the state must either surrender the power to limit the return or else concede to the business a compensating privilege to preserve its capital intact."

Justice Cardozo then quotes from the Knoxville decision:

> "Before coming to the question of profit at all the company is entitled to earn a sufficient sum annually to provide not only for current repairs, but for making good the depreciation and replacing parts of the property when they come to the end of their life."

He then continued:

> "It is idle to argue that a company using up its capital in the operations of the year will have received the same return as one that at the end of the year has its capital intact and interest besides."

This quotation is identical with the statement appearing in the Dayton Power and Light case decided April 30, 1934.

The telephone utilities and railroads stand alone in their exclusive use of the straight-line method of figuring annual depreciation. As a result they have accumulated in many instances reserves materially larger than the actual depreciation in the property.

Practically all other utilities have depreciation reserves which currently amount to approximately one half to one third of the reserves that would be computed on a straight-line basis. It is with this great number of properties that the retroactive adjustment of the depreciation reserve is so serious. It is, however, most significant that in these telephone cases of excessive reserves the Court reduced the annual allowance rather than declaring the excessive reserve to be "actual" depreciation.

The NARUC committee report realizes that the retroactive adjustment is a serious problem but it nevertheless makes it even more serious when it states:

> "The depreciation reserve should not be readjusted gradually through modification of the annual depreciation rates when the difference between the book reserves and proper reserve (straight-line) is substantial."

With most utilities this difference is substantial, probably averaging 100% or more of book reserves. The stipulation above quoted closes the door to the only means of collecting depreciation reserves from the consumers whose service used up the property. Since the utility is precluded from a gradual readjustment through collections from the consumers, the only alternative necessarily results in impairment of its property. To require the utilities to deduct from capital amounts which they have allowed to collect through rates under regulation is contrary to all precedent and ethical procedure.

It is of interest to note that the recommendation of the NARUC committee on retroactive accounting is not new. In 1926, in the original order in Docket No. 15100, the Interstate Commerce Commission, Commissioner Eastman handing down the opinion, said (118 I.C.C. on p. 384):

> "Past depreciation unprovided for. In the case of steam railroads, and perhaps to some extent in the case of telephone companies, a difficulty which will be encountered is that as a rule depreciation accounting has not in the past been observed with respect to fixed property. In such cases there is no depreciation reserve which now covers that part of the service value of existing units which has already been consumed. The theoretically correct way of meeting this situation would be to establish the amount of past accrued depreciation which has not been provided for, and concurrently credit this amount to the depreciation reserve and charge it to profit and loss. It is the latter account which has profited in the past from the failure or partial failure to accrue depreciation charges. In view of the fact that such procedure might, in some and perhaps in many instances, result in converting a profit and loss surplus into a deficit with a consequent impairment of credit, it seems desirable that for the present the amount so credited to the depreciation reserve should be concurrently charged to a suspense account on the assets side of the balance sheet, instead of to profit and loss. This suspense account could then be gradually extinguished by charges to profit and loss over a maximum period of years or in such shorter time as the carrier might elect."

This ruling, which deducted approximately 20% of the total cost of reproduction found by the Commission from the basic valuation which was to be used in establishing the new accounting, was criticized by the railroads at the subsequent hearings. There were many objections but the principal one was that, in many instances, the effect of disregarding former accounting and setting up the "past accrued depreciation," as developed by the formula of the Commission, would be to seriously decrease or wipe out the profit and loss surplus, and to seriously impair the credit of all railroads. The device of a suspense account did not in any way relieve the railroad from the burden of liquidating these enormous sums through profit and loss and was merely a makeshift.

In the Proposed Report, dated August 15, 1929, the Commission substantially changed its position and in all the succeeding years has never placed retroactive depreciation accounting into effect.

Paper No. 2294

STEWARDSHIP OF PROFESSIONALISM GIVEN HIGH PRIORITY

ADDRESS AT THE ANNUAL CONVENTION, SPOKANE, WASHINGTON, JULY 17, 1946

By W. W. Horner,[1] President, ASCE

This is our first Summer Convention in three years. During those years we, together with all other Americans, have been concentrating on the war effort. A great many of our members have been in the armed services, and many others were engaged in activities essential to the successful and early conclusion of the conflict. It is a source of deep satisfaction to know that members of our Society, together with other men of science, played an important rôle in this most scientific of all wars. I am confident our pride in our part of the atomic bomb project, which contributed so much to hastening the cessation of hostilities, will be judged a pardonable one.

Now it is time to face the problem of peace with the same singleness of purpose and in the same spirit of unity which characterized our war effort. I am certain that the members of our Society are not unmindful of the innumerable problems which are vexing and perplexing the country in its uphill reconversion efforts, and although I could dwell at great length on what stake we, as engineers, have in the prompt and proper solutions of those problems, I shall not do so.

For this, it seems to me, is an occasion for discussion of Society affairs and of Society aims and efforts. Those of you who have been members of your Section membership committees at one time or another, and who have endeavored to explain to prospective members, the advantages of belonging to ASCE, will readily understand what I mean when I say, and heartily concur in my opinion that, the most intangible, though perhaps the most valuable, of all our aims is the one we call "professional improvements" of our members.

In choosing that phase of our activities for discussion here today I take particular cognizance of the increasing attention our Society has been devoting to the subject of its younger members, and, with the permission of you older members, I should like to direct my ensuing remarks principally to my junior colleagues.

---

[1] Cons. Engr. (Horner & Shifrin), St. Louis, Mo.

Not long ago, there came my way an opportunity for a man-to-man talk with members of a Student Chapter of the Society. It was a heart-warming and revealing experience, and one which stimulated my thinking on the subject of the younger members of our Society.

Most of these fine young men had returned from service in the armed forces to resume their war-interrupted education. Many had seen action in foreign lands. They were, I am happy to report, much more maturely serious than students I had known previously, and were keenly interested in discussing their future. They had definite ideas as to what they felt they ought to do.

I asked them if, in the light of recent events and developments, they had felt at all inclined to reconsider their decision to enter the engineering profession. Had they, I inquired, ever thought that there might be a greater reward in a craft under the protection of organized labor?

The replies I received were most definite. Yes, there had been a good deal of serious thinking devoted to the all-important subject of their future, and the glittering and immediate beneficial results held out to them by organized labor had received the attention such seeming prizes would naturally attract, especially from youth. But their decision to become members of a profession, rather than of a trade or craft, was declared emphatically. Definitely, they were in for the longer and harder pull. They expected to be free to develop their careers along constructive lines, and could not see the leveling process of union rules, which they felt would restrict their activity, as fitting into their picture of what they wanted for themselves in an America which they had fought to keep free. Theirs was no philosophy of doubt or compromise, in which "higher wages now" were to compensate for inhibition of initiative. They were concerned with fundamentals— opportunities for the future, salaries commensurate with professional status, and a satisfactory scale of living to reward them for their years of study, learning, and development into the careers of their choice.

And they were equally forthright in their inquiries as to what assistance they could look for from the older and established members of the engineering profession. What had the profession done to help them? What was it doing to assure them a fair chance? What were its plans for future aid to the younger fellows?

It was obvious that they weren't too well satisfied with what they had heard and that there was grave doubt in their minds that we elders had done all that it was possible for us to do. They inferred that possibly we had been sticking too close to our personal knitting and, by implication, asked whether we had not failed to develop a professional feeling to a reasonable degree.

Under the cross-examination of these straight-thinking young men, my derelictions were beginning to appear in the record, and I found myself feeling apologetic and definitely on the defensive. It became apparent that I, and not they, needed to reflect and reconsider.

I have done this at some length and have concluded, for myself and my contemporaries in the profession, that perhaps it is best that we plead guilty and ask the clemency of the new generation, who are so sure of themselves and so ready and willing to take over.

In throwing ourselves on the mercy of the court, so to speak, I think it just, however, that we be permitted to offer an explanation—hardly an excuse—for our conduct of our professional affairs to date. I think a review of such extenuating and mitigating circumstances as may be found to exist is in order at such a time, and I think, also, that I can best present it in terms of my own experience. This I shall proceed to do, presenting it (again with the leave of my older colleagues) in the form of remarks directed at our Junior Members and to the mature and earnest Student Chapter Members who will soon join them in our professional ranks.

When I entered the Junior grade of membership in ASCE, America was emerging from the gay nineties and plunging into the ensuing railroad panic of 1907. Immigration was still at high tide. Labor was plentiful and practically unorganized. Business and industry were enjoying freedoms they long since have lost—were, in fact, abusing their privileges in a manner so ruthless that it could lead nowhere but to the curtailment and abrogation of those privileges. It is significant that the loss of those freedoms and privileges, upon which we now look back as something which occurred overnight, was not, in fact, any single event which took place in anything even approaching so short a time. Deprivation of privilege came about gradually, as the people grew increasingly incensed over the abuses. Corrections were instituted piecemeal, as has been the case with remedial measures throughout history. Controls were instituted not only as the need for them arose, but in most instances only after the abuses were so flagrant as to cause the people to wonder if the means of abolishing them were to be forthcoming in time to avert national calamity. In short, just as today we are inclined to despair over abuses at the pendulum's other extreme, so did the people of the time of my youth fret and worry and fume and wrangle over the injustices and the inequities which menaced the opportunities which they sought and which they deemed it their right to have.

In those days, government was law and order and taxes, and had not yet entered business to an appreciable degree. Public works were largely municipal utilities and federal postoffices, and the taxes for their construction were so relatively slight that the average man did not have to concern himself about them. Certainly, a newcomer to the professional ranks of our Society, starting out to earn his livelihood as an engineer, was immune from them. Comparatively small though it was, his paycheck was all his own when he received it, and he was not afflicted with that relatively new malady, the "deducts," as are we today.

The American Society of Civil Engineers then was to the young man an order of eminent mystics who met primarily to compare notes on great achievements. Then the Junior was received into the Society after careful scrutiny and was thereafter seen, but for some time, not heard. Then, as now, the Junior needed a friend and friendly help, but the devil took the hindmost.

We Juniors did have impressed upon us sound ideas of professional integrity and an understanding that the results of our work must be always in the public interest. But the notion that we should devote some time to social and economic improvement of the membership was not advanced in any manner whatsoever. One got a job and, if fortunate, a chance to work under an accomplished elder. By hard work, he could rise in his profession. Individual engineers carried through classic projects and made great contributions to technological advance. Many members of the Society rendered conspicuous public service, and the profession profited and grew in the public esteem.

From World War I, we emerged with an increased prestige, for even the crude tanks and the handful of airplanes of that conflict, captured the public imagination to the extent that many called it "an engineers' war." From the war, we gained a broader professional solidarity, but our energy soon became diffused through a number of specialized societies. The ASCE began to modify its objectives in the direction of professional welfare with a faint sense of the beginning of the social revolution which we since have been undergoing. Technically and economically, we began to become closely related to industry, business, and public works, and we increasingly assumed major responsibility for technological advancement and for management and direction, as well as for our earlier endeavors in the realm of planning.

It is evident that we had little training in the service of the profession. The important social and economic side was at best a spare-time sideline for comparatively few members of the Society. Wiser heads recognized the need for enhancing the status of the profession, and occasionally voices sought to be heard on the subject. But the membership was busy, and the voices were heard but briefly and ineffectually. We were immersed so deeply in our individual improvement problems that for a long time we did not recognize the benefits or the essentiality of improving our position as a profession.

When it did come, our awakening was a gradual process. We created the Engineers' Council for Professional Development and supported it after a fashion. We saw the light on the need for legal recognition of the profession in the public interest, and got together to put through state registration. Our committee work began to point out somewhat more strongly the need for such things as professional recognition and adequate salaries and fees.

We were not well prepared to meet the bulge in the revolutionary tide that accompanied the economic depression and the New Deal. In that era, we did perform important service and the profession suffered comparatively little. While we had some economic distress of our own, we did not organize to produce widespread leadership, for which there was then great opportunity. A better conception of our responsibilities and a strong presentation of engineering ideals and ideas might have damped the swing to the left somewhat and might have placed your younger generation in a stronger starting position for the work you have to do.

In summary, we gave ourselves wholeheartedly to our engineering work; we made major contributions to developing the United States into the greatest and most capable nation of the world, a condition which was to stand her, and us, in good stead when World War II required of us that we be the arsenal of democracy. So we had little time to organize ourselves as a profession. Yet some members—a small part of our Society, and all too few—worked in that direction. In the past decade particularly some orderly procedure has been developing. The membership of ASCE and of the other major engineering societies has been increasing rapidly, and a greater part of those memberships has displayed a growing interest in professional welfare.

The need for unity in the profession as a whole has resulted in the federation of Society Sections with other engineering bodies in the metropolitan areas and in some of the states. Most recently, Engineers Joint Council has met at least in part, the need for unified action on the national level and has proved to its five constituent societies that they have much in common, can work together in harmony, and in doing so can render public service of a higher order than has heretofore been possible.

World War II has left us with a still greater recommendation of our capacity for service. Out of the war has come the realization by the public of the value of research and technological development. It took the atom bomb to do it, but the country now looks to scientists and engineers to make secure the future of the nation, as well as to enhance its mode of living. Engineers are directly concerned with scientific research. Basic and applied research in engineering provide the tools with which we practicing engineers earn our livelihoods. We bear the same relationship to fundamental research in the science of engineering as does the practicing physician to the basic investigations of the medical scientist in medical and biological fields. It rests with us to make use of the fruit of scientific engineering research and to turn it to the practical service of our fellowmen. It is our duty to accept the challenge offered by the scientific developments of the war and to strive for the same degree of progress in peace as we made during the war.

But thorns, as well as roses, adorn our postwar path. Collective bargaining on the one hand and a growing regimentation of the men in public service into "bigger," if not always "better," bureaucratic agencies on the other, have focused the spotlight of self-searching analysis on our present weaknesses.

We have in our Society, and with our affiliations, created the skeleton of good professional organization. At the present time, that organization is undermanned; too few of us are actively engaged in the relatively new task of molding firm flesh onto that skeleton. Too many of the older members retain their earlier individualistic tendencies, and too many of all ages are too busy with private affairs, thus bidding fair to repeat the errors of our earlier ways to which I am now, as I stated, pleading guilty.

That is why I am especially pleased to see you younger men come into the picture. Your awareness of the social and political scene, your concentration on the intrinsic value of the professional attitude, your determination to see that matters you consider essential are acted upon, and the natural zest of youth which you bring with you, provide the new light and the new energy which should transform our slower progress into accelerated achievement.

Today, the organization of the American Society of Civil Engineers is well distributed over the country. Its foundations and its strength are in its Local

Sections. Your real service to the profession must necessarily be applied there and at that level it can be adjusted best to the circumstances of your job and your environment. As you come into the Local Section membership, you will invariably find that these member groups are fulfilling a first essential task, that of extending the acquaintanceship between professional men into friendships and sympathetic understanding of the other fellow's problems and performance. Many of the members quickly will find time to become interested in you and to be helpful as advisers. In some of the Sections, you will find an arranged elder brother system, which assures you of welcome, personal guidance, and opportunity for service in the directions indicated by your interests and talents. You will find generally that your Section has both social and technical programs, and that you can participate in them and in arranging for them to good advantage. If, in some instances, they have not been well organized, there is a constructive service waiting for you.

Many of the Sections are member bodies of local engineering councils or federations generally interested in public questions and in the development of intelligent engineering opinion and expression with respect to them. Volunteer to serve on their special committees. You will come to recognize the varying viewpoints of the different branches of the profession and how they may be reconciled. You also will be introduced to local civic and political problems, and will find an opportunity for direct public service—a field in which we engineers have been all too inactive.

Either in your Section programs or through your personal work you may find encouragement to enter civic or business organizations, with the further opportunity of broadening your viewpoint while acting constructively for the public. Separately, there is opportunity here to demonstrate to the citizenry at large that the engineer has more than a one-track, technical mind. To those who may be inclined to question the fitness of professional men injecting themselves into community affairs, rather than waiting to be consulted, I would point out that our professional brothers, the doctors and lawyers, have followed this pattern, not only have they avoided impairment of their professional status, but they actually have enhanced their community positions by manifesting an interest in nonprofessional affairs.

Should you find that your job brings you into the sphere of employer-labor relations discussions that may involve you in collective bargaining procedure, your Section officers can obtain from the Executive Secretary pertinent, up-to-date information as to what you had best do to protect your professional status. The Society's past activities on this score are too well known to you, I am certain, to require repetition here. What I do want to pause long enough to do, however, is to give reassurance to any who may need it that the Society's position on this all-important matter is unchanged and that we propose, within the restricting limitations which the laws of the country impose on us, to continue our efforts to insure that professional employees shall be guaranteed the right to determine directly by their own votes whether or not they wish to bargain collectively; and, where they desire, to do so through representatives of their own choosing in a bargaining unit of their own choice. We shall continue to oppose regimentation of professional men into heterogeneous labor organizations in which they are outnumbered by nonprofessional men and where they have no mutuality of interests with the majority of the members.

In the past, Local Section activity has not been closely coordinated with matters of interest to the membership in the national field or of national legislation having a possible effect on the membership of the profession and its welfare. New procedure in this direction is now being developed. Your Board of Direction and its committees have been improving their work in this field and approaching the limits of what can be done by central bodies. To be fully effective, further development must be carried out by the entire membership, wherever it may be situated. Local Sections will find need to form committees on national affairs and to work very closely with the new National Affairs Committee of the Society. This latter is developing action procedure intended to give force to, and to seek results under, the broader policies which the Society is, from time to time, approving. It is not at all unlikely that some of the more forward-looking of our younger men may be called upon to join panels which will present the engineers' viewpoint to legislators and administrators. This would seem to be particularly indicated where the problem is one of improving the economic status of the younger man.

I trust that in this account of the older engineer's stewardship of the welfare of our profession you find cause for agreement that, while we have given less than the desired attention to that subject, this field of endeavor has not been wholly neglected by us, and that it is now given a high priority on the program of your Board. Further, we have developed a deep and sincere conviction of your ability to complete the job in a way that will be satisfactory to you, and to that end we are prepared to stay in the game even more effectively than heretofore. Full success requires your leadership.

It is my fond hope that as you ascend to that leadership, and as we turn it over to you, we both may profit by the experiences which we older men have had.

An excellent example of the advances that have been made toward obtaining for the engineering profession the recognition we all desire for it, and one which bids fair to open new avenues for recognized public service, is provided by the recent report on industrial disarmament of Japan which was sponsored by Engineers Joint Council. This council, as I am sure you know, is comprised of the presidents, junior past-presidents, and secretaries of the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Society of Mechanical Engineers, American Institute of Electrical Engineers, and American Institute of Chemical Engineers.

I am proud to recount that two ASCE members played important rôles in the preparation of this report and of the report for the disarmament of Germany, which preceded it, one as chairman of the National Engineers Committee, which prepared the report and the other as chairman of the Engineers Joint Council Executive Committee.

I am sure we are all sufficiently familiar with the nature of the report to recognize it as a major contribution of the engineering profession toward what we all hope will be lasting peace. Its transmittal to the State, War, and Navy departments attracted even more attention in the press than did its predecessor report on the disarmament of Germany,[2] when it was made public by the National Engineers Committee of Engineers Joint Council last September.

What strikes me as particularly significant, however, and as a milestone in our progress toward the kind of public recognition that will extend the engineers' scope of usefulness to the public incalculably, is an editorial that appeared in *The New York Times* on June 15, within a day or two after the Japanese report was made public.

Under the heading, "A National Resource," *The Times* stated editorially:

> "The National Engineers Committee was appointed in February 1945, by representatives of the five national engineering societies at the request of the then Secretary of State, Mr. Stettinius, to bring the best American engineering thought to bear on the problem of the industrial disarmament of aggressor states. Last September it completed a report on Germany, the recommendations of which were substantially all included in the directive of the Allied Control Council of last March 29 for the limitation and control of German industry. Now its report on Japan has been made public in Washington, with the hearty endorsement of the State, War and Navy departments, as well as that of General MacArthur. It thus clearly foreshadows long-range American policy toward our defeated enemy in the Pacific.
>
> "The basic controls put forward for Japan are at variance with those proposed for Germany. That report based the broad primary control on the allocation of coal, since 85 per cent of Germany's electric power is generated by steam. In Japan, on the other hand, 73 per cent of her electrical energy at the wartime peak came from hydro-plants, which were both numerous and widely scattered. This necessitated a different approach to the problem. The engineers committee has recommended the regulation of the mineral and metals industries, the heavy chemical industries, the fuel industry and the construction industry, supplemented by the absolute prohibition of scientific research for military application, especially with regard to all forms of nuclear energy.
>
> "One of the most striking things about the present report is nowhere to be found in it, able document though it is. This is the availability for national purposes of such organized entities as the engineering profession, whose technical competence is matched by their freedom from any suspicion of political motivation. General Clay has acknowledged that the report on Germany has been his most effective instrument in dealing with both the British and the Russians. The latter, in particular, trust American technologists, whereas they look with suspicion upon our diplomats. Our own Government might do well to utilize even more fully such a national resource."

With such recognition, in its infant stage though it is, as a beginning, to what limitless heights may we not aspire for our profession as a whole? If the nontechnical segment of our population is commencing to visualize the engineering profession as "a national resource," must we not find inspirational hope for our profession in such stirrings of acceptance and recognition? As engineers, we have known for a long time, of course, that there are many additional services we can render. This latest and so clearly stated recognition of our potential by nontechnical men, coming as it does at a time when our younger men are so ready and able to assume their position in the affairs of our

---

[2] *Civil Engineering*, November, 1945, p. 524.

Society, seems to me to make for an ideal situation and to provide added stimulus to the ambitions of our younger men.

I am convinced that the time has come when the work in the field of professional improvement can no longer be that of a few committees, but must be the business of the entire membership, with much of the work done at the Local Section level, and by younger members. There you young men will find full opportunity to render service to the public, to the profession, and particularly to your generation of engineers.

Today you need not worry about a job. For the next several years there will be a scarcity of men to perform the great volume of engineering work waiting to be done. You will have a better opportunity than we had to select the line of work which most interests you. You will certainly find ready at hand obvious opportunity to assist in the improvement of the profession and of its social and economic status. If you put into that work the serious interest and the ability I see in you, the engineers of the succeeding generation can take pride in their place in society without reservation, and will call you blessed.

MEMOIRS OF DECEASED MEMBERS

GEORGE TILLEY SEABURY, M. ASCE[1]

Died May 25, 1945

When George T. Seabury died on May 25, 1945, he had completed a few months more than twenty years of service as Secretary of the Society. Having also recently reached the retirement age, he was ready to relinquish his work; his successor had been appointed; his official affairs were in perfect order. It might be stated then that his work for the Society was complete, his work for George T. Seabury, about to begin. That he was thus able to finish his task was a great boon to the organization for which he gave his all, during the best years of his life. No record can adequately give a true appreciation of this accomplishment.

The Seabury family was of English origin, first appearing in American annals during early Massachusetts days in the person of a sea captain who settled in Duxbury in 1639. Perhaps the most famous name in the succession was that of Bishop Samuel Seabury. One branch of the family moved to Tiverton, R. I., and part of this group, still later, moved further to near-by Newport. There T. Mumford Seabury, father of George T. Seabury, established a boot shop in 1840, where through many years the old residents as well as the summer "Four Hundred" kept their favorite shoe lasts on file and could replenish their supply by custom manufacture, to their own specifications. To T. Mumford and his second wife, Mary S. (Tilley) Seabury, was born on April 12, 1880, George Tilley Seabury. His father was then fifty nine and he was not only the youngest son, but the youngest by twenty-two years. Thus, each of his three half brothers was old enough to be his father.

When George was a boy, his father was a dignified and rather old-fashioned person, wearing a long circular broadcloth cape and, on dress occasions, a high hat. Among George's cherished memories was his recollection of several trips made with his father. The first of these was abroad, when he was only twelve years old. The family did not tell George about this trip until the night beforehand. It was then he first knew that he, rather than his mother, was to accompany his father. This trip of a young lad not yet in his teens with a man who was then a septuagenarian must have been somewhat unique.

George promised his mother to keep a diary of his experiences and for the purpose bought himself a five-cent notebook. This seems to have disappeared, but the story of his trip the next year with his father to Niagara Falls, N. Y., to the Chicago (Ill.) World's Fair, and to Denver, Colo., in 1893 still lives vividly in a five-cent notebook with an energetic looking skyrocket on its cover. Inside a meticulous record written in ink relates many thrilling impressions, punctuated faithfully with comments on the quality of the meals. Once, "While at dinner the waiter expecting to be tipped called me 'My Lord' but he didn't get it." "Next we went to the Cave Dwellers exhibit—it cost 25 cents to get in but it was worth it." Also, "We saw a man with trained lions—it was the same show we saw in the Crystal Palace in London but with three wild boars and two elephants they did not have in London. Dinner was very good—what there was of it."

---

[1] Memoir prepared by Henry E. Riggs, Past-President and Hon. M. ASCE, and Van Tuyl Boughton and Sydney Wilmot, Members, ASCE.

Another five-cent notebook is entitled "European Tour—1896," in which he describes how he and his father "left Newport [R. I.] on the New York [N. Y.] boat *Puritan* at 9.15 P.M. Bright and Pleasant" and the next day saw Trinity Church, the Stock Exchange ("We went into one place to look down into the 'Pit' "), Central Park ("Had a dinner for 25 cts. each and then went to the Park"), and the Eden Musee. Then a faithful account of days at sea and landing in England at Liverpool. Not a trick could have been missed in seeing dear old Victorian London, and an especially festive season it was, for

> "The Princess Maude was married to Prince Charles of Denmark. * * * She was rather pretty and well-dressed of course, and had a guard of about twenty-eight fine horse-men, all on black horses. * * * We could only see the top part of the coach-men—they were covered with gold lace. We got back to lunch late because the streets were crowded."

Then in Windsor,

> "We saw the Queen herself go by in her carriage with us standing on the side-walk. She was going to London to attend the wedding of one of her grand-daughters. We got home at 6.30 P.M. a little late for dinner—but we had seen the Queen."

Then he went to Paris, France, and later back to London and to Edinburgh, Scotland.

This diary was finished in pencil, but was faithful in all details, ending with a list of fellow travelers and an artistic flourish with "FINIS" in large firm letters. On the last page of the diary appeared the following:

> "My trip to Europe is ended. It has been a very pleasant trip and I have met some very pleasant people yet I am not sorry to get home again. When we started Papa wished me to take it in as much as possible and get as much good out of this trip as possible. I have tried to. And I have derived a good deal of pleasure and I think some profit. He did his best to please me and refused me nothing reasonable, for which I thank him with all my heart."
>
> Aug. 15th, 1896.
> George T. Seabury.

Meanwhile he had been giving considerable thought to his future profession. With an engineering ideal in view and some latitude of choice in colleges available, that section of New England offered only one unquestioned answer to his quest for training—"Boston Tech." George Seabury's college record was good, even outstanding; he worked hard and was graduated with his class in 1902. Throughout his life he held a warm regard for the Massachusetts Institute of Technology.

In the next few years, like many another ambitious young man, he was connected with a variety of heavy construction projects. These were in or near New York City, of which the most prominent were the Grand Central Terminal and Riverside Drive.

About that time, one of the notable projects of engineering history was getting into full swing—the Catskill Water Supply for New York City. Its possibilities and opportunities for association with other graduates of "Tech" attracted George Seabury. Hence, he took the civil service examination, and was appointed to this great work in 1906 continuing until 1914. His first two years with the Board of Water Supply were spent in the Northern Aqueduct Department, as first assistant to the division engineer on preliminary field work for the Ashokan Dam and Reservoir in the hills back of Kingston, N. Y., on the west side of the Hudson River.

This was the key structure of the supply, from which a large one hundred forty-mile aqueduct led south; then under the river and again south to Kensico Dam near White Plains, just north of New York City (Southern Aqueduct Department); and then again south to and under the city (City Aqueduct Department) as far as Silver Lake reservoir on Staten Island. The whole construction totaled about $175,000,000. The details are of interest because Mr. Seabury had varied contacts with different parts. Perhaps most interesting, as he later recalled, was the two years, directly under his beloved "Chief," J. Waldo Smith, Hon. M. ASCE, in which he was one of two special "trouble shooters" on organization problems involving an engineering force totaling one thousand two hundred engineers. One phase of this work comprised trips and reports on the proper value of water power belonging to private enterprise, before condemnation and absorption by the city. His success in these various dealings with his fellows was perhaps a training for his later greater success with larger numbers spread over the United States.

Equally significant for his future were the five years he spent in the Southern Aqueduct Department, again as first assistant to a division engineer, Wilson Fitch Smith, M. ASCE. This work covered all the varied phases of aqueduct, gatehouse, aerator, and venturi-meter construction, as well as Kensico Dam and Reservoir. Here Frank E. Winsor, M. ASCE, division and later department engineer, had a chance to size up his young assistant. The two were intimately thrown together for the succeeding thirty years in warm friendship and professional association.

Graphic evidence of Mr. Seabury's intense efforts on this fascinating construction is his technical paper entitled "A Study of the Internal Temperatures of a Large Masonry Dam." Details of measurement installations throughout Kensico Dam, of months of temperature readings, and of broad interpretations are given with his usual care, completeness, and clarity. The paper was so long that the Society was unable to publish it in its entirety; and he did not find time to shorten it. Found in his effects after his death, the manuscript has been deposited in the Engineering Societies Library.

The account of Mr. Seabury's work with the Board of Water Supply would not be complete without reference to the men he met there, who appear to have had great influence on him personally and on his success in Society activities: J. Waldo Smith, Col. Merritt H. Smith, Alfred D. Flinn, George H. Honness, Robert Ridgway, Thaddeus Merriman, Walter H. Spear, and Frank E. Winsor. His associates also included such men as John P. Hogan, W. W. Peabody, and Lazarus White. All these men were loyal members or officers of the Society, many of them during the tenure of Mr. Seabury's secretaryship.

In 1912 he went into partnership with his friend, Albert A. Northrop, M. ASCE, with whom he had previously been associated in the New York Board of Water Supply work. Under the title of Seabury and Northrop, consulting engineers, they planned to do such work as landscape construction for private estates, retaining walls, and sea walls. However, the growing war clouds made a very uncertain future for such work, and it was considered best to close out the new firm.

When Frank Winsor completed his work on the New York Board, he became chief engineer of the proposed water supply development for Providence, R. I. In casting about for key assistants to himself and deputy chief Peabody, he naturally turned to George Seabury. This prospect was appealing. He was given field charge of preliminary studies, of surveys, and of actually beginning construction on the new Scituate supply.

Because of World War I, the work was perforce slow, and after two years, in April, 1918, his employment was finally interrupted. At that time Mr. Seabury resigned to become a Major in the Construction Division of the Quartermaster Corps. Until June, 1918, he served as supervising construction quartermaster in charge of maintenance at Camps Devens, Upton, Mills Merritt, Dix, Meade, and Lee—all near the north Atlantic seaboard.

When he came out of the Army in June, 1919, he was anxious to enter a field of activity that had long appealed to him—heavy contracting; and he took it with his eyes open. He had too long observed the hazards of such work, in peacetime and wartime pursuits, to be ignorant of its difficulties and its dangers.

In executive ability, financial sense, and good judgment he was wel equipped, but he was not trained to shoddy performance in cutting corners He experienced, as in a sizable road contract in Massachusetts, difficulty with the constantly rising cost of labor. Materials in the postwar period were als serious handicaps. Nevertheless, he persisted in this work for four years an fulfilled his contracts to the owners' satisfaction if not to his own.

It would be gratifying to record that this work was a most profitabl success. Fortunately for the Society, it was not. Otherwise he might hav gone down in engineering history as another increasingly successful contractor instead of an outstanding Society official. He did have the satisfaction, however, of closing this disappointing experience in a manner worth of respect.

For almost two years, beginning in March, 1923, he served as manager c the Providence Safety Council. There he succeeded in establishing rotar traffic—a new concept for a conservative city—and in promoting all th interests of public and private safety. He found it possible to use his engineering to a limited degree; but, more than this, he could develop his knack of dealing with and directing people. The training was definitely of great benefit. He left with warm friendships and a beautiful gift watch, which he treasured as a reminder of his successful work and his pleasure in accomplishment.

Meanwhile the American Society of Civil Engineers had also been going through successive periods of development and preparation. Following its firm financial and ethical strengthening under Charles Warren Hunt's long term of office, it was ready for expansion in all directions, in line with a basic report by its Committee on Development. After brief tenures by Col. H. S. Crocker and E. M. Chandler, the Board of Direction in 1922 called John H. Dunlap as its Secretary. Success seemed assured—every indication pointed to continued advance under this young progressive and idealistic leader.

However, an unkind fate intervened when Mr. Dunlap was fatally injured in a train wreck, returning from a Society meeting on the west coast in July, 1924. Immediately a search for a permanent secretary was actively instituted. Promising young men from all over the United States were considered in detail, among them George Seabury.

He had no national reputation to commend him—in fact, he was relatively unknown in this wider sense. His endorsers were perhaps few but they had this to commend them—they knew him intimately and had firm faith in his capabilities. His prime recommendation came from the then Directors Frank E. Winsor and Thaddeus Merriman, who because of their intense and loyal service to the Society carried great weight with the Board. They continued to support him magnificently during their lifetimes. It was no idle gesture on his part that their photos, framed together, held a prominent place in the Secretary's office through all those years.

It was at the December 1, 1924, meeting of the Board that George T. Seabury was elected Secretary. He took office on January 1, 1925, and with him began a new era in Society history. Be it said in all fairness that his predecessors had laid the foundations well. Its internal struggle resolved, the organization was a united force. A few years of engineering prosperity were at hand, and the outlying sections were more than ever ready and anxious to get under the load and help forward the corporate activities.

So it might be said the time was propitious; but it was also true that the new secretary himself was more than ready for his great lifework. His earlier jobs have been mentioned rather briefly rather than covered in detail—not that they were unimportant, but that they were simply preliminary and preparatory to a far greater opportunity and to a more glorious service.

What did he bring to his new work? First of all, a thorough training, an excellent education, faithfully pursued. Then there was variety of experience—in the consulting field; in civil service on a number of large public projects; in contracting, both as an employee and as manager; and, furthermore, in the field of public relations. Beyond these Mr. Seabury possessed in generous measure those inestimable values of heart and mind, a judicial attitude, an ingrained habit of honest thinking, and a natural executive ability. These in themselves were enough to guarantee that the venture would be a success; but, in addition, he brought to the new work that priceless quality—a deep and passionate love for the organization.

It might be thought that, with these many and favorable auspices, success was inevitable. To think so is to ignore the travail and midnight oil, the unending journeying and conferences, the utter selflessness of being a servant to twenty thousand engineers. He succeeded—yes; but at terrific cost. He gave his all and finally himself. The history of George T. Seabury for the following twenty years is the story of the American Society of Civil Engineers itself.

A few—and a few only—of his problems and more significant accomplishments can be mentioned, and those only in skeleton form. Many difficulties faced Mr. Seabury when he took over the administrative responsibility for the Society. In the closing years of the secretaryship of his eminent predecessor, Charles Warren Hunt, the organization had been deeply stirred by conflicting views as to what its future policies should be. Out of this controversy had come a new Constitution calling for the decentralization of control of the Society through division of the United States into Zones and Districts with locally designated Vice-Presidents and Directors, establishment of local sections and creation of Technical Divisions.

The Constitution was adopted in 1921, the year that Mr. Hunt retired. In the years intervening before Mr. Seabury took over the office a series of unfortunate circumstances, which culminated in the tragic death of Mr. Seabury's immediate predecessor, Secretary John H. Dunlap, had resulted in four men serving as secretary or as acting secretary in the brief four-year period. That chain of events, through no fault of the men who loyally carried on until a permanent appointment could be made, resulted in an accumulation of issues to be settled by the new Secretary and many matters of policy to be laid before the Board of Direction by him.

George Seabury took over the handling of these problems with the skil and diplomacy that characterized all his years of service to the Society. He did much to bring about the smooth working of the new Constitution and to eliminate causes of dissatisfaction which had been in existence in earlie years. He served in the period of transition of the Society from a primaril eastern seaboard organization to a truly national society. He contributed very greatly to the change that took place over the years in the more friendl attitude of many members and in the increased loyalty to the Society on th part of all members.

He was an exceptionally fine executive officer and a good administrator Fully informed at all times of the business affairs of the Society, he neve brought matters of minor detail to the Executive Committee or the Board o Direction, but if there was any serious trouble that called for advice he kep the President and Executive Committee fully informed. He laid facts a he saw them before the Board, but never took the lead in pressing for actio

As a result of these characteristics, his relations with the Board wer uniformly harmonious and cooperative. Few men could view a difficul problem as objectively as he could, and few had his quiet tenacity of purpose in seeking a correct solution once he had made up his mind what the correct solution should be. As a result, few of the controversial issues that arose were settled in a way that was unsatisfactory to him.

If George Seabury had one outstanding characteristic, it was ability to attain his objectives without appearing to take the lead. Superficially, the Board of Direction or the Executive Committee appeared to be shaping Society policy on important matters, but if Mr. Seabury had had an opportunity to think them through to a conclusion beforehand, as was generally the case, it was he who provided the initiative by a suggestion here or a quizzical inquiry there. The groundwork for many a Society policy was laid in a quiet discussion between him and one or two of the Directors around the morning cup of coffee or during an evening tête-à-tête.

In the Board meetings that followed, proposals to set up a new Society policy came from the Directors; Mr. Seabury seldom volunteered a suggestion, but spoke his mind freely if asked for an opinion. When he volunteered a suggestion, it generally meant that he saw the Board heading for trouble.

Outstanding among the changes in policy that originated with Mr. Seabury was the Society's acceptance of leadership in a movement to increase the compensation of engineering employees. This was one of the rare instances in which he found it necessary to take the initiative himself. When he became Secretary, the subject of better compensation for employed engineers was being actively agitated; but little progress was being made. Immediately he was deeply interested in the matter and came to the conclusion that the ASCE should take an active part, using its prestige to support the weaker and less well-known organizations then carrying the ball.

An opportunity to act came some three years later. Engineers in the employ of New York City were then endeavoring to get better pay, but the success of their efforts was in doubt—strong support was needed. Laying the matter before the Board of Direction, Mr. Seabury sought and received its permission to appear personally before the Board of Estimate of the City of New York to urge that engineers in city employ be paid at least as much as the mechanics they supervised. His making such an appeal was approved, and ultimately the increases were authorized.

This but marked the beginning of Mr. Seabury's active interest in bettering the working conditions and compensation of employed engineers—an interest that never lagged. Much of the success of the later activity of the Society in developing and approving schedules of salaries for engineers and engineering employees was due to his continued and unfailing support.

Getting successive Boards of Direction to give more than lip service to the idea that the Society should sponsor such salary schedules was one of his major accomplishments. When he had done that, he set out to see whether the Board's ideas could not be made the pattern for similar action by the other major engineering societies. In this, however, his efforts failed; the boards of other Founder Societies were unwilling to undertake similar studies in their fields.

When the financial collapse of 1929 brought loss of jobs to hundreds of engineers, Mr. Seabury was among the first to urge the Founder Societies to set up some system of aiding destitute men. That move resulted in the establishment of the Professional Engineers Committee on Unemployment, which provided financial aid and assisted many men in finding new jobs. He also took an active part in getting the federal government to expand its survey work as a means for creating jobs for engineers. To this end he made numerous trips to Washington, D. C. The ensuing government employment gave much needed help to more than twelve thousand engineers in their emergency.

When it became evident that the federal government would have to create work as a means for checking the spread of unemployment, the Society took the lead in advocating the desirability of constructing worthwhile public works as "pump priming." In that effort Mr. Seabury took an active part, especially in the selection of men to head the regional offices of the federal relief agencies. Subsequently, he was tireless in his efforts to raise the pay of engineers working for relief agencies to the level of the scale for skilled mechanics.

Improvement of interprofessional cooperation was another activity to which Mr. Seabury gave much of his time. When the Society finally joined the American Engineering Council (A.E.C.) after a heated controversy, Mr. Seabury worked arduously to make A.E.C. a success. Later, when he became convinced that its usefulness was limited and that in some respects it served as an actual check on attainment of the Society objectives, he had the courage to recommend that the Society withdraw its support, despite sharp criticism from influential members who wanted A.E.C. continued.

Ultimate abandonment of A.E.C. as an agency to represent engineers on national matters did not change Mr. Seabury's views as to the desirability of close cooperation between the Founder Societies. Consequently, he turned his attention to development of the Joint Conference Committee, which ultimately became the Engineers' Joint Council shortly before his death.

His acumen in dealing with financial matters which affected the organization is nowhere better illustrated than in the handling of the Society's property at 220 West 57th Street in New York. His partner in this activity was Col. Lincoln Bush, who also had a deep interest in Society affairs and an uncanny grasp of real estate matters. Which of the two was primarily responsible for the splendid solution of this problem is unimportant. Suffice it to emphasize that each supplemented the other most effectively and that a division of the credit still leaves ample for each.

This project was first active about 1921. Through the succeeding years the Board of Direction repeatedly discussed the matter, feeling that the Society should not continue in the real estate business and that its resources could be better cared for if invested in securities; at one time it even authorized the sale of the Society house and property at a figure which actually proved to be but a mere fraction of its value. This latter fact quickly became evident to Mr. Seabury, and it was shortly confirmed when offers for lease as well as for sale disclosed that the current value was far in excess of the Board estimate. More detailed investigations revealed that the Society investment in this particular district had been most fortunate and that the whole area was enhancing rapidly in value and offered rosy prospects for the future.

The Board, therefore, accepted Mr. Seabury's advice that the title be retained but that the property itself be subject to lease. The first tenant, for a few years only, was an automobile tire manufacturer. Meanwhile extended studies were under way, with negotiations for a more permanent tenant. In due course final arrangements were consummated with a permanent lessee, an old established New York restaurant of outstanding reliability. The lease was for twenty-one years, subject to revision at the end of that period and to two more extensions of like period, with possible increase but not reduction in rental. Part of the income was earmarked for amortization of the mortgage, and at the same time the maintenance and taxes were made the responsibility of the lessee.

As a result the rental was net profit to the Society, in such amounts that the mortgage was soon extinguished and the property made free of encumbrance. The idea of building up a reserve by annual allotments from this annual income was Mr. Seabury's. As a result of that plan, the Society now can modernize the building at any time without drawing on its other assets. The entire arrangement is indicative of the business foresight in the original purchase of the 57th Street property; but this value could only have been certified to the present membership by the outstanding wisdom displayed by Colonel Bush and George Seabury, leaving the Society forever in their debt.

Of those Society activities in which he had a major part and in which he took obvious pride none surpassed the establishment and operation of *Civil Engineering*. He was not the only one who had seen a vision of such a publication, but he was the one destined to bring it to realization. It was not an easy job, because the conservatism of the Society was still a hurdle.

To try out the idea in a preliminary way he set up a four-page illustrated supplement to *Proceedings,* designated under the innocuous title, Part II. It dealt with Society news, as well as with professional activities and personalities, both current and historical. It ran from the middle of 1926 to the fall of 1930. The membership obviously liked it—also the Board of Direction.

However, when the idea was extended to the next obvious step, a full-blown monthly publication, the Society fathers were hesitant, in spite of the fact that theirs was the only one of the Founder Societies without such a magazine. The question of commercial advertising was only one of the stumbling blocks. By Mr. Seabury's quiet persuasiveness, by conferences, committee meetings, and reports, the Board was finally won over and the publication begun in the fall of 1930.

Perhaps no worse time to inaugurate such a venture could have been found, as the full effect of the financial collapse of 1929 was only then beginning to be felt. It is therefore all the more to the credit of the administration that the effort was pursued without let-up and it is especially to

Mr. Seabury's glory that it was successful. His were the basic ideas and his the control of policies. His satisfaction in the outcome was not heralded but it was acknowledged openly to friends. It was all the more real because he knew it was justified.

Early in the depression that followed the financial collapse of 1929, Mr. Seabury saw with concern but no panic the spread of unionization among engineers employed by the relief agencies as well as in some of the engineering organizations in the civil engineering field. Immediately, he got the Board to appoint a small committee to study the subject and to report on its implications for the Society. He even went so far as to attend a union mass meeting in an endeavor to learn what the union strategy was to be.

Then when passage of the National Labor Relations Act made it obvious that collective bargaining was here to stay and might ultimately include many engineers, Mr. Seabury convinced the Board that there should be a man on the staff who would devote most of his time to questions relating to collective bargaining and related matters. About the same time the Society's Committee on Unionization was replaced by a large committee with the broader assignment of the economic status of engineering employees.

Out of the new committee came the unprecedented proposal that the Society sponsor the formation of collective bargaining groups among engineering employees. None saw the implications of that proposal more clearly than Mr. Seabury. Nevertheless, he was so convinced it was a long step in the right direction that he was willing to see the Society face the risks clearly indicated in such a movement.

Because he was convinced that the young engineering employees needed some such agency as the Society proposed to set up, he was willing to see the Board take an arbitrary attitude in refusing to submit the whole matter to a referendum until the emotional excitement had passed and the membership at large had had time to think the subject through. It was characteristic of Mr. Seabury that he could laugh off the criticism aimed at him as the instigator of that arbitrary action; but, despite his superficial lack of concern, the long controversy was a trying experience that sapped his strength more than he or anyone else realized. It proved to be the last major Society activity in which he was to play a leading part.

It is impossible to evaluate fully his services to the Society or his influence on the membership. His fine personality, his excellent memory for names and faces, his nationwide acquaintance due to his many contacts with members at Society headquarters and his extensive travel, not only to Society meetings, but to many Local Section meetings and district conferences all over the United States, probably brought him into personal contact with more members than any other officer the Society has ever had.

In dealing with these thousands of members he was most unusual in his sympathetic handling of the many personal problems all through the difficult years of the depression. Some of them were hard to solve. Many of them, if handled differently, would have left only sore spots, but none among the hundreds who were necessarily dropped from membership for financial reasons failed to keep the highest regard for the way Mr. Seabury handled the case. Hundreds of these took the first opportunity to resume their memberships.

His relations with the staff were also uniformly successful. He was intensely loyal to his associates and knew the strength and shortcomings of every employee. During the difficult years of the depression, from 1932 to 1939, when there were times, in the preparation of the budget, that it appeared probable that there would not be sufficient income to meet current expenses and that reduction of staff or salaries would be necessary to balance the budget, Mr. Seabury was willing to, and did, accept cuts in his own salary, but strenuously opposed reduction of pay of members of his staff. With extreme reluctance he finally acceded to the plan whereby a number of department heads shared with him in the necessary reductions.

George Seabury possessed in very large measure all the qualities which made him the model administrative officer of a great professional society—the personality which endeared him to the thousands of members, young and old, whom he met in his twenty years of service; the wisdom that kept him free from any taint of politics or clique; the executive ability that enabled him to conduct a great business well and smoothly without bringing details to his Executive Committee or Board of Direction; and the loyalty to his subordinates and to the department heads which resulted in a maximum quality of service from all.

To aver that George Seabury was a great Secretary of the Society is to give but a trite expression to a deep truth. He was so recognized everywhere —not only in the organization but in all gatherings of engineers. As early as 1930 no less an authority than the Italian Senator Luigi Luiggi, Hon. M. ASCE, spoke of him as "the ideal secretary." This is significant in that he then had been in office only five years. Certainly he lost nothing in capacity or in stature in the remaining fifteen years.

Acknowledging the fact, it still is not easy to analyze the basis of great accomplishment. Certainly it was not in a single tremendous personal asset, but rather in the unusual possession of many important but lesser attributes, which combined, went into the making of an extraordinary character. If there was nothing in him transcendentally brilliant, it is nevertheless true that there was no one facet of his make-up that was not perceptibly above average. It was this unusual combination that created the remarkable fact of George T. Seabury.

First and foremost, he was an industrious worker—too much so for his own good. He was a seven-day week type of Secretary. Night work and Sunday work were not strangers to him. He never gave a mere casual glance at a Society problem; instead, he was too apt to go into it exhaustively. As a result his associates tried to save him from himself by clearing up mutual matters at brief conferences, and avoiding reference to anything except basic questions. However, no one could relieve him of Board and policy matters —these he did carefully, faithfully, and minutely. The Board appreciated this loyalty and at the same time its dangers. In 1937 it instructed him to take a three-month leave for recuperation; a sea trip to Europe worked wonders, since it isolated him effectively from Society problems.

During World War II, conditions were particularly difficult. One after another of the staff were called into service and he acquiesced loyally, although recognizing the added burdens entailed. In each instance he tried to shoulder some of the transferred load. There was no complaint, yet there was no blinking at the increased work. Only his associates and Society officers realized the tax on his strength. In sober truth he, too, was a casualty of the war.

The amount of work Mr. Seabury did was prodigious, especially in connection with the many Society committees. Few committee chairmen failed to avail themselves of his counsel. As a result, the impress of his own judgment was felt throughout.

In statistical or financial matters he was at his best, as witness his handling of the 57th Street property. Every important file would contain somewhere a correlation or tabulation, perhaps on cross-section paper, revealing a summary of cogent data. There was also a methodical quality to his work, whether it was an important appointment for Society service, the remembrance of some employee's long service, or the preparation of his list of hundreds of Christmas cards. The Society was always the gainer in that no critical hazard was permitted to develop personal friction, simply because he foresaw and prevented that possibility. His financial sense was also uncanny, although probably his intense grasp of budgetary matters resulted more from midnight oil study than from any intuitive hunch. Certainly the Society's social as well as business affairs were most capably handled. When he left his office that last spring evening, not realizing he would never return, he left his Society and his personal affairs in perfect order. There was no "unfinished business."

In all Society matters he was a perfectionist. Questions of textual expression had to meet his very critical judgment. Of two ways to handle a problem only the better satisfied him, even if it happened to cost more. He was very jealous of the Society's prestige—the best hotels, the best printing, were not too good. He loved to recall the comment from a prominent member of another engineering group: "I notice that whatever your Society undertakes, it does a most creditable job." This was not meant as a personal compliment, but actually it was. The fact of doing things well was not just an accident. He had not only a passion for the best but the necessary drive to achieve it. In a personal letter he once confided, "I could not live without enthusiasm." This was characteristic of his whole life.

One might differ with Mr. Seabury's conclusions, but no one could successfully take issue with the fundamental soundness of his approach and the unimpeachable probity of his attitude. Thus it was that his official actions took on the strength of a moral quality, and thus seldom were they successfully contested. At times he had to delay execution on some borderline case unti the opinions of others caught up with his, but, in the end, nine times out of ten, it would be his judgment that was vindicated.

At such times he had a quiet method of approach, of rationalizing a difficulty. He could see the other person's point of view but he would quietly, patiently develop his own side until the weight of his arguments would usually win. Naturally, he was exceedingly diplomatic, which only added to his effectiveness. On a survey for water supply development—this happened during his Providence work—he came across an irate and obdurate farmer, who declared no survey party would touch foot on his land; and he had a shotgun to emphasize this argument. By gentleness and firmness combined, George Seabury secured a conference and within a half hour, in the man's own parlor, won him over. The man capitulated, but only with the proviso that George Seabury conduct the survey.

This consideration and courtesy in dealing with others paid handsome dividends. It inspired the loyalty not only of Board and Society members, but of the staff. All who ever worked with him, even if they disagreed, held him in utmost respect, often in affection. This was largely because they recognized his happy faculty of doing things, even unpleasant things with a gracious thoughtfulness of others. He curbed his feelings because he felt that such restraint was due the Society he represented.

No account of George Seabury's remarkable services would be complete without acknowledgment of the way in which Mrs. Seabury shared in those services. Her wide acquaintance, her interest in, and cordial relations with, the wives of Society officers and members were second only to his with respect to the men. As a wife her work complemented his work. She was always thoughtful of others, and to make them happy made her happy. The wives of Board members will long remember the enjoyable evening party held in the Seabury apartment on Washington Square each year at the time of the Annual Meeting.

It was Mrs. Seabury's custom to give a dinner to the wives of the members of the Board of Direction and officers of the Society, so that the newcomers might become pleasantly acquainted with those already accustomed to Society gatherings. Long years of warm friendships among the ladies who attended with their husbands have made very delightful the quarterly meetings held in all parts of the United States, and this has added materially to the unity and effectiveness of the Board.

Relatively few members of the Society had the opportunity to know the real George Seabury in a social atmosphere. His official manner was one of seriousness and dignity, but he could unbend, and successfully. He dearly loved those informal moments—as witness the whimsical response he gave at the Illinois Section's dinner on the occasion of his last Board Meeting in April, 1945. He loved most of all to gather around the piano in friendly singing; he had a pleasing, fairly strong, baritone voice, an ear for harmony, and much enjoyment in simple group singing. During his years in Rhode Island he was a loyal and enthusiastic member of the University Glee Club of Providence, which ever remained a pleasant memory in his busy life.

Members who were so privileged will best remember him at his office desk, always ready to defer some pressing work for professional or individual matters. Normally his decision would not be a snap judgment. Slow in reaching a conclusion, he was all the more sure of his ground and seldom had recourse to revoking it. That his judgment and advice were uncommonly good is evidenced by the results. Under his guidance, the organization grew in moral stature.

It also grew in size during his twenty years of service from about 11,200 in 1925 to about 20,700 when he died. The most notable aspect of this growth was in the number of Juniors which showed the remarkable increase from 736 to more than 6,500 during his tenure. Partly this was due to the operation of the new Constitution, but much was also attributable to Mr. Seabury's intense interest in, and appeal to, the younger men. Even through a great depression the Society kept a remarkable hold on its membership, at the same time ministering in varied ways to engineers both in and out of the Society. The relation was but a reciprocal one to Mr. Seabury's own attitude —the Society was his life, beyond which no personal consideration was permitted even a hint of precedence.

Of the work which he did to bring about better understanding and a closer relationship between the different branches of the engineering profession but little is generally known. This, however, was a very real service which he did well. His intimate relationship with the secretaries of the other great engineering societies did much to bring these separate groups together as one united profession in the solution of problems created by the war. His associations with the Engineering Institute of Canada were especially close and congenial, both as to the organization itself and as to countless individual members who were proud to claim personal friendship.

In ways other than length of tenure he was dean of American engineering secretaries. That his monumental work had impact far beyond the Society alone was evident in the spontaneous eulogies at his death. One of the clearest and most sympathetic of these appeared as the leading editorial of the July, 1945, *Mechanical Engineering*, organ of the American Society of Mechanical Engineers. It was from the pen of the editor, George A. Stetson, friend and confidant of Mr. Seabury during the full twenty years of Society work, and gave the following glowing appreciation:

> "What manner of man was George T. Seabury * * * for twenty years secretary of the American Society of Civil Engineers and for much of that time dean of engineering-society secretaries in the United States? Short, slender, with thinning hair, level steady eyes behind rimless spectacles, fair, clean-shaven, with a straight mouth that curled up on the right side when he smiled, he was a man of quiet dignity whose conservative dress was never awry. His voice lacked volume; was persuasive rather than commanding; at times, animated and buoyant, at others, unemotional and businesslike. For in him nature contrived to combine the contradictions of New England reticence and austerity with a warm friendliness and generous human impulses. The frankness of his speech was tempered by an astute diplomacy. His pleasures were not in athletics but in the quiet pursuits of simple living. He enjoyed the company of his friends. In convivial surroundings he would relax, tell stories, and throw his head back in wholehearted laughter, or punctuate an apt phrase with a snap of the fingers. When his less restrained constituents in the

sections laid care aside, he entered into the spirit of their horseplay and good-naturedly let them make him the butt of their jokes. This thoroughgoing humanness won for him affection without loss of respect.

"Energy without noisy and tiring bustle, enthusiasm and sincerity without affectation, intellectual and physical courage without braggadocio, frankness without malice, precision without pedantry in expression, were the qualities he brought to the conduct of his affairs. Wisdom, seasoned with experience, guided his judgments and his counsels.

"Seabury possessed the engineering characteristic of realistic planning. He could think objectively about himself and his job. One sensed that he viewed retirement from the secretaryship as a matter of obligation and wise policy and not as an opportunity for greater leisure. In a letter to the Board of Direction asking to be relieved of the secretaryship on his sixty-fifth birthday he wrote: 'I have given all that was in me to give . . It has been an arduous job and I have thoroughly enjoyed it, but . . . I should give none other than my best years to it.' It was apparent to his friends that he faced an emotional conflict over the problem of giving what aid and counsel he could to his successor without standing in the other's light or giving the impression of wishing to influence actions or decisions. It was apparent also that the warmhearted friendly Seabury was in conflict with the impersonal objective alter ego with its selfless sense of obligation to the greater good. This dilemma had been happily resolved by the action of the Board of Direction which was loath to lose Seabury's experience and wisdom and hence had created for him the post of assistant to the president. Scarcely more than a week before Seabury's successor took up the responsibilities of the secretaryship, Death itself intervened.

"The twenty years during which Seabury served as secretary of the American Society of Civil Engineers were critical ones for that society and for the Nation. They included the reconversion period which followed World War I, the great depression of the 1930's in which engineers experienced greater hardship and unemployment than ever before in their history, the era of made work and extensive public works projects, the fiasco of the N.R.A., the intense activity in construction that accompanied preparedness and national defense programs, and the global war in which we are still engaged.

"In the affairs of engineering societies these same years saw the rise and fall of the American Engineering Council, the organization of the Engineers' Council for Professional Development, the formation of the Joint Conference Committee of presidents and secretaries of the Founder Societies (now known as the Engineers' Joint Council), the almost complete acceptance of engineering licensure, comprehensive studies of the economic status of engineers, vigorous action for the relief of unemployed engineers, incorporation and extension of the Engineering Societies Personnel Service, Inc., constant struggles to upgrade engineering fees and salaries, and vexatious developments in collective bargaining for engineering employees. Those two decades from 1925 to 1945 were also marked by steady and gratifying growth of membership of the American Society of Civil Engineers, stability of its financial structure, the attainment of harmony and a progressive co-operative attitude in its management, and the initiation and successful development of a monthly magazine, *Civil Engineering,* to supplement the technical publications, *Proceedings* and *Transactions* issued by the society.

"In these and other events of the years covered by his secretaryship, Seabury played an important part, and although he scrupulously maintained the relationship of 'servant' to the Board of Direction and the committees of the Society, persons who knew him well must confess that his wisdom, intelligence, experience, and knowledge of men and affairs were powerful influences in the formation as well as the administration of society policies. Nor was his influence confined to the society he served as secretary; it was felt and gratefully acknowledged by sister societies and their officers and by other organizations in which members of the engineering profession hold common interests.

"A profound sense of personal loss, deep affection, and grateful appreciation of wise counsel frequently asked and never denied make it difficult for the writer of this appraisal and tribute to treat the subject with the restraint and objectivity which Seabury himself would demand. To one who was close to Seabury during the twenty years of his secretaryship yet sufficiently remote from the immediate environment in which his work was done, the greatest factor in Seabury's life was his powerful influence, frequently exerted in the face of criticism, in the welfare of civil engineers. One could not always agree with him and would sometimes be astonished at views and opinions that disclosed the conflicting emotions of realism and idealism in his nature, but one never questioned his courage, his integrity, and his sincerity. For oneself, for Seabury, and for his friends and family, one regrets his sudden death which robbed him of the satisfactions of an old age with its less strenuous tasks and its less onerous responsibilities. One regrets also that the suddenness of his going forestalled the high tribute in perpetuity to his memory that honorary membership in the society to which he gave so much of himself would have been.

"At the height of his career, with his prestige as a faithful servant and leader unimpaired, Seabury had the wisdom and courage to step down, unwilling to give any but the best years of his life to the task he performed so well. Twenty fruitful years of the history of the American Society of Civil Engineers will constitute his monument."

Many besides Mr. Stetson greatly mourned his death. Expressions of sympathy and eulogy were numbered by the hundreds, including those from personal or family friends. Reference will be made here only to a few typical ones among those having Society or other professional connotation:

From the Seattle Section—

"WHEREAS the Giver of all good and perfect gifts, the Designer and Builder of the Universe, has so ordered the lives of men that they know not what may be their span of life, and

"WHEREAS it is given to each according to his ability to weave a pattern or build a single part in the great structures of earth, and

"WHEREAS there comes a time in the affairs of every man when he is called upon to lay aside his responsibilities of life and go to a far country from whose bourne no one returns, and

"WHEREAS there has gone from our midst, a fine leader and Secretary of the American Society of Civil Engineers, George T. Seabury, and

"WHEREAS, we, of the membership of the Society who have known and loved him for his sterling character, shall miss his wide leadership and his friendly counsel;

"*Now, Therefore,* the Seattle Section of the Society wishes to record the highest admiration which we have had for Mr. Seabury, whose memory we will always cherish both as Secretary of the Society and as a friend."

From the Philadelphia Section, to Mrs. Seabury—

"Words are wholly inadequate to express the feeling of loss which we share with the entire engineering profession. For us, in the Philadelphia Section, the feeling is particularly keen because we had the privilege of knowing him personally, of having him and yourself with us from time to time, and of benefiting more directly than many from his wise guidance and counsel.

"With the engineering profession, we have lost and outstanding leader and one who worked long and earnestly in our behalf. More than this, however, we have lost a warm and kindly friend."

From a former member of the Board who has—

" * * * watched with the greatest admiration the way in which he has handled the affairs of the ASCE. The reason for his unmatched success was that we all loved him as well as trusted him. Te was gentle in all his dealings yet never yielded a principle."

From an English member—

"I never had the pleasure of meeting him but I corresponded with him as a member of the Society. I somehow felt that he went out of his way to be helpful to many of us recent members during the war. In particular he has been very kind to me personally and I had hoped to thank him in a personal way when I could have come to the States."

From one of the oldest members (New England)—

"I had great respect for him. He gave all he had to the Society. In its effect that was much. As Secretary he was a model of propriety and discretion. I have not met his equal."

From an officer of the Engineering Institute of Canada—

"Not long ago, a group of seven past-presidents of the Institute and a few other prominent members [met] in Montreal. * * * The three members of the Institute who are honourary members of the American Society of Civil Engineers were all present, and [one] spoke for them as well as for everyone else, when he recounted some of the things that George had done for the cause of engineering and for our Institute. Among other things, [he] said, 'He was a lovable and beloved friend of us all. He always looked for the good qualities in a person, rather than their faults. The high standing of The Engineering Institute of Canada with its sister societies in the United States is due almost entirely to his interest in us and his friendliness toward us.'

"In my own capacity as a friend, I want to tell you of the great loss which I have experienced. Almost from my first day of office with the Institute, George has been chief guide, mentor, and counsellor, in all matters relating to the profession and to professional organizations. Very early in my term of office, * * * he took me in hand, gave me a great deal of information and advice, and a warm friendly reception, which has been helpful and inspirational to me ever since.

"I never visited New York, no matter what my business may have been, without calling on him, and no matter how busy he was, he always took out time to see me. Although I am describing only my own case, I know there are dozens of others who have had the same experience with him. He was indeed a tower of strength to a great many of us."

From a retired staff member—

"Those of us who had the privilege of working with Mr. Seabury * * * we of the staff—past and present—will never forget him, as leader and friend."

From a member in far-off New Zealand—

"One who was so helpful and kind to us when in America, and one whom it was an honour and privilege to know—a true gentleman who was happy in furthering the interests of the profession and of the Society. Mr. Seabury's personal interest in all the members and, particularly for me, his very real interest and kindness to those, like myself, far from Headquarters and outside the United States, has always been for me a very pleasant knowledge, and we do very sincerely feel that in his passing we have lost a real friend.

"I often remember, and I mention it now as one little instance of my visit. In the Hotel Seneca in Rochester, N. Y., I was sitting alone—although due to the Society, I could not claim to be a stranger in a strange land—just before the Fall Meeting in 1938. Mr. Seabury came over to me and said 'Should I not know you?' His interest was in every Member of the Society. I believe every one of the 20,000 members of the Society knew Mr. Seabury as a friend, and for the very fine gentleman he was."

From a Canadian member—

"Mr. Seabury was my ideal of the perfect secretary, kind, thoughtful, considerate of everyone around him, and, with all that, very clear headed. He gave me the impression of knowing very well, all the time, just what he was about, yet never appeared as a sycophant; a hard fighter for what he deemed necessary, but a kind hearted man; and one full of interest in all he met. May the world be blessed with many more like him."

From the past-president of a sister professional society—

"In working with him for many years on interprofessional committees of various kinds I found him that rare thing—an efficient worker who was first and last high-minded, idealistic and yet practical!"

From a staff member—

> "For fifteen years it was my privilege to call Mr. Seabury my Chief. His inherent kindness, his understanding nature, his generous helpfulness and his wise counsel endeared him to me. He was the finest man with whom I have ever worked."

From a college dean, regarding association—

> "* * * during the years we served on the Board of the Society.
>
> "The joy of it all was the fact that no matter what differences of opinion or viewpoint might turn up in our formal meetings, our informal gatherings were always—well, I was about to say, like those of a happy group of grown up children. George was always so much a part, the essential part, both of our labors and our happiest moments, that it cannot be the same American Society of Civil Engineers without him."

From one of the women members—

> "When a life has been lived so richly and so fully, right up to the hilt, as Mr. Seabury's was, it can accept its Divine rest and Eternal Peace with the comfort that the job is well done."

From a long-time associate in another society—

> "There was not a small thing about George and the great contribution he made to his profession will last long."

It was but natural that he should receive the major credit for Society advances during his long and successful term of office. He cared little for credit and indeed he instructed that his name be avoided or minimized in any Society publicity. Nevertheless it was impossible thus to sidestep the acknowledgment so richly deserved. He received ample credit, in spite of himself, and inwardly it gratified him. So it was he was proud of the various tokens of esteem, represented in numerous social, professional and honorary organizations. Besides his Society pin, he always wore his Chi Epsilon and Tau Beta Pi keys.

In chronological order his engineering affiliations included:

Organization	Date
Engineers Club of New York	1925
Society for Promotion of Engineering Education	1926
Society of American Military Engineers	About 1927
American Water Works Association	1930
Ritual of the Calling of an Engineer (honorary)	March 27, 1931
National Society of Professional Engineers	January 1, 1935
New York State Society of Professional Engineers	1935
Royal Institution of Netherlands Engineers (honorary)	August 2, 1937
Chi Epsilon (national honorary)	March 8, 1939
Engineering Institute of Canada	August 14, 1943
Tau Beta Pi	May 3, 1944

George Seabury asked the Board of Direction at the end of its January, 1945, meeting to permit him to retire as soon as a successor could be found. He saw more clearly than his associates that he could no longer carry the full load; and, as he expressed it, he was determined to "give none other than my best years" to the service of the Society.

In April, 1945, William N. Carey, M. ASCE, was chosen by the Board to succeed Mr. Seabury and Mr. Seabury was appointed to the newly created position of Assistant to the President. By this arrangement it was hoped that he could be relieved of all administrative routine and yet would be available to represent the president on intersociety boards where his knowledge of Society affairs would be most useful—but death intervened to bring that plan to naught.

Following a coronary thrombus in the early morning of May 23, 1945, he rallied for a day or two but succumbed in the Post-Graduate Hospital in New York City on May 25. He is survived by Mrs. Seabury (who was Margaret Howard Knight of Providence before their marriage in 1904); by a daughter, Mary Knight (Mrs. Medley P. Ray) of New York City; and by a small granddaughter, Margaret Ray. All his brothers had predeceased him.

Services were held in the Church of Ascension on Fifth Avenue, New York, on May 28. The Society office was closed for one day, as well as many an engineer's office. Past officers came in great numbers; officials from other national societies; Local Section representatives from as far as the Middle West; Army and Navy officers; retired and active staff members; and relatives—including little Peggy who came to leave with her granddaddy as her last tribute a choice toy that they had played with so often. Later, that afternoon the body was laid to rest in the family lot, on a wooded hillside at Swan Point Cemetery, Providence, beside the two children, Howard Knight and Thomas Mumford, III, who had both died in boyhood.

Thus ended a strong and a successful career, devoted to intense activity and wholesome service to his generation—its last twenty years given over without reserve to the ideal of making the Society a more useful instrument in American life.

George T. Seabury was elected as Junior on March 31, 1903, elevated to Associate Member on December 1, 1908, and transferred to Member on May 7, 1913. He was Secretary of the Society from January 1, 1925, until his death on May 25, 1945.

WILLIAM WESLEY AMBURN, M. ASCE[1]

DIED FEBRUARY 27, 1944

William Wesley Amburn was born in Nevada, Iowa, on January 18, 1865, the son of Allen Amburn and Mary Ellen (Utterback) Amburn. Both parents were descendants of early Colonial families.

---

[1] Memoir prepared by C. F. Thomas, M. ASCE.

Mr. Amburn attended elementary schools in Iowa and South Dakota, and entered Sioux Falls University, in Sioux Falls, S. Dak., in 1883 where he was a student until 1888.

He started on a career, largely associated with railroad location and construction, in 1889, as a rodman for the Burlington and Missouri River Railway (later a part of the Burlington System). From 1890 to 1893, he was employed by the Northern Pacific Railway on location and construction work, between Chehalis, Wash., and the Pacific Coast, at South Bend, Wash. He advanced through the usual grades from chainman to chief of party and then to bridge inspector and engineer in the Bridge Department.

In 1893, the City of Portland, Ore., decided to bring a pure water supply from Bull Run Lake, near Mt. Hood, some forty miles distant. The natural resources of the Northwest were an attraction to Mr. Amburn. Therefore, he joined the staff at the headworks in the Cascade Range forest area. He had charge of placing the upper ten miles of the forty-two-inch pipe line, and later he had charge of the placing of a similar line across the Willamette River at Portland.

Much of Mr. Amburn's engineering work, between 1897 and 1924, was directly associated with railroad location and construction on all the large railroads of the Northwest.

After completing work on the Portland water supply line, he was assistant engineer in charge of ten miles of construction for the Oregon Railroad and Navigation Company (later a part of the Union Pacific System). He also had charge of twelve miles of construction for the Northwestern Railway, along the Snake River in Oregon.

Mr. Amburn was then employed by the Great Northern Railway and made reconnoissance and location surveys in Montana, Idaho, Washington, and British Columbia. An especially difficult location survey was made for the Vancouver, Victoria and Eastern Railway, from the summit of the Cascade Range to Princeton, B. C., Canada, and from the summit to Hope, B. C.

For the Chicago, Milwaukee and St. Paul Railroad, Mr. Amburn worked as location engineer on lines in Montana, Idaho, and Washington, and he was in charge of main line revisions from the Bitter Root Mountains in Idaho to the Columbia River in Washington.

Mr. Amburn's work was not continuous on main line railroad location and construction. From February, 1904, to August, 1905, he was principal assistant engineer in charge of topographical surveys for the Deschutes Irrigation and Power Company. In this capacity he made locations for, and was in charge of the construction of, the Pilot Butte and Central Oregon canals and laterals.

Mr. Amburn did extensive work in connection with the location and construction of standard gage logging lines in western Oregon and Washington, involving tunnels and construction of unusual timber bridges, one of which was one hundred and eighty feet high.

After 1924, Mr. Amburn worked on planning and property development. The era of new railroad construction was over. In 1935, in charge of a Civil Works Administration (C.W.A.) project, he made a terminal and transportation survey for Portland, involving a coordination of railroad, street car, and vehicular traffic. This plan was known as the "Amburn Project." World War II interrupted the completion of this work.

Mr. Amburn's personal life was simple and quiet. He was particularly fond of camping and was an ardent fisherman. Most of his active life was spent in the great outdoors. Mr. Amburn was a member of Patrons of Husbandry.

Mr. Amburn was elected an Associate Member of the American Society of Civil Engineers on September 2, 1908, and a Member on June 4, 1913.

HORACE ANDREWS, M. ASCE[1]

DIED FEBRUARY 21, 1945

Horace Andrews' active life in engineering covered a period of approximately forty years, nearly all of which were spent in public service. In this work Mr. Andrews constantly fulfilled his passion for careful and accurate accomplishment, of which an early associate said: "He always did any piece of work a little bit better than it was necessary to do it." A scientific and systematic turn of mind was natural to him, for it lay in his inheritance and training; his grandfather, Ethan A. Andrews, having shown it in his work on Latin vocabulary and grammar; a great-uncle and a brother—the latter, Prof. E. A. Andrews of Johns Hopkins University, Baltimore, Md.—having shown it in the realm of biology.

Horace Andrews' background was New England, Dutch, and Scotch by origin. He was born on March 19, 1852, at the home of his maternal grandfather, William Johnson, at York Square, New Haven, Conn. His parents, Horace and Julia Russell (Johnson) Andrews, were residents of New York, N. Y., although of Connecticut origin. His ancestor, the Rev. Thomas Hooker, was the founder of the Connecticut colony.

After preparing for college, in New York and New Haven, he entered the then small and little-known Sheffield Scientific School of Yale at New Haven, in the class of 1871, which comprised twenty-five members. At graduation he received the Bachelor of Philosophy degree; and after a year of graduate work and teaching at Yale he received the degree of Civil Engineer (being one of the first to be awarded this degree).

From 1872 until 1876 Mr. Andrews was employed by the City of New Haven, and then by the U. S. Coast and Geodetic Survey, in field work and drafting for triangulation, hydrography, and plane-table work in and about New Haven Harbor, Connecticut, for the commissioners who were determining the harbor line. Following a summer of triangulation and retracing lines for the Horicon Iron Company on and near Lake George, New York, he spent the winter and spring of 1877–1878 in hydrographic and triangulation work for the U. S. Coast and Geodetic Survey. This work was done on the Indian and Banana rivers, along the east coast of Florida, and was, of course, long before the development of the resorts in that area, and when only scattered orange groves indicated the settlements of today.

---

[1] Memoir prepared by the Rev. Theodore Andrews, St. Peter's Church, Mountain Lakes, N. J.

In 1878 Mr. Andrews worked with the New York State Trigonometrical Survey (the State Survey), which took him to many parts of the state on trigonometric and topographic work. These surveys entailed extensive trips by horse and buggy through the rural areas of central New York—regions where conditions then were very primitive.

He established his residence in Albany in 1879 where he brought his bride, Adeleine Louise Downer, of Hamden, Conn., to whom he was married on October 13, 1881.

The field work of the Survey being terminated in 1884, he spent the following year at work on the volume embodying its final report. From 1883 to 1886, he was employed from time to time by the New York State Board of Health. Many of his researches and reports are to be found in this Board's annual proceedings; chief among these were studies of the sewerage system of Keene, N. H., and of two localities in Albany where the existing conditions were deleterious to public health.

In 1886 Mr. Andrews obtained a civil service appointment as examiner in the U. S. Patent Office. Before he could accept, he was offered the post of city engineer by the Hon. John Boyd Thacher, then Mayor of Albany; this office he accepted, and began his duties in May of that year. During his tenure of office, a number of public improvements (to which he contributed his professional skill) were initiated and accomplished. Chief of these improvements were the Knox Street, Northern Boulevard, and Southern Boulevard viaducts, and the Beaver Creek Sewer. He was ex officio member of the city Board of Contract and Apportionment, and the Board of Health. He was chairman of the Board of Plumbing Examiners; as well as being a member of the State Board of Examiners for New York State engineering posts for seven years. The writer well remembers that, although every contract called for an inspector, it was very often Mr. Andrews' task to inspect the inspectors! His activities are detailed, although in a way hidden, in the reports of his office from 1891 to 1899. At the close of the latter year, the city passed under a new charter designed to be uniform for cities of the second class (rated by population); this year also marked the close of his work as city engineer.

From 1900 to 1910 he was engaged in practice as consulting engineer, with office in Albany; during this period he designed and constructed under a contractor the sewerage system of Plattsburg, N. Y. He also examined the foundations of some bridges, and was consulted as to pavements in Cohoes, N. Y., and in New Haven. (The first asphalt and brick pavements in Albany were laid during his term as city engineer.)

Much careful literary work, some of it incidental to his professional activities, and some undertaken independently, added to the fruitfulness of these active years. Aside from the annual reports mentioned, the following are from his hand: The chapter on "City Surveying" in Staley's revision of Gillespie's "Higher Surveying" (1897); the final results of the New York State Survey

(1886); a number of papers in the annuals of the American Society of Municipal Improvements; and contributions to the *Transactions* of the American Society of Civil Engineers, to the *Engineering News,* and to numerous other professional publications. An example of his research is his work on a series of maps for Hooper's History of St. Peter's Church in the City of Albany, illustrating the former properties and burial grounds of that old parish. His inquiry into the correct rendering of the seal of the City of Albany shows the same interest.

In 1910 Mr. Andrews retired from active practice, and soon thereafter began to reside for the greater part of the year in Coconut Grove (which was later a part of Miami (Fla.), although he visited Albany every summer until 1941.

He was a fellow of the American Association for the Advancement of Science; for twenty-five years, he was a member of the Deutschen Geometerverein; and, from soon after its organization until 1915, he was a member of the American Society of Municipal Improvements. He was also a member of the Society of Engineers of eastern New York, and of the Yale Alumni Association of that area. He was a member of the ASCE Board of Direction from 1908 to 1910. He had belonged to the Fort Orange Club of Albany since 1887, and was a member of St. Peter's Protestant Episcopal Church in that city since 1893.

In his later years, Mr. Andrews studied bookbinding which, in his methodical and careful way, he followed in the spirit of a true and painstaking artist. Mathematics, photography, historical and genealogical research, and household carpentry were with him more than hobbies, they were means of artistic expression.

By his first wife, Adeleine Louise Downer, who died on December 8, 1893, he had three children, of whom two survive: The Rev. Theodore Andrews and Bertha A., wife of Dr. James E. Maloney. On June 15, 1910, he was married to Frances Eleanor Green, of Hull, England, who died on September 6, 1927; the children of this marriage, Dorothy Andrews and Mrs. Hilary Andrews Pyeatt, survive him.

Mr. Andrews was elected a Member of the American Society of Civil Engineers on April 6, 1887.

ASHER ATKINSON, M. ASCE[1]

Died January 3, 1946

Asher Atkinson, the son of Asher D. and Emma Jane Barnes (Bell) Atkinson, was born on June 10, 1867, in Brooklyn, N. Y. He was of Dutch and English ancestry. When he was about four, he and his family spent about eight months traveling in Europe and then settled in New Brunswick, N. J. Asher celebrated his fourth birthday in Frankfort, Germany. His early education was obtained at Rutgers Preparatory School in New Brunswick; and his technical training at Rutgers University. He received the degree of Bachelor of Science in Engineering in 1885, and the degree of Civil Engineer in 1887.

---

[1] Memoir prepared by Willem Rudolfs, M. ASCE.

After graduation, from 1897 to 1902, he was employed by the Middlesex and Somerset Traction Company, constructing about fifty miles of electric railroad, a powerhouse, carhouses, and bridges (some of which, of a new and at that time rather daring design, are still in use). From 1902 to 1904, he was with the East Orange (N. J.) Water Works, designing a reinforced concrete reservoir, concrete standpipe, pumping station, and coal pocket. During this period he experimented with reinforced concrete, and the results of his experiments later were incorporated into a dam for the New Brunswick water reservoir. From 1905 to 1911, he was engineer in charge of the New York (N. Y.) office of the Corrugated Bar Company on the design of concrete structures. From 1911 to 1913, he was employed by the New York office of McArthur, Perks and Company, in charge of work connected with the construction of piers for the Port of Havana Dock Company in Havana, Cuba, principally checking designs and forwarding material for the work.

Most of his life—namely, from 1891 to 1905, from 1913 to 1914, and from 1915 to 1939—was spent as city engineer for New Brunswick. During his tenure, the city grew, requiring the design and construction of streets, paving, sewer system, water works, filtration plant, standpipe, pumping plant, and the Farrington water reservoir and dams. Also a chemical sewage treatment plant including force mains and pumping stations was constructed under his direction. In 1896 he took time out to travel extensively in Europe, and having been engaged in considerable surveying during the previous year in hilly country, was able to wear out a guide while climbing mountains in Switzerland. Mr. Atkinson retired, in 1939, after forty years of service as city engineer, and then became consultant to the city on water supply and water treatment plant operation until his death.

Mr. Atkinson was an enthusiastic golf player and amateur astronomer, especially interested in "shooting stars" which he plotted for many years. During his younger days he was intensely interested in water sports, building rowboats, sailboats, and, finally, a motorboat. He liked all kinds of sport and participated actively in bicycle clubs, taking long-distance pedaling trips. During his entire adult life he was an active member of the Second Reformed Church, being an Elder, Deacon, and chairman of the building committee for a new and beautiful church. In addition, he sang in the choir, did all kinds of committee work, and, when necessary, acted as janitor. He used to state he did everything for his beloved church but preach.

Mr. Atkinson had a fine personality. He was much liked by his associates and many friends for his honesty, loyalty, and genial nature. His kind and unpretentious manners were an inspiration to younger men. He was greatly interested in the progress of younger men, going out of his way to help them and trained a number of men, who did not have an opportunity to go to college, for an engineering career.

Mr. Atkinson was a member of the American Water Works Association, New Jersey Sewage Works Association, American Society of Professional

Engineers, and New Jersey Health and Sanitary Association, and a charter member and former president of the Kiwanis Club. He belonged to the Chi Xi fraternity.

In 1899, Mr. Atkinson was married to Elizabeth Vroom Knox of New Brunswick. Mrs. Atkinson; two sons, Asher, Jr., and William Knox; and four grandchildren survive him.

Mr. Atkinson was elected an Associate Member of the American Society of Civil Engineers on April 5, 1905, and a Member on March 12, 1918.

EDWARD PERRY BABCOCK, M. ASCE[1]

Died November 15, 1944

Edward Perry Babcock was born on October 11, 1887, at Chicago, Cook County, Ill. He was the son of Alfred Perry and Ida May (Winkleplek) Babcock.

After attending the English High School and Manual Training School in Chicago, he entered the Armour Institute of Technology (later part of Illinois Institute of Technology), also in Chicago, from which he was graduated in 1909 with the degree of Bachelor of Science in Civil Engineering.

Mr. Babcock's professional career evidenced special aptitude and skill in both civil and mechanical lines. From 1909 to 1911 he was with George W. Jackson, Inc., of Chicago on design and supervision of construction; from 1911 to 1923 he was employed by the Engineering Department of the City of Chicago as designing engineer on structures for the Chicago Water Supply System, bridges, and other miscellaneous structures in steel, concrete, and timber; and from 1917 to 1919, during World War I, he was chief hull draftsman on steel ships and plant structures for the Pensacola Ship Building Company. At various times from 1923 to 1944 he was associated with the writer, in Chicago, as designer and principal assistant engineer on bridges, buildings, docks, and other structures. During World War II, he was connected with J. W. Beretta, engineers of San Antonio, Tex., on reports, design, valuation, and supervision of construction; with Holabird and Root, architects of Chicago; and with Whitman, Requardt and Smith, consulting engineers of Baltimore, Md., on war projects.

Mr. Babcock had a keen analytic mind, was a hard worker, and devoted himself to the task at hand. His outlook was good, and he possessed not only keen perception of the various phases involved in a problem but also skill in reaching solutions. He was a member of the Chicago Engineers Club.

In 1922 Mr. Babcock was married to Edna Stephenson of Crystal Lake, Ill.

Mr. Babcock was elected a Member of the American Society of Civil Engineers on June 9, 1930.

---

[1] Memoir prepared by I. F. Stern, M. ASCE.

ROBERT EDWARD BARRETT, M. ASCE[1]

DIED OCTOBER 13, 1945

Robert Edward Barrett, the son of Frederick Barrett and Laura Maria (Nutting) Barrett, was born on June 28, 1881, in Framingham, Mass.

He attended the public schools of Framingham and after graduation from high school in 1898, entered upon his active career as assistant in the engineering department of the Metropolitan Water Board of Boston, Mass. He did field work on the construction of the Wachusett Dam and reservoir at Clinton, Mass., and the aqueduct and tunnels connecting that reservoir with the Boston metropolitan distribution system.

In 1902, seeking a technical education, he entered the Lawrence Scientific School at Harvard University, at Cambridge, Mass., as a student in civil engineering, completing his work in the class of 1905. He was then employed as an engineer in the designing division of the Charles River Basin Commission of Massachusetts.

Having decided to specialize in hydraulic engineering, he turned from Boston to New York, N. Y., in 1907 where he became associated with the construction of the Catskill water supply system then being constructed for greater New York. He was occupied in this work until 1914. Here he served as civil engineer designer and, in addition to the supervision of the rock tunnel work in the Bronx, he was called upon to design the gatehouses and regulating works for the Ashokan Dam and the regulating works of the Kensico storage dam above White Plains.

In 1913, Mr. Barrett received an appointment as designing engineer from the Massachusetts Commission, then known as the Directors of the Port of Boston, and returned to Massachusetts to begin his new duties. He later became acting chief engineer in charge of all engineering activities of the Commission. This work consisted of dredging ship channels in Boston Harbor and design and construction work for the Commonwealth Pier and the South Boston Dry Dock. It was his plan, for the revision of Boston Harbor lines, which was adopted by Chapter 334 of the Special Acts of the Legislature of 1915, and which created a plan for the future development of both the South Boston and East Boston lands of the Commonwealth.

In 1916, he became associated with Fay, Spofford and Thorndike, consulting engineers of Boston, for whom he designed the foundations of the Memorial Bridge crossing the Connecticut River at Springfield, Mass.

In 1917, he was appointed construction engineer of the Turners Falls Power and Electric Company, which was then engaged in the construction of a 40,000-hp steam electric station on the Connecticut River at Chicopee, Mass. This corporation later became a major unit of the Western Massachusetts Electric Company. Subsequently, Mr. Barrett was employed in hydraulic engineering work at Turners Falls, Mass., and in supervising the construction and maintenance of various water storage dams and reservoirs built by the Connecticut River Conservation Company in Vermont and New Hampshire.

---

[1] Memoir prepared by Alexander B. Ferguson, Asst. Treas., and Allin W. Ladd, Hydr. Engr., both of Holyoke Water Power Co., Holyoke, Mass.

In February of 1920, Mr. Barrett accepted the position of treasurer of the Holyoke Water Power Company in charge of the management of the company. In 1923 he was also elected president of the company. For these positions he was eminently qualified by reason of his long engineering experience and executive talents. This company traces its history back to the incorporation in 1792 of the "Proprietors of the Locks and Canals on the Connecticut River" and the completion of the first dam on the Connecticut River in 1795. Since that time many developments of the first magnitude in hydraulic engineering have had their origin in Holyoke.

Since 1920 the Holyoke Water Power Company, under the leadership of Mr. Barrett, has been actively engaged in supplementing its hydraulic power system with an electrical system. Hydroelectric and steam generators have been installed, which supply energy to most of the large industries of Holyoke, as well as to the municipalities of Chicopee and South Hadley, Mass. Electrical energy is also supplied by the company to the United States Army Air Base at Westover Field. Sales of electrical energy by the company increased from 4,380,000 kw-hr in 1920 to 121,357,000 in 1945. An extensive district steam system, supplying steam for heating and process work to a part of the industrial section of Holyoke was developed under his direction.

As president and treasurer of the company, Mr. Barrett, through his engineering experience, was able to lay a firm foundation for future engineering expansion, and through his skill as a financier promoted the conservation of the company's assets and made possible the sound financial structure of the company as it exists today.

He came to the organization at a time of change and growth in the country at large. As a result of his recommendations and under his executive management the plant as a whole and especially the steam and electric departments have been enlarged and strengthened so that it has been possible to serve new territories in new ways through a most modern distribution system. With great energy, courage, and aggressiveness, he advanced the interests of his company and no proper opportunity was lost to build up its resources and extend its usefulness. However, at all times and in all places, his integrity, his attractive personality, his courteous, kindly, and friendly nature won over even his rivals so that at the last the company stands at a peak of physical and financial development of good will in the community.

February 1, 1945, marked the twenty-fifth anniversary of Mr. Barrett's service in the Holyoke Water Power Company, and in March 1945, his fellow directors—aware that the growth of the company through those twenty-five years, the extension of its business and the remarkable increase in its physical assets and facilities were in the very largest measure due to his foresight, wise business judgment, distinguished professional attainments, and unremitting attention to the advancement of the welfare of the company—declared a special commemorative dividend of twenty-five cents a share in his honor. Future annals of the Holyoke Water Power Company and the City of Holyoke will tell of the engineering genius of Robert E. Barrett and his great power for putting his dreams into reality and making them work for those who will follow. It is always the purpose of the engineer to build the bridges for those coming behind to cross over.

> "Might of the roaring boiler,
> Force of the engine's thrust,
> Strength of the sweating toiler,
> Greatly in these we trust.
> But back of them stands the schemer,
> The Thinker who drives things through;
> Back of the Job—the Dreamer,
> Who's making the dream come true."

Mr. Barrett was for many years a director of the Third National Bank and Trust Company of Springfield, and a trustee of the Mechanics Savings Bank of Holyoke. He was also a director of the Holyoke Chamber of Commerce and of the Holyoke Hospital, and a trustee of the Holyoke Public Library. For several years Mr. Barrett served as chairman of the Massachusetts Division of the New England Council. He was a member of the Harvard Club of Western Massachusetts, the Rotary Club of Holyoke, and the Newcomen Society of England.

On June 13, 1908, Mr. Barrett was married to Grace Le Baron Esty of Framingham. He is survived by his widow; two sons, Robert Edward, Jr., and Frederick Park; and one daughter, Dorothy (Mrs. Howard Hollis Allen).

Mr. Barrett was elected a Junior of the American Society of Civil Engineers on January 31, 1905; an Associate Member on December 6, 1910; and a Member on June 16, 1919. He became a Life Member in January, 1945.

GILBERT JAMES BELL, M. ASCE[1]

DIED APRIL 29, 1945

Gilbert James Bell was born in Bainbridge, Putnam County, Ind., on September 9, 1854, and in his early childhood came to Illinois with his parents, John R. and Emily (Gordon) Bell. He was reared on a farm near Farmington, Ill., where he received a public school education.

The Peoria and Farmington Railway, later part of the Minneapolis and St. Louis Railway, was under construction in 1881 near Farmington, with John Findley Wallace (Past-President, ASCE[2]) in charge of location, construction, and operation. Mr. Bell became identified with this construction in September, 1881, as rodman. He was advanced to assistant engineer on construction in 1882, and from January, 1883, to July, 1885, he held the same position on the Iowa Central Railway which included the newly constructed Peoria and Farmington Railway. From July to October of 1885 he was transitman and inspector on the construction of the Iowa Central bridge over the Mississippi River at Keithsburg, Ill., and from January, 1885, to January, 1886, he was assistant engineer on the construction of approaches to this bridge. For the period from January to October of 1886 he was assistant engineer for the Iowa Central in general railroad engineering and on construction of its bridge over Black Hawk Chute, Mississippi River, near Keithsburg.

---

[1] Memoir prepared by Frank T. Darrow, Albert F. Reichmann, and R. A. Van Ness, Members, ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXXV (1922), p. 1635.

Five years of railroad right-of-way and bridge construction experience under the exacting tutelage of Mr. Wallace was an enviable asset to a young engineer and it was on this foundation that Mr. Bell built a monument of constructive engineering during the subsequent fifty years. Mr. Bell spent a few months in 1886 and 1887 as assistant engineer on the construction of the second Union Pacific Railway bridge over the Missouri River at Omaha, serving under the later internationally known bridge engineer, George S. Morison (Past-President ASCE).[8]

Mr. Bell's old chief, Mr. Wallace, had been made chief engineer in 1887 on the construction of Atchison, Topeka and Santa Fe Railway Company ("the Santa Fe") bridge over the Missouri River at Sibley, Mo.; and Mr. Bell joined him there in February of that year as assistant engineer. He continued on this work until its completion in 1889, little suspecting that some twenty-two years later he would have a very responsible part in the construction of a second, heavier structure at the same location.

After the completion of the Sibley Bridge Mr. Bell was transferred from construction to the "Santa Fe" engineering department in charge of building and sinking mattresses, and constructing other forms of protection from the encroachments of the Missouri River against the right of way. He was very active in constructing steel bridges and arch culverts when the second track was built in Missouri and Illinois. He supervised the construction of pneumatic foundations and erection of truss spans over the Canadian River near Purcell, Okla., the pneumatic piers at the Cimarron River near Guthrie, Okla., and a concrete dam for the Thatcher, Colo., reservoir. Culvert and steel bridge construction on the Western and New Mexico divisions was included in the busy period which kept him constantly on the move from 1889 to 1908.

Promotion in January 1908, after nineteen years of traveling from project to project on the "Santa Fe," to division engineer of the Missouri Division at Marceline, Mo., met with the hearty approval of both Mr. Bell and his wife. (He was married to Elizabeth Eddington on May 7, 1885, while stationed at Keithsburg.) At last here was the opportunity to enjoy that settled home life which they had looked forward to for twenty-three years.

As division engineer, until July, 1915, Mr. Bell had a very responsible part in building the second Missouri River Bridge at Sibley. He was also responsible for directing the general engineering work on the division.

Promotion to district engineer of the Western District came in July, 1915;

---

[8] For memoir, see *Transactions*, ASCE, Vol. LIV (1905), p. 513.

Mr. Bell's headquarters were moved to Newton, Kans., where he had charge of engineering on three divisions. A transfer in 1918, with the same title, to the Eastern District with headquarters at Topeka, Kans., brought added responsibilities in directing engineering on four divisions. Mr. Bell was intimately connected with many projects until his retirement in July, 1936. Among these were the pneumatic piers and steel erection for a bridge over the Illinois River at Chillicothe, Ill., and for a bridge over the Mississippi River at Fort Madison, Iowa. (The Mississippi River bridge had a swing span which, at the time, was the longest and heaviest in the world.) Other projects were the construction of open piers and the erection of steel for a bridge over the I and M Canal at Joliet, Ill.; and the work of the reinforcing or replacing steel bridges, and protecting the banks of the Mississippi, Missouri, Kaw, North Canadian, and Colorado rivers.

Mr. Bell was of modest and dignified bearing, ever helpful to his associates in suggestion and counsel based on years of broad experience. Because of his diverse knowledge his advice was frequently sought.

His family life was ideal and the success he attained was equally credited by him to his wife through sixty years of loving association. Although there were no children, Mr. and Mrs. Bell gave a well rounded home life and educational advantages to a niece.

When Mr. Bell retired in 1936 at the age of eighty two, he was described by many of his close acquaintances as "among the best known and most beloved railway engineers in the Middle West," a worthy summation of a long and useful life.

Mr. Bell was always active and in good health until April, 1939, when a broken hip curtailed his physical energy and no doubt hastened his death. He is survived by his widow.

He was a life member of the American Railway Engineering Association and had been for three years a director of the National Drainage Congress. He served as a Director of the Society from 1927 to 1929.

Mr. Bell was elected a Junior of the American Society of Civil Engineers on September 7, 1887, and a Member on October 6, 1897.

EDWARD EVERETT BETTS, M. ASCE[1]

DIED JANUARY 18, 1945

Edward Everett Betts was born on August 30, 1863, in Cincinnati, Ohio. He was the son of Charles Suydam and Martha Jane (Lyon) Betts, who were of English stock. Mr. Betts was a dignified, studious, and gracious gentleman; and his high attainments were the result of the scholarly application of a very able mind.

Mr. Betts began his professional career in 1880 as a rodman with the Toledo, Delphas and Burlington Railway Company on tunnel surveying and construction. At the age of seventeen, he moved south and worked for the

---

[1] Memoir prepared by C. E. McCashin, M. ASCE.

New Orleans and Northeastern Railroad Company (later part of the Cincinnati, New Orleans, and Texas Pacific Railway Company). During 1884 and 1885 he was assistant engineer and inspector of masonry, trestlework, and pneumatic foundations for Henderson Bridge and Henderson Bridge Railroad companies; assistant engineer for the Springfield, Effingham, and Southeastern Railroad Company; and assistant engineer on Wabash River bridge construction.

In 1886 he moved to Chattanooga, Tenn., and then, from time to time, was assistant engineer on maintenance of way for the Cincinnati Southern Railway Company, Alabama Great Southern Railroad Company, New Orleans and Northeastern Railroad Company, and Vicksburg and Meridian Railroad Company. Mr. Betts was resident engineer on surveys and construction of the Chattanooga and Lookout Mountain Railroad in 1887. In 1888 he became assistant engineer on street paving and sewer construction for the City of Chattanooga.

After these engagements he opened a consulting office in Chattanooga, later becoming assistant engineer in charge of construction of the steel-truss Walnut Street Bridge across the Tennessee River. This bridge was dedicated in 1891.

When the Chickamauga and Chattanooga National Military Park was being built, Mr. Betts acted as topographic and construction engineer. In 1895 he was appointed chief engineer; and, while serving in this capacity, he was detailed by the Secretary of War as special consultant on the development of the Vicksburg (Miss.) National Military Park. On both these jobs he had charge of topography; road surveys; location; construction; and maintenance of roads, bridges, buildings, and observation towers. He resigned from this position in 1911. The part he played in the development of the Chickamauga and Chattanooga National Military Park was the source of Mr. Betts' greatest pride. In 1911 the Hamilton County Highway Commission launched a half million dollar improvement program, and Mr. Betts was made chief engineer.

The Edward E. Betts Engineering Company (later the Betts Engineering Company) was established in the fall of 1912. Mr. Betts headed this company until his retirement in 1930. During this time the firm was responsible for many municipal and land developments in Chattanooga and in neighboring towns. Some of the projects were water supply systems for the towns of Signal Mountain and Lookout Mountain, and the East Brainerd Utility District of Hamilton County, Tennessee; improvements of street paving, sewerage systems etc., for South Pittsburg, Cleveland, and Lookout Mountain, Tenn., and the towns of Riverview and St. Elmo (later a part of Chattanooga); and land developments of Fairyland Estates on Lookout Mountain in Walker County, Georgia, and partly in the corporate limits of Lookout Mountain, and Dallas Heights, Glenwood, and Battery Heights in Chattanooga. He was also city engineer for the towns of Lookout Mountain and St. Elmo.

On April 4, 1889, he was married to Sarah May Aull. After her death, he was married to her sister, Idola Aull, who died in 1929. He is survived by one son, Clifford A. Betts, M. ASCE.

Mr. Betts' hobbies were traveling and modeling ships. He loved new horizons—at the age of seventy five he drove from Greenwich, Conn., to San Francisco, Calif., returning by water through the Panama Canal to New Orleans, La., and by auto to Chattanooga, and enjoyed every mile of the trip. His sincere, quiet, friendly manner, combined with his broad-minded, clear thinking, attracted a host of friends in many parts of the United States. He was an honorary member of the Chattanooga Engineers Club.

Mr. Betts was elected an Associate Member of the American Society of Civil Engineers on April 5, 1899, and a Member on February 4, 1913. He became a Life Member in January, 1934.

JOHN SOULE BUTLER, M. ASCE[1]

Died October 19, 1934

John Soule Butler was born in Rogersville, Tenn., on May 25, 1872. His parents were Francis A. Butler and Sarah F. (Stringfield) Butler. The great-grandparents on both sides of the family were born in the United States prior to the Revolutionary War, and were of Scotch-Irish and Welsh stock. His father's grandfather served in the Revolutionary War with great credit. His mother's great-grandfathers, Col. Joseph Williams of North Carolina and James King of Virginia, were both officers in the Revolutionary War, and served their country with distinction. The ancestors of the Butlers were represented on the Supreme Court Bench, in Congress, and as military officers.

John S. Butler attended the public schools of Knoxville and Nashville, Tenn. On June 20, 1894, he was graduated from Vanderbilt University of Nashville with the degree of Bachelor of Science in Civil Engineering. He was a thorough and conscientious student. In his class was Lytle Brown, M. ASCE, later Major General and Chief of Engineers of the War Department of the United States Army.

After graduation Mr. Butler went directly into the civilian employ of the U. S. Engineer Department and for the succeeding twenty-three years was engaged in the improvement of rivers and harbors, mostly on the Cumberland River, in connection with the Engineer Office at Nashville, Tenn.

During this period he established lines and levels, and laid out work for the construction of temporary buildings, cofferdams, and other necessities at Lock A. He supervised the reinforcement of foundations, the construction of masonry locks, the quarrying and cutting of stone, and the construction of a unique gravity trainway at Lock No. 5. He was responsible for the preparation of plans for new work, including estimates, designs, and the construction supervision of several locks, dams, abutments, and retaining walls. These were the first calculations and designs for steel lock gates, dams, and operating machinery prepared for the Cumberland River.

---

[1] Memoir prepared by James O'Sullivan, Irrigation Asst., Columbia Basin Comm., State of Washington, Spokane, Wash.

As junior engineer, Mr. Butler worked on the complete set of plans for Lock and Dam No. 21, the first concrete lock built on the Cumberland River; and on plans for steel gates for the Hales Bar Lock on the Tennessee River. Later he was placed in charge of the construction of Lock and Dam No. 21, the contractor having failed after two years of effort, and completed the work at practically contract prices.

On February 10, 1912, he was made assistant engineer and visited various river and harbor works in the United States and Canada, and the Canal Zone which was then under construction. On August 17, 1912, he was assigned to regular duties in the Nashville Engineer Office and supervised all work on the Cumberland River, including, among other work, preliminary investigations and reports on the advisability of improving various streams.

On July 5, 1917, Mr. Butler received a commission as Major in the Engineer Officers' Reserve Corps, National Army, and was assigned to active duty with the General Engineer Depot, Washington, D. C., where he had supervision of the receiving, storing, and forwarding, or issuing, of all engineer materials and supplies in the United States, as well as the operation of the Port Depot engaged in forwarding engineer materials and supplies overseas. He was also the accountable officer for this property. When the Depot Department was transferred to the Purchase, Storage, and Traffic Division of the General Staff, on November 20, 1918, Major Butler was appointed as special assistant to the Director of Storage. He was then transferred, at the request of the Director of Finance, to the Finance Office, where he did important work in the settlement of Army contracts.

Effective July 18, 1918, Major Butler was promoted to the grade of Lieutenant Colonel of Engineers, National Army, and on August 18, 1919, he was honorably discharged from the Emergency Forces.

On September 30, 1918, Lieutenant-Colonel Butler was commissioned as Major, Corps of Engineers, Regular Army, and assigned to duty as Chief of Construction Division No. 2, in charge of the construction of the powerhouse (estimated cost $19,500,000) at Wilson Dam, Muscle Shoals, Ala., on the Tennessee River. He was in charge of this work until December 31, 1923. On December 27, 1923, Lt.-Col. George R. Spaulding, Corps of Engineers (then District Engineer at Florence, Ala.), wrote Major Butler in regard to his work on Wilson Dam as follows:

> "You came here four years ago. At that time no work of any kind had been done on the Power House section of this dam. Placed in charge of that section, with a very small force of men and under great obstacles, you at once began the pioneer work of plant and railway installation. You have remained in charge of division No. 2 ever since, devoting your entire time and physical and mental strength to the job.
>
> "Until the leave which goes into effect December 31, you have had practically no relief from the onerous duties of your position.
>
> "By your energy, leadership, and splendid organizing ability, you have brought the work to such a state of completion and the force engaged upon

> it to such a state of loyal, cooperative efficiency, that our work in carrying on will be simple. You have a right to be proud of what you have accomplished, as we who have worked with you are proud of it."

On February 21, 1924, Major Butler was assigned to duty with the Eleventh Engineers at Corozal, Canal Zone, and from May 12, 1924, to July 1, 1927, was District Engineer in charge of the works for the fortification of the Panama Canal. This work included the preparation of plans, the emplacement and installation of the largest seacoast rifles at that time, the construction of tracks, magazines, switchboards, plotting rooms, fire control systems, and other incidental work. The transportation and emplacement of these heavy guns (the heaviest pieces weighing about 165 tons) in a tropical jungle country involved many difficulties. It was then said: " * * * that this lay-out of modern guns is believed to be the most modern and up-to-date that has ever been undertaken by this, our government, or any other government." On April 2, 1927, Maj.-Gen. C. H. Martin, Department Commander, Canal Zone, wrote Major Butler as follows:

> "The Secretary of War has asked me to express to you his appreciation of arrangements made by you for his inspection of the work at Bruja Point under your charge. He was very favorably impressed by the magnitude of the work that you have accomplished at Bruja Point and by the difficulties that you have overcome in transporting and mounting the heavy armament."

Major Butler was then assigned to the Wilmington, Del., office as District Engineer. Before this assignment became effective, however, he was made District Engineer at Seattle, Wash., where he assumed his duties in July, 1927.

The selection of Major Butler for this highly important post was a tribute to his ability to plan wisely the development of a great river system. Under the River and Harbor Act of January 21, 1927, the Secretary of War was authorized and directed, in accordance with House Document No. 308, 69th Congress, First Session, to survey United States river systems, where power development appeared feasible and practicable, to determine their best uses for navigation, flood control, water power, and irrigation. The survey of the Upper Columbia River in Washington and minor tributaries from the Snake River to the International Boundary, a distance of 425.3 miles, was under the jurisdiction of Major Butler. This river is the greatest potential power stream in the United States.

A comprehensive plan for the best uses of the Upper Columbia River involved the determination of the best means, if any, for the irrigation of 1,200,000 acres of potentially rich but arid land in Grant, Adams, Franklin, and Walla Walla counties in Washington. Grand Coulee Dam and accessory irrigation features were later designed to solve this problem.

After completing the survey of several rivers flowing into Puget Sound, Major Butler and his staff undertook the survey of 425 miles of the Upper Columbia River. A reconnaissance survey (April, 1928, to February 11,

1929) indicated that a detailed survey of the upper river was justified from the power, storage, and irrigation standpoints, navigation being a subsidiary benefit.

The detailed survey, which was begun on June 4, 1929, and completed on July 31, 1931, involved the investigation of hundreds of questions and the solution of many complicated problems. Such investigation, for example, included the various sources of water supply for irrigation and the areas irrigable from them, the extent of storage required for the gravity system, the location and size of canals, the reclassification of the lands, the duty of water for irrigation, a resurvey and core drilling of dam and reservoir sites, designs and estimates of the cost of irrigation works, irrigation and settlement of the land by units and the effects thereof, the economic feasibility of irrigation including the productivity of the land, the market for its produce, transportation facilities, trends in population growth, present industries including the timber industry, the mineral resources of eastern Washington and northern Idaho, and the important question of the feasibility of large-scale pumping at Grand Coulee.

On July 31, 1931, Major Butler submitted to the Chief of Engineers, U. S. Army, his famous report[2] on the Upper Columbia River. To increase the low-water flow of the Columbia River and hence its prime power, he recommended that upstream storage of 4,260,000 acre-ft be created eventually at Hungry Horse dam site, in Flathead Lake, Montana; and in Pend Oreille Lake, Idaho.

As the best plan of power development on the Upper Columbia River, he recommended the construction of dams and power plants on the following sites: Grand Coulee, 151 miles downstream from the International Boundary; Foster Creek, 51 miles downstream from Grand Coulee; Chelan, 42 miles below Foster Creek; Rocky Reach, 30 miles below Chelan; Rock Island (then under construction), 21 miles below Rocky Reach; and Priest Rapids, 56 miles below Rock Island. Beginning at Priest Rapids, each dam would back the water to the next dam upstream. The power plants at these dams would have an installed capacity of 3,880,200 kw, and would utilize for power purposes 87% of the total drop of the river in this section. The cost, with interest during construction, was estimated at $357,000,000. It was estimated that both sections of the Columbia River could produce one third of the electric energy produced in the United States in 1930.

Major Butler also recommended, for future construction, locks and lateral dams at miles 15 and 40 above the Snake River, and navigation locks at Priest Rapids and Rock Island, estimated to cost $8,950,000.

Major Butler found the gravity system of irrigation from the Pend Oreille River economically infeasible. He recommended that the Columbia Basin lands be irrigated by pumping 16,000 cu ft per sec of water from the pool formed by the Grand Coulee high dam into the Grand Coulee, an average height of 280 ft, by using mainly the floodwater or secondary electric energy developed at the Grand Coulee Dam.

---

[2] **"Columbia River and Minor Tributaries," by J. S. Butler,** ***House Doc. No. 103,*** 73d Cong., 1st Session, Vol. 2, pp. 565-1402.

It required great vision, daring, and courage on the part of Major Butler to recommend a dam at Grand Coulee of such unprecedented height on a river as large as the Columbia and such a tremendous pumping plant; yet, without such vision and courage, Grand Coulee Dam would probably never be built and the irrigation of the Basin lands would not be possible. In the short time that Grand Coulee Dam has been constructed it has demonstrated its great value to the Pacific Northwest and the United States.

In 1932, the Bureau of Reclamation concurred in the report of Major Butler and in 1933, and 1934, undertook, with certain modifications, the construction of the Grand Coulee high dam recommended by him.

In August 1931, Major Butler was transferred from Seattle to Omaha, Nebr., where he served as U. S. Corps Area Engineer, Seventh Corps Area. About September 1933, he was promoted to Lieutenant Colonel, Corps of Engineers.

On December 22, 1934, Gen. Douglas MacArthur, Chief of Staff, U. S. Army wrote:

> "Lt. Col. Butler was an able officer of quiet, pleasing manner, mature judgment, and wide experience in Engineering projects. Thoroughly reliable, well versed in his profession, and at all times displaying a high sense of responsibility, he performed his various assignments with characteristic zeal and efficiency. His death is deeply regretted by his associates."

Upon the death of Lieutenant-Colonel Butler, the Columbia Basin Commission of the State of Washington, which was created to secure the construction of the Columbia Basin Project, passed the following resolution:

> "The report of Lt. Col. Butler on the Upper Columbia River has in no small measure laid the foundations for the future growth and prosperity of the Pacific Northwest and made possible the reclamation of the Columbia Basin lands by recommending the construction of the Grand Coulee Dam. Lt. Col. Butler, through his broad vision, unswerving integrity, and outstanding courage and ability, has rendered to the Pacific Northwest and the Nation a service that cannot be repaid."

Lieutenant-Colonel Butler contributed an article for *Civil Engineering* in September, 1931, entitled "The Columbia River—for Irrigation and Power." He was a charter member of the Society of American Military Engineers, and a member of the military affairs committees of the Seattle and Omaha Chambers of Commerce. On many occasions, he was called to Washington, D. C., to advise with the Board of Engineers for Rivers and Harbors, and in 1932 appeared before the Irrigation and Reclamation Committee of the House of Representatives in behalf of the construction of the Grand Coulee-Columbia Basin Project.

Lieutenant-Colonel Butler was married on November 16, 1908, to Abbie Holten Throop of Nashville. He is survived by his widow, two sons, and one daughter, namely, Phares Throop Butler, Francis Stringfield Butler, and Clyde Smith Butler (Mrs. Stanley F. DeVore). A third son, John Soule Butler, Jr., died on December 18, 1940.

Lieutenant-Colonel Butler was elected an Associate Member of the American Society of Civil Engineers on March 4, 1908, and a Member on April 2, 1913.

THOMAS HENRY CARVER, M. ASCE[1]

Died December 22, 1944

Thomas Henry Carver was born in Lebanon, Ohio, on November 16, 1871. He was the son of Harrison Newton and Mary (Dickey) Carver who resided for many years at Valparaiso, Ind. His father served as a member of the Valparaiso (Ind.) University faculty, and also as dean of the faculty, for a total service of thirty-nine years.

Mr. Carver attended the public schools at Valparaiso; and, from 1888 to 1892, he was a student at Valparaiso University. From 1893 to 1894, he was a transitman on land surveys; and, from 1894 to 1898, he served as county surveyor of Porter County, Indiana. Together with his duties as county surveyor, he served as city engineer of Valparaiso for three years (1895-1898) and, in the latter capacity, designed and built twelve miles of macadamized highways and ten miles of sewers. He entered the University of Michigan at Ann Arbor, in 1898, and for two years studied special courses in civil engineering. In 1900 he accepted a position as transitman with the city engineer of Salt Lake City, Utah.

From 1901 to 1905, Mr. Carver lived in Utah and was employed, successively, as transitman by the Oregon Short Line Railroad Company, as superintendent on the construction of an irrigation dam, as assistant engineer on construction by the Southern Pacific Railroad Company, and as assistant engineer with the state engineer of Utah on irrigation investigations.

In 1905 he joined the staff of the city engineer department of Seattle, Wash., then directed by R. H. Thomson, Hon. M. ASCE. Because of his general experience, Mr. Carver was assigned to the Water Supply Division of the department. Entering this work in a minor capacity, he made rapid progress through the various positions in the organization and, in 1907, he was appointed engineer in responsible charge of the design and construction of the city's water supply and distribution system. In 1911 his duties were increased to include the direction of enlarging Seattle's municipal Cedar River (Washington) hydroelectric power development project by the construction of a masonry dam and power tunnel, and the reconstruction of the powerhouse, penstocks, and machinery. He also directed the design and construction of an auxiliary steam power plant to serve the city's lighting system.

From 1928 to 1932, his duties included the responsible direction of much of the design and the construction of the Diablo Dam and powerhouse on the Skagit River in Washington and about 100 miles of permanent transmission line from the powerhouse to the city. The Diablo Dam project ranks as the largest municipal hydroelectric power project yet completed in the West.

---

[1] Memoir prepared by O. A. Piper, M. ASCE.

Mr. Carver's service with the city engineer department of Seattle extended over a continuous period of thirty-six years (1905-1941). During all this time, coincident with other duties, he was actively engaged in enlarging and extending the city's water supply and distribution system together with its many special features of headworks, aqueducts, storage basins, service reservoirs, subaqueous tunnels, and fire protection. His work involved an increase of more than 500 miles in the pipe lines of the distribution system.

To anticipate the needs of a rapidly growing city and its environs (the population increased from about 80,000 to about 400,000 during his period of service), Mr. Carver's work involved advance planning for a water supply system of sufficient capacity to serve a population of 1,000,000 people, distributed over a disproportionately large area, and also to serve the included industrial activities adequately.

A large measure of appreciation is due him, and the able engineers with whom he served, for the thorough planning in all the projects entrusted to his direction; and also for the high standards of quality required in their construction.

Mr. Carver was the type of engineer who devoted most of his energies to his work. At intervals, however, he found time to take part in the affairs of engineering and allied organizations. These included the Pacific Northwest Society of Engineers (activity discontinued about 1915), the American Association of Engineers, and various water works organizations. Mr. Carver was quiet and retiring by nature, but was always ready to devote time and energy to any efforts that would advance a greater recognition of the engineering profession.

In 1902 he was married to Bertha Pool of Valparaiso. He is survived by his widow and his two sisters, Katherine Carver and Ada Belle (Mrs. Arthur Kelso).

Mr. Carver was elected a Member of the American Society of Civil Engineers on August 31, 1915. He became a Life Member in January, 1942.

CHARLES FRANCIS CHASE, M. ASCE[1]

Died December 28, 1945

Charles Francis Chase, the son of Arthur and Garafelia (Davis) Chase, was born at Claremont, N. H., on February 2, 1864. He was the eldest in a family of three boys and four girls. His grandfather, the Right Reverend Carlton Chase, was the first Episcopal bishop of New Hampshire.

His boyhood was spent in the town of his birth and his early training was in its public schools. He was graduated from Claremont High School in 1881. Following a short period at Lehigh University in Bethlehem, Pa., Mr. Chase transferred to Dartmouth College in Hanover, N. H., and was graduated in 1885, with the degree of Bachelor of Arts. He continued his studies in Hanover at the Thayer School of Civil Engineering, receiving the degree of Civil Engineer in 1889.

---

[1] Memoir prepared by George B. Taylor, Assoc. M. ASCE.

The civil engineering curriculum of that day was comprehensive. In addition to general courses in mathematics, surveying, mechanics, and hydraulics, it included such specialized subjects as roofs and bridges, roads and railways, rockwork, mining and tunneling, heat, steam and engines, river and harbor engineering, and sanitary engineering. Mr. Chase's grade in these varied subjects was an over-all average of 94.

The class of 1889 at Thayer was an interesting group, including among its eight members the late Otis E. Hovey,[2] Hon. M. ASCE, long-time Treasurer of the Society, Charles L. Carpenter[3] and Frank B. Sanborn, Members, ASCE, and William R. Michie,[4] Assoc. M. ASCE. Mr. Chase roomed with Mr. Sanborn while they were coguardians of Dartmouth Observatory for some years.

Mr. Chase's first engineering engagement was with the Vermont Construction Company of St. Albans, Vt. In 1890 he joined the engineering staff of Berlin Iron Bridge Company of East Berlin, Conn. This enterprising concern, credited with the introduction of corrugated roofing siding for buildings, and the promotion of the lenticular or "parabolic" bridge on a country-wide scale, was a pioneer fabricator of structural iron and steel. While at East Berlin, Mr. Chase was concerned with the design and construction of the 447-ft span drawbridge over the Connecticut River at Middletown, Conn., reported locally to be the longest in the United States at the time of its erection—about 1890.

When the East Berlin Company was absorbed by the American Bridge Company, of the United States Steel Corporation, at the turn of the century, Mr. Chase joined former associates who "went across the street and opened up another shop," the Berlin Construction Company. He was chief engineer for the young concern, specializing in structural steelwork. Mr. Chase remained with the company throughout his life—during the period covering the change from the use of iron to steel; the transition from the light-riveted bridge and building construction to the use of the heavier, wide-flanged, rolled, sections; and the introduction of welding. As chief engineer of this bridge company, which specialized in both steel and concrete construction in its early years, he was consulted on many railroad, electric railway, and early highway structures in the period from 1900 to 1910. He became one of the elder statesmen group of Connecticut engineers, prominent at this time.

Elected to the presidency of the Berlin Construction Company in 1925, Mr. Chase successfully guided the concern through the depression years which took such a heavy toll among steel fabricators and placed it in a position to serve New England's defense industry in the prewar and later years.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 108, 1943, p. 1537.

[3] For memoir, *ibid.*, Vol. 94, 1930, p. 1495.

[4] For memoir, *ibid.*, Vol. XLI, June, 1899, p. 647.

In 1945 failing sight forced him into partial retirement, but as chairman of the company's board of directors, and by almost daily visits to the plant, he maintained his close interest in its affairs until his death.

Mr. Chase was a resident of New Britain, Conn., keenly interested in its welfare and active in public affairs. He served as chairman of the city water board during the enlargement of the supply system (from 1908 to 1912). For twenty-five years he was chairman of the city welfare commission.

Reared in the tradition of the Episcopal Church, Mr. Chase never wavered in his devotion, giving to it his lifelong service as a loyal layman. For more than fifty years he was a communicant of St. Mark's Episcopal Church in New Britain, also serving as vestryman, parish clerk, junior warden and senior warden, filling this last post for many years until his death. On the fiftieth anniversary of his association, the parish expressed its appreciation of his long and faithful service in a public testimonial. As one of Connecticut's leading laymen, he was always a delegate to annual diocesan conventions, taking an active part in the deliberations. He served a term as president of the Church Club (Episcopal) of Connecticut and a term as secretary of the Church Club (Episcopal) of the United States.

Since Mr. Chase outlived so many of his contemporaries, the details of his early tastes and activities are not accessible to his later associates. He was an early and enthusiastic motorist, able to cope with the trials of motor and tire trouble during the infancy of the automobile. He enjoyed touring New England and was thoroughly familiar with the geographical and geological features of this region. Not athletic, at least not in his later years, he found golf "too artificial" but enjoyed the outdoors, picnics, fishing, and gardening. Family, home, and church, in spite of many activities, were his chief interests; and a keen game of bridge, his recreation.

Reserved and unassuming in manner, when the time arrived for him to comment or make a decision, he did so, clearly and forcibly. He had the passion for detail not uncommon in executives, as the junior engineer, bringing in a project not fully worked out, found to his sorrow. It is perhaps characteristic that, although elected to Phi Beta Kappa at Dartmouth, Mr. Chase never wore the key and later associates were unaware of this early honor.

A true son of his native state, there was more than a trace of "the granite of New Hampshire" in his make-up. While no Puritan, he was representative of old New England at its best—in personal rectitude, public service, private benevolence, and hatred of sham.

While his chief business interest was with the Berlin Construction Company, Mr. Chase was prominent in local financial circles. He was president of the City Realty Company, president of the New Britain Real Estate and Title Company, and a director of the New Britain National Bank. He was a charter member of the New Britain Rotary Club and a member of the New Britain Lodge of Elks, the Shuttle Meadow Country Club, New Britain Club, Church Club of Connecticut, and Sons of the American Revolution. Mr. Chase was an early member of the Connecticut Society of Civil Engineers, its president in 1907, and later an honorary member. In 1927, he was president of the Connecticut Section of the Society.

In 1894, Charles Francis Chase was married to Elizabeth Hance Parker of New Britain. They had two children: Eugene P. Chase and Helen (Mrs. Vincent Huertardo). Mrs. Chase died in 1911. In 1914, Mr. Chase was married to Ruth Arnold of Cambridge, Mass. Two daughters were born to them: Margaret (Mrs. W. H. Judd, Jr.) and Alice (Mrs. G. B. Taylor, Jr.). Mr. Chase is survived by his widow; four children; five grandchildren; a brother, the Rev. Arthur Chase; and a sister, Alice Chase.

Mr. Chase was elected a Member of the American Society of Civil Engineers on February 5, 1902.

WALTER SHERMAN LYLE CLEVERDON, M. ASCE[1]

Died March 25, 1945

Walter Sherman Lyle Cleverdon was born on October 11, 1877, in Brooklyn, N. Y., the son of John F. and Catherine A. Cleverdon. His boyhood days were spent in Coram (later Shelton), Conn., where he attended the district school. The family later moved to Tremont in New York, N. Y., where he attended the public schools. In 1896 he entered the College of Engineering of New York University, in New York, and was graduated, in 1900, with the degree of Bachelor of Science in Civil Engineering. He received the degree of Civil Engineer in 1901.

Following his graduation, Mr. Cleverdon became assistant engineer for Woodlawn Cemetery and Associates Land Company, in charge of parties making topographical and city surveys, doing landscape work, and building retaining walls and foundations. From October, 1902, to October, 1904, he was topographical draftsman for the Department of Water Supply, Gas and Electricity in Brooklyn, and chief draftsman from 1905 to 1906, designing pumping stations and equipment, pipe lines, well systems, infiltration galleries, etc. In 1904 he was placed in charge of construction for the same bureau. In 1907 Mr. Cleverdon was appointed assistant engineer (designer) for the New York City Board of Water Supply designing various structures for the Catskill Water Supply System. In 1910 he became personal assistant to the chief engineer of the Bureau of Water Supply of New York City, transferring to the Bronx office as assistant engineer in 1912, and continuing there until 1918. He then resigned to accept an appointment as lecturer in engineering in the College of Engineering of New York University. In 1919 he was appointed supervisor of property for the University at the University Heights campus, and from 1920 to 1925 served as associate professor of sanitary engineering. In 1925 he was placed in charge of all New York University property, including the Medical and Dental School centers, the Trinity Building at the Wall Street center, the fifty-acre campus at University Heights, and the group of buildings at Washington Square. The value of these properties reached a total of $13,000,000 during his incumbency. He retired in 1938, after a serious illness from which he never fully recovered but which did not, however, diminish his interest in his many activities.

---

[1] Memoir prepared by William R. Bryans, Asst. Dean, College of Eng., New York Univ., New York, N. Y.

He was the author of many articles on sanitary engineering, and of two books, "The Water Supply of Buildings and Rural Communities," published in 1925 by D. Van Nostrand Company, Inc., and "Plumbing Engineering," published in 1937 by the Pitman Company.

Mr. Cleverdon was active in church work, and served for many years as treasurer of the University Heights Presbyterian Church, and later as an officer of the West Center Church of Bronxville, N. Y. For many years he had been interested in the Alumni Association activities of his alma mater and held the office of treasurer and later president of the Engineering Alumni Association. He was a member of the American Water Works Association and the New York University Faculty Club.

Possessed of a jovial disposition, he had a host of friends and acquaintances in the engineering fraternity, and he assisted many a young graduate to obtain his first position. In recognition of his efforts for alumni welfare the University, in 1933, awarded Mr. Cleverdon the Alumni Meritorious Service Medal.

Mr. Cleverdon was married in September, 1906, to Jessie E. Thomson and to this union two daughters were born, Catherine Lyle and Jessie Thomson (Mrs. Eugene Minteski), all of whom, together with a brother, Frederick R. W. Cleverdon, M. ASCE, survive him.

Mr. Cleverdon was elected a Member of the American Society of Civil Engineers on March 7, 1921.

HARRY EDMOND COTTON, M. ASCE[1]

Died October 12, 1945

The sudden and untimely passing of Harry Edmond Cotton at the age of sixty-four removed a well-known and respected engineer from the field of construction drainage.

Harry, the son of Frank and Sarah Cotton, was born on September 8, 1881, on a farm near Cedar Falls, Iowa. His early life was typical of any Iowa farm boy, helping with the many farm duties and attending country school. After graduating from the Cedar Falls High School, he attended Iowa State Teachers College (Iowa City) for two years, then Iowa State College at Ames, from which he received the degree of Bachelor of Science in Civil Engineering, in 1906. While in college and for several years following, he played amateur and professional baseball. His interest in that sport never ceased to give him much pleasure.

Immediately upon graduation, Harry started on his engineering career as a draftsman for the Paxton and Vierling Iron Works in Omaha, Nebr. In May, 1907, he started working as a draftsman in the Omaha City Engineer's

---

[1] Memoir prepared by George E. Shafer, Assoc. M. ASCE.

Office. He interrupted this engagement for two years to work for the Omaha Structural Steel Company; but returned to the city engineer's office in August, 1915, to assume charge of all drawing, design, and estimates for public improvements. In June, 1921, he was appointed assistant city engineer and served in this capacity for six years, the latter two as a member of the City Planning Commission. From November, 1927, to January, 1928, he did estimating work with the Nebraska Department of Public Works. In January, 1928, he left the public service field to enter the commercial field as municipal engineer for the Armco Culvert Manufacturers Association, with headquarters at Middletown, Ohio.

As municipal engineer his early interests were primarily in adapting metal drainage structures to municipal uses. With the increasing interest and activity in airport construction, Mr. Cotton became vitally interested in airport drainage. "Airport Drainage," his first of many papers presented to engineering groups, was given in February, 1930, to the Iowa Engineering Society at Council Bluffs.

His interest spread to highway drainage, and in January, 1931, he transferred to an association member company, the New England Metal Culvert Company, at Boston, Mass. This company was very active in solving troublesome drainage problems throughout the New England States. After five years in New England, gaining valuable field experience, he returned to Middletown where his ideas could be developed on a national scope.

Harry was known throughout the United States and Canada for his investigational work and planning of highway and airport drainage. He was consulted by many highway departments and railroads and his advice was sought on drainage for important military and civilian air bases.

In 1941, Mr. Cotton was invited to discuss drainage at the National Defense Training Course on airport engineering conducted by the State University of Iowa in Iowa City. Later he lectured on drainage at Harvard University, Cambridge, Mass., in connection with special airport drainage classes for the Army Air Forces.

Harry Cotton had many convictions. One of these was that miles of paved surface are pounded into the mud of their subbases because engineers will not take the time or trouble to use a soil auger to find where the water is and where it comes from. With that known, he maintained that drainage, if properly installed, was the best and cheapest insurance for highways and airports.

In addition to his original thinking on drainage, Mr. Cotton was also thoroughly versed in hydraulics, sewer design, and load research problems. His writings included contributions to various engineering journals, and drainage handbooks and bulletins.

He loved nothing better than to work on engineering problems, or possibly for variety, a good competitive game of cards and an occasional fishing trip.

Harry always had a smile to prove his good disposition. He was never heard to speak a word against anyone. He was rugged and dependable. Those who knew him appreciated his forthright honesty and matured judgment. He was persistent, painstaking, logical, and thorough. He was not quick to form a final opinion; but, once the opinion was formed, no one could hold a more rational one or defend it more reasonably.

Mr. Cotton was elected an Associate Member of the American Society of Civil Engineers on September 9, 1919, and a Member on December 23, 1932.

JAMES FRANCIS CULLEN, M. ASCE[1]

Died February 24, 1945

James Francis Cullen, the son of James Francis Cullen and Mary Catherine Cullen, was born in Spruce Creek, Pa., on July 16, 1865.

He attended Mount St. Mary's College, Emmittsburg, Md., and was graduated in 1888 with the degree of Master of Arts. He entered the University of Pennsylvania, at Philadelphia, completing a two-year special course in civil engineering in 1890.

After completing his technical education he entered the service of the Pennsylvania Railroad Company in the chief engineer's department. Here he served as rodman and levelman from 1890 to 1894 on corps engaged on changes of line and grade on the Philadelphia Division and on the construction of stone arch bridges over the Little Juniata River in Pennsylvania.

He was promoted to transitman in 1894; and served in that capacity until 1901 on work in connection with the construction of the Delaware River bridge at Frankford, Pa., and bridge line connecting with the West Jersey and Seashore Railroad at West Haddonfield; also on the construction of a warehouse at Baltimore, Md., surveys for, and the construction of, the Camden Terminal of the West Jersey and Seashore Railroad.

He was appointed assistant engineer in May, 1901, and held that position until September, 1923, when he was appointed engineer of construction. This was an era of rapid growth and expansion of the Pennsylvania Railroad; an extensive program of improvements was carried on almost continuously to keep step with the rapid increase in the volume of freight and passenger traffic. Mr. Cullen was in charge of engineering on many of the important projects completed during this period; namely, the four-track stone arch bridge over the Delaware River at Trenton, N. J., the steel and masonry bridge over the Susquehanna River between Perryville and Havre de Grace, Md., and the steel and masonry bridge over the Raritan River between Perth Amboy and South Amboy, N. J.

He supervised the construction of important buildings, including locomotive construction and repair shops at Altoona, Pa., a 2,000,000-bushel grain elevator and engine terminal facilities in Philadelphia; passenger station improvements at Greensburg, Pa.; and many grade crossing elimination projects.

He was a member of the St. James Roman Catholic Church, Philadelphia.

---

[1] Memoir prepared by S. A. Sloan, Asst. to Chf. Engr., Pennsylvania R.R., Eastern Region, Philadelphia, Pa.

Mr. Cullen was a skilful and accomplished engineer and a man of high principles and integrity; he was devoted to his family, and was held in the highest esteem by his many friends and associates.

He was married at Philadelphia, on June 13, 1899, to Anna Beatrice Neville. He is survived by a daughter, Beatrice (Mrs. R. T. Brown).

Mr. Cullen was elected a Member of the American Society of Civil Engineers on May 2, 1906. He became a Life Member in January, 1936.

OSCAR FREDERICK DALSTROM, M. ASCE[1]

Died April 13, 1945

Oscar Frederick Dalstrom was born at Wyanet, Ill., on August 15, 1871. He was the son of Anders John and Anna Christina (Jacobson) Dalstrom. Mr. Dalstrom was graduated from the Fremont (Nebr.) Normal School in 1895. Mr. Dalstrom taught in district and village schools from 1894 to 1897. After studying civil engineering at the University of Nebraska in Lincoln for one year (1897-1898), he later attended Rensselaer Polytechnic Institute in Troy, N. Y., and was graduated on June 19, 1901, with the degree of Civil Engineer.

After his graduation, he began his engineering career as a draftsman for the Pennsylvania Steel Company. From 1902 to 1903 he was a shop inspector for the Pennsylvania Steel Company; from 1903 to 1904, a draftsman for the Scherzer Rolling Lift Bridge Company; from April, 1904, to December, 1904, a draftsman for the Riverside Bridge Company in Martins Ferry, Ohio; and, from 1904 to 1906, a draftsman for the Pennsylvania Steel Company.

In 1906 Mr. Dalstrom saw greater opportunities on the larger railways of the Middle West, and began his career of thirty-five years in the service of the Chicago and North Western Railway Company. He was, successively, draftsman from 1907 to 1909, chief draftsman from 1909 to 1917, and engineer of bridges from 1917 to August 31, 1941, when he retired.

As engineer of bridges, Mr. Dalstrom displayed an untiring zeal and devotion to duty. He was highly respected for his technical ability, as well as for his attention to detail. One of the larger improvements made under his direction was the replacement, in 1923, of the three 330-ft steel truss spans of the railroad bridge across the Missouri River at Blair, Nebr., with steel spans of heavier load-carrying capacity.

Mr. Dalstrom recognized his obligation to the profession, and responded by taking an active interest in the recognized engineering societies. He belonged to the American Railway Engineering Association, the Western Society of Engineers, the American Railway Bridge and Building Association, the Chicago Engineers Club, and the Rensselaer Polytechnic Institute Alumni Association. For the American Railway Engineering Association, Mr. Dalstrom served on Committee No. 15, Steel Bridges, from 1921 until his death (chairman of this committee from 1923 to 1926), taking a keen interest in the study of correct bridge details. He was also on the Editing, Publications, Standardization and Water Proofing Committee. He served on the Special Committee on Live-Load and Impact from 1935 to 1938, and on a joint committee of the American Railway Engineering Association and the American Society of Civil Engineers. He was chairman of this latter committee from 1926 through 1929. He was a trustee of the Western Society of Engineers from 1917 to 1920, and served as trustee and as chairman of the Library Committee. He was a member of the Committee on Bearing Value of Pile Foundations of the American Society of Civil Engineers in 1938, and a director of the American Railway Bridge and Building Association from 1921 to 1923.

---

[1] Memoir prepared by A. E. Bechtelheimer, Engr. of Bridges, Chicago and North Western Ry. Co., Chicago, Ill.

When Mr. Dalstrom retired from the Chicago and North Western Railway Company in 1941, he looked forward to a period in his life which he could devote to personal affairs, and went to Princeton, Ill., to reside near his farms. However, after the attack on Pearl Harbor, Hawaii, in 1941, Mr. Dalstrom was called to Washington, D. C., by the War Production Board. He spent two years in Washington from January, 1942, until the latter part of March, 1944. He liked his work because he was happy to have a part in the war effort. In February, 1944, he underwent a major operation and his doctor advised him to return to Princeton and enjoy more leisure. Returning to Princeton, he avoided overexertion and within a few months again felt fit to resume his work as a member of Committee 15 of the American Railway Engineering Association, in addition to supervising and planning improvements for his farm. On March 29, 1945, Mr. Dalstrom suddenly became ill and entered the hospital at Princeton where he died on April 13, 1945. As it was his wish to be cremated, this was done. He was never married.

The friends of Mr. Dalstrom remember him for his fine moral character and his untiring devotion to his chosen profession.

Mr. Dalstrom was elected a Member of the American Society of Civil Engineers on April 25, 1921.

ARTHUR DANIELS, M. ASCE[1]

Died June 27, 1945

Arthur Daniels, the son of Addison L. Daniels and Clara (Hodges) Daniels, was born on December 25, 1884, at Marion, Iowa. He attended the local public schools and high school before entering Iowa State College, at Ames, from which he was graduated in 1907 as a civil engineer. He spent his summer vacations from 1903 to 1907 working as a rodman for the Engineering Department of the Chicago, Milwaukee and St. Paul Railway Company.

His entire professional life was spent with the "Milwaukee" railroad—a period of thirty-eight years. Beginning as an instrumentman in 1907 he was advanced to assistant engineer in 1909 and assigned to making field surveys, and supervising masonry construction. In 1912 he was assigned to valuation work for one year, and from 1913 to 1918, inclusive, he was in charge of extensive track elevation work at Milwaukee, Wis. In September, 1918, he was made district engineer for the Northern District, with headquarters at Minneapolis, Minn., supervising the engineering work on 3,000 miles of main lines. On July 1, 1935, he was made assistant superintendent of track maintenance, with headquarters at Chicago, Ill., which position he held until November, 1937. Then he was made division engineer of the Twin City Terminal and the Iowa and Southern Minnesota divisions, having charge of all construction and maintenance work on the two divisions. He held this position, in Minneapolis until his death.

---

[1] Memoir prepared by W. H. Penfield, M. ASCE.

Mr. Daniels was married at Marion, on October 19, 1910, to Jessica Merchant. He is survived by Mrs. Daniels; a son, Lowell Preston Daniels, a Lieutenant Commander in the United States Naval Reserve; and a daughter, Dorothy Harriet Daniels.

Mr. Daniels was very well known in the northwest, especially in Minneapolis and St. Paul, Minn., where for years he participated in many civic affairs. His engineering ability and good judgment were always recognized and respected. He was a member of St. Luke's Episcopal Church in Minneapolis, and a member of the American Railway Engineering Association.

Mr. Daniels was elected an Associate Member of the American Society of Civil Engineers on December 6, 1915, and a Member on May 28, 1923.

FRANKLIN DAVID DAVIS, M. ASCE[1]

Died February 15, 1945

Franklin David Davis, the son of Edwin and Mary Register (Pope) Davis, was born on March 21, 1885, in Baltimore, Md. After private schooling in Baltimore, he attended the Baltimore Polytechnic Institute in 1896, from which he was graduated in 1902.

On September 21, 1902, he entered the service of the Western Maryland Railway Company at Baltimore, as a rodman in the Engineer Corps, assigned to the building of the Tidewater Extension of the railroad around the City of Baltimore. On June 1, 1903, he was employed by the Pennsylvania Railroad Company as a levelman in the Engineering Department; and, after passing through the grades of rodman and transitman, he was appointed an assistant supervisor of track in the Maintenance of Way Department at Media, Pa., in June, 1907. He was transferred to a similar position at Freeport, Pa., in November, 1909; and in May, 1910, he was made acting supervisor of track at Jersey City, N. J. Subsequently, he was supervisor of track at Barnesboro, Pa., Wilkes-Barre, Pa., and Jamesburg, N. J. In April, 1918, he became an assistant freight trainmaster in charge of the Waverly (N. J.) Yard on the

---

[1] Memoir prepared by R. W. E. Bowler, Engr., Maintenance of Way, The Pennsylvania R. R., Buffalo, N. Y.

New York Division, Transportation Department. He then received the following promotions:

March 1, 1920, division engineer of the New York Division at Jersey City;
July 1, 1922, superintendent, Norfolk Division, at Cape Charles, Va., in charge of the Transportation, Maintenance of Way, and Maintenance of Equipment departments;
October 24, 1923, superintendent of the New York Division, in Jersey City;
October 16, 1925, acting general superintendent of the New Jersey Division at New York, N. Y.;
April 1, 1926, general superintendent of transportation of the Western Region at Chicago, Ill.; and
June 16, 1927, general superintendent of the Northern Division at Buffalo, N. Y.

On October 15, 1944, he was granted a leave of absence because of illness.

On October 28, 1907, he was married to Muriel Janney, who survives him, together with one son, Edwin Janney Davis.

Mr. Davis was a member of railroad clubs in Buffalo, New York, and Toronto, Ont., Canada; and the Buffalo Club, Buffalo Athletic Club, Buffalo Country Club, Landmark Lodge No. 442, F. and A. M., and Craftsmen's Club of Wilkes-Barre.

Mr. Davis was elected a Member of the American Society of Civil Engineers on July 11, 1921.

GEORGE FREDERICK ECKHARD, M. ASCE[1]

Died December 28, 1945

George Frederick Eckhard, at the time of his death, was dean of the College of Engineering at the University of Vermont, in Burlington, chairman of the Vermont State Board of Registration for Professional Engineers, and a prominent figure among the engineering educators of New England. He was born in Waverly, Iowa, on November 21, 1878, the son of George and Katherine (Freiberger) Eckhard. He received the degree of Master of Didactics from Iowa State Teachers' College in 1900, and was graduated from the University of Iowa (Iowa City) in 1905 with the degree of Bachelor of Science in Civil Engineering. In 1910 he was granted the degree of Civil Engineer by his alma mater.

Soon after his graduation he went to Guantanamo, Cuba, as an assistant engineer on the Cuba Eastern Railroad, and returned early in 1907 to take charge of sewer construction in Cedar Falls, Iowa. Later in 1907 he was appointed professor of civil engineering at the New Mexico School of Mines (Socorro, N. Mex.), a position he held for two years, also serving as city engineer for Socorro and (from 1908 to 1909) as United States Deputy Mineral Surveyor for New Mexico. From 1909 to 1912 he was professor of civil engineering at James Millikin University, Decatur, Ill. The next three years he spent as assistant and associate professor of structural engineering at Pennsylvania State College (State College), where he was in charge of the department of structural engineering. In April, 1915, he came to the University of Vermont as professor of structural engineering, and in 1932 he became dean of the College of Engineering.

---

[1] Memoir prepared by Louis B. Puffer, M. ASCE, and James A. Bullard, Prof. of Math. & Mech., Univ. of Vermont, Burlington.

During the years that he served as dean, the college acquired a large amount of valuable new equipment for its laboratories; the space available for its work was greatly increased; and most of its activities were transferred from the old and inadequate Engineering Building to quarters in the spacious new Waterman Building. A lover of perfection in all things, it was Dean Eckhard's constant ambition to improve the physical plant and the scholastic work of the college in every possible way. In his teaching, which he never entirely gave up, he was insistent on quality, accuracy, and completeness, and would never tolerate careless or slipshod work. After his death the president of the University, John S. Millis, said:

> "I take consolation in the fact that the sound condition of the College of Engineering is a worthy memorial to Dean Eckhard's intelligence and energy. He built well, so that even with his passing, the affairs of the College have gone forward."

Although his principal interest was in the field of engineering education, and although he liked best to be known as a structural engineer and a teacher, Dean Eckhard did not limit his activities to teaching and college administration. He gave much time to state and civic affairs, serving for nearly twenty years on the Burlington Street Commission, the City Planning Board, and various other public bodies. He also acted as an expert for the State of Vermont in the final settlement, by the United States Supreme Court, of the century old controversy over the Vermont-New Hampshire boundary. With Mrs. Eckhard he traveled widely through the United States and Canada, mostly by automobile, and visited most of the great engineering works in both countries.

The same love of perfection that characterized his professional relationships was also evident in all departments of his private life. He loved the outdoors, particularly boating, fishing, and gardening; and he was one of those happy persons for whom choice flowers loved to bloom. He enjoyed working with his hands, and whatever he made had always to be of the highest quality, whether a photographic enlargement or a 36-ft cabin cruiser.

He was a fellow of the American Association for the Advancement of Science; a member, for thirty-five years, of the Society for the Promotion of Engineering Education (member of the council from 1937 to 1940); and a member, for nearly thirty years, of the Vermont Society of Engineers (of which he was president in 1932 and 1933). He was also a member of Sigma Xi (Sigma Xi Club) at the University of Vermont. During his residence in Burlington he was a loyal member of the College Street Congregational Church, and served it in various capacities.

Dean Eckhard was a man of highest character and unquestioned integrity. Associates and students alike had great respect and affection for him. The following sentences are from a memoir prepared by a committee of the faculty of the College of Engineering of the University of Vermont:

> "Nearly his whole professional life was devoted to the training of young engineers; and none, we believe, came under his influence who was not made better by it. He was, in the truest sense of the word, a fine man, and in his passing we have lost a dear friend; our college, a trusted leader; and the University of Vermont, a sound and valued counselor."

On Sept. 1, 1908, George Eckhard was married to Henrietta Plock at Burlington, Iowa. Dean Eckhard is survived by his widow; a daughter, Elizabeth (Mrs. Frank McMullan); two grandsons, John and David McMullan; and two sisters, Clara (Mrs. William Langlas) and Lydia (Mrs. John Biggs).

Dean Eckhard was elected an Associate Member of the American Society of Civil Engineers on October 11, 1920, and a Member on April 12, 1937.

THEODORE HORATIO ELLIS, M. ASCE[1]

DIED MAY 26, 1945

Theodore Horatio Ellis, the second son of Prof. John Millot and Minerva Emeline (Tenney) Ellis, was born in Oberlin, Ohio, on February 20, 1867. He was a lineal descendant of Lt. Richard Ellice of Dedham, England, who came to Boston, Mass., in 1632, and settled in Dedham, Mass., where he took a prominent part in the political and social life of the community.

Lieutenant Ellice's grandson, Col. Timothy Ellis, was born in Dedham, Mass., and later (1765) moved to Keene, N. H., with his wife and eight children. He was a soldier and a statesman, taking an active part in the Revolutionary War and holding the office of selectman in Keene for five years. He was a delegate to the Provincial Congress, in 1775, and a representative in the Legislature from 1776 to 1778.

A grandson of Colonel Ellis, Seth Brittun Ellis, moved from Jaffrey, N. H., in 1840, to Oberlin. (Oberlin College had just been founded as the first coeducational school in the United States.) One of his sons was John Millot Ellis. He was educated at Oberlin College and was graduated in 1851. He then attended the Oberlin Theological Seminary, receiving a degree in 1857. John Ellis was a professor at Oberlin College (from 1858 until his death in 1894), Mayor of Oberlin (from 1861 to 1862), a "Delegate to the Battleground" in the United States Christian Commission, associate pastor of the Second Congregational Church of Oberlin (from 1867 to 1874), and United States Commissioner to Europe for the World's Columbian Exposition (in 1891). (In the latter capacity he conferred with representatives of

---

[1] Memoir prepared by Alfreda Brennan Ellis, Summit, N. J.

Great Britain, Germany, Denmark, Sweden, Norway, and Russia.) In 1862, Professor Ellis was married to Minerva Emeline Tenney, a graduate of Oberlin College (1858) and a teacher in the college preparatory department.

Theodore Horatio Ellis spent his school and college days in Oberlin. In 1890 he left Oberlin College, after his sophomore year, to begin his business career with the Missouri Lumber and Mining Company of Grandin, Mo. He served in various capacities—as surveyor, railroad construction engineer, and chief of the land department.

In 1892 he became interested in the producing and refining of petroleum; and in 1893 he organized the Tiona Manufacturing Company, building a refinery at Tiona, Pa. He was president and manager of this company until 1901, when the business was absorbed by the Standard Oil Company. During five years of this period Mr. Ellis served as justice of the peace.

From 1901 to 1905, he worked for the Sun Company and assisted in the design and construction of an oil refinery at Marcus Hook, Pa. In 1905, Mr. Ellis organized the Ellis Company, manufacturers of petroleum products. As president of this company he designed and erected a refinery at Curtis Bay, Md., and operated it until 1910 when the Ellis Company was absorbed by the United States Asphalt Refining Company, a subsidiary of the Interocean Oil Company of New York, N. Y. As consulting engineer for the Interocean Oil Company and as director of the United States Asphalt Refining Company, Mr. Ellis designed and constructed an addition to the $1,000,000 refinery at East Brooklyn, Baltimore, Md., and designed and constructed a $500,000 oil refinery at Carteret, N. J. He also designed and constructed a refinery for the Netherlands Petroleum and Asphalt Company at Flushing, Holland; and, for the Interocean Oil Company, the Chesapeake and Curtis Railroad Company, the United States Petroleum Corporation, and the Santo Domingo Development Corporation, designed and supervised installation of a dock and terminal at Tampico, Mexico. He investigated possibilities of obtaining petroleum in the Dominican Republic and started development work there. In 1918, he resigned to accept a commission in the Army.

On November 8, 1918, Captain Ellis was ordered to report to the Commanding General, American Expeditionary Forces, in France, for duty as an "Expert Internal Combustion Engine Lubrication Engineer." The Armistice canceled these orders; and on November 30, 1918, he was assigned to duty as assistant port utilities officer in New York. Shortly afterward he was honorably discharged from the Army.

From 1919 to 1923, Mr. Ellis was employed as consulting engineer for fuel oil stations by the United States Shipping Board. In this capacity Mr. Ellis designed and erected fuel oil stations at the following places: St. Thomas, Virgin Islands; Honolulu, Hawaii; Pago Pago, Samoa; Manila, Philippine Islands; Mobile, Ala.; and Craney Island, Norfolk, Va. (Craney Island was the largest fuel oil station on the Atlantic Coast with storage capacity for a million barrels of oil; at its two wharves, the station could bunker two ships at a rate of 4,000 barrels an hour). The total cost of these plants was $2,250,000. When the refineries were completed, Mr. Ellis resigned and entered private practice as a consulting engineer at Summit, N. J.—his home for thirty years. Mr. Ellis made a number of inventions in connection with refining petroleum on which he secured patents.

Mr. Ellis was married to Harriet Emily Cumings, a daughter of Capt. Henry Harrison and Charlotte Jane (Sink) Cumings, of Tidioute, Pa., on August 27, 1888. They had three children: Bernard Tenney, Charlotte Cumings (Mrs. Stanley W. Fenton), and Minerva Tenney (Mrs. Thomas E. McCracken, Jr.). Mrs. Ellis died on October 9, 1922.

On February 26, 1927, Theodore H. Ellis was married to Alfreda L. Brennan, daughter of Alfred Lawrence Brennan (a noted illustrator of periodicals for over half a century) and Harriet Lucy (Lee) Brennan.

Theodore Ellis was a charter member of the American Legion, Summit Post 138, and of the Old Guard of Summit, organized in 1930. The latter group, composed of retired men of diverse professions and backgrounds, met once a week with a speaker. Mr. Ellis attended all meetings as long as his health would permit. He was also a member of North Star Lodge, F. and A. M. of Warren, Pa.; the Sons of the American Revolution; the Engineers' Club of New York; the Canoe Brook Country Club, Summit, N. J.; the Baltimore Yacht Club; American Society for Testing Materials; and the Society of American Military Engineers.

Among his other interests were golf and fishing and a workshop, where he made some lovely bits of furniture and small items in wood. During the last months of his life he completed several war contracts—handles for kits of tools for the armed forces made by Westinghouse—and he looked forward to repeat orders.

Theodore Ellis is survived by his widow; three children; and six grandchildren, Bernard Tenney Ellis, Jr., John Theodore Ellis, Thomas E. McCracken, Jr., Charlotte Elizabeth Fenton, Virginia Doris Fenton, and Esther Marjorie Fenton.

Mr. Ellis was elected a Member of the American Society of Civil Engineers on April 19, 1920. He became a life Member in January, 1945.

PAUL EMERY, M. ASCE[1]

DIED AUGUST 27, 1945

Paul Emery, the son of William and Elizabeth (Fisher) Emery, was born at Topeka, Kans., on September 27, 1890. He attended the public schools in Topeka. From 1910 to 1912 he was a student of engineering in the University of Illinois at Urbana.

During vacations, and after he left the University of Illinois, in June 1912, he was employed by the Topeka (Kansas) Bridge and Iron Company; here he detailed structural steel, and designed and estimated the cost of bridges. After several years of office work, he was placed in charge of the construction of a number of bridges, with headquarters in San Antonio, Tex. In 1917 he again took up structural steel detailing, this time with the Lackawanna Bridge Company, in Buffalo, N. Y. Shortly thereafter he became associated with the Robert Ingalls Iron Works, at Birmingham, Ala., first designing and detailing structural steel, and later as office and sales engineer in charge of the New Orleans, La., office. In January, 1919, he was engaged by the American Rio Grande Land and Irrigation Company, Mercedes, Tex., to design concrete structures and canals; he remained with this company until August, 1925.

---

[1] Memoir prepared by Oscar B. Coblentz, Pres., McLean Contracting Co., Baltimore, Md., with the assistance of Alexander Maitland, Pres., Kansas City Bridge Co., Kansas City, Mo.

In September, 1927, for a period of six months, he worked for the American Bridge Company, at Ambridge, Pa., detailing bridges. From March, 1928, to January, 1929, he was assistant bridge engineer to the County Engineer of Cuyahoga County, Cleveland, Ohio. From January, 1929, to September, 1929, he was engaged in designing and estimating bridges for the Virginia Bridge Company at Roanoke, Va.

He joined the organization of the Kansas City Bridge Company, Kansas City, Mo., in September, 1929, as office engineer in charge of the drafting room. During the eleven years he was part of this organization, his work included the development of construction methods and procedures for various types of substructures; and the construction of the substructures of locks and dams, quay walls, wharves, and bridge foundations. He was instrumental in developing the method that was used in the construction of the foundations of the bridge across the Mississippi River, at Baton Rouge, La. During these years he designed various types of marine equipment used by the company in that period. He was promoted from office engineer to assistant chief engineer on July 15, 1939. He was in charge of all the superstructure work, including the preparation of estimates and proposals, the supervision of the work to completion, and the direction of the company's Kansas City shop.

When the national defense program of the United States became active in the fall of 1940, he resigned his position with the Kansas City Bridge Company to accept a position on December 1, 1940, as project engineer for the McLean Contracting Company. This company had a cost-plus-fixed-fee contract with the Bureau of Yards and Docks, Navy Department, for constructing a supply pier at the Naval Operating Base, Norfolk, Va.—one of the largest such piers on the east coast. The McLean Contracting Company was awarded additional work in the Norfolk area, which, between the date Mr. Emery came with the company and the time of his death, aggregated approximately thirty million dollars. He was in charge of the office engineering, as well as the engineering forces in the field. This work included the construction of piers; the construction of twenty-five 50,000 barrel pre-stressed reinforced-concrete tanks; the reconstruction of the oil handling facilities at the Naval Fuel Depot Annex, Craney Island, Virginia; the construction of a magnetic range in the middle of the Chesapeake Bay; and the construction of a "deperming" station, used in demagnetizing steel ships. After war was declared, the Navy decided to protect the steel fuel tanks at Craney Island, and at the Naval Operating Base in Norfolk, with splinterproofing consisting of reinforced concrete fifteen inches thick. Mr. Emery developed a tongue-

and-grooved reinforced-concrete member, that could be pre-cast and set up to form a circle around these tanks, that could be removed without damage to the tanks, and that at the same time could be used for the construction of bulkheads and similar work. This plan, which he developed, worked out so satisfactorily at Norfolk that it was used elsewhere by the Navy. His duties also included the development of designs and design details in cooperation with the Officer-in-Charge of Construction and his representatives.

Both of Mr. Emery's parents were musicians, and from his childhood until his death he was extremely fond of classical music and was a patron of the Kansas City Philharmonic Orchestra. He was fond of sports and was an ardent baseball fan.

He was physically strong, conscientious, and an untiring worker. He was endowed with the rare ability of reconciling the conflicting views of engineers, so that the desired result could be accomplished in the shortest possible time, and at a reasonable cost. He died from a heart attack, while working at his desk at the Naval Operating Base in Norfolk.

He was married to Grace A. Shimer on September 7, 1912, at Topeka. He is survived by his widow; one daughter, Pauline (Mrs. James P. Biedenharn); one son, James; and a sister Mrs. Lydia McAfee.

Mr. Emery was elected a Member of the American Society of Civil Engineers on April 10, 1939.

OZRO NOWLIN FLOYD, M. ASCE[1]

Died November 30, 1944

Ozro Nowlin Floyd was born on a farm near Hampshire, Maury County, Tenn., on April 12, 1878. He was a son of Henry W. and Celia Jane (Weatherly) Floyd, both members of early Tennessee pioneer families. Mr. Floyd was educated in the public schools of his native county, early attracting attention through his unusual ability in mathematics. He was graduated from the University of Tennessee, at Knoxville, in 1905 as an honor student, receiving the degree of Bachelor of Science in Civil Engineering.

Mr. Floyd's subprofessional engineering work was done in the service of the Louisville and Nashville, Cairo and Thebes, Cairo and Norfolk, and Southern railways. He spent six years in railroad work, rising to the position of chief of party on location and drainage surveys.

In September, 1911, he made a connection which was to fix the trend of all his subsequent career, and which introduced him to the type of work in which he rose to a pre-eminent position. He entered the employ of the Morgan Engineering Company of Memphis, Tenn., as chief of party on drainage surveys and construction, in Arkansas and Mississippi, continuing in this work until May, 1913.

The great Dayton, Ohio, flood of 1913 gave him his first real opportunity to develop and display his genius in flood control work. He arrived in Dayton soon after the waters of that disastrous flood had receded, and at first was in charge of surveys and certain other field investigations. This was two and a half years before the Miami Conservancy District was organized, and long before a comprehensive plan for the control of floods in the Miami valley was perfected. Mr. Floyd was the principal assistant to Arthur E. Morgan, M. ASCE, and had an important part in all of this preliminary work. By 1915, the Ohio Conservancy Act had become law; and a plan for obtaining flood protection, by means of retarding basins and channel enlargement, through centers of population had been officially adopted. Mr. Floyd remained with the District to the end of construction in the latter part of 1922. Particularly efficient was his relocation of steam and electric railways through the District, and his conduct of negotiations with the executives and engineers of the several lines involved.

---

[1] Memoir prepared by Frank W. Chappell, M. ASCE.

Through the years from 1923 to 1925, Mr. Floyd served as principal assistant engineer on the design and construction of two large dams for the Wichita Falls (Tex.) Irrigation District, and of a water supply dam for the City of Dallas, Tex. The total cost of these projects was $9,500,000.

He entered a partnership with J. L. Lochridge, M. ASCE, in 1925, and continued this association into 1933. Notable commissions executed by Floyd and Lochridge were a water supply dam for the City of Waco, Tex.; a storage dam for the West Texas Utilities Company near San Angelo, Tex.; consulting service to the City of San Antonio, Tex., in a $1,000,000 river-straightening project through that city; a storage dam for the Dallas Power and Light Company, costing $1,250,000; and special studies and reports for the large utility companies of Texas.

After the dissolution of the partnership, Mr. Floyd confined his practice to personal service consulting work. Back in 1929, he was retained as consultant to the New Orleans District of the Corps of Engineers, U. S. Army, to advise that office on matters relating to condemnation proceedings for acquisition of flowage rights for the Bonnet Carré Spillway, particularly with respect to the rights of way of the Illinois Central Railroad Company, the Yazoo and Mississippi Valley Railroad Company, and the Louisiana and Arkansas Railway Company, all of which cross the floodway. Mr. Floyd acquitted himself with distinction on this work and performed a highly useful service.

During recent years Mr. Floyd's consulting engagements were numerous and important. Among them may be listed the following, although the list is by no means complete:

1. The Federal Power Commission: To determine the legitimate cost of the Conowingo power development on the Susquehanna River.

2. The Tennessee Valley Authority (TVA): After 1934 he was a member of the board of consultants, and devoted much of his time to the many and varied problems of design and construction arising during the comprehensive development of an entire river basin.

3. Red Bluff Water Power Control District, Pecos, Tex., 1935-1937: An irrigation, flood control, and hydroelectric power project.

4. Vicksburg (Miss.) District, Corps of Engineers: On the Sardis Dam, 1935-1940, and the Arkabutla and Wallace Lake dams, 1934-1944.

5. Memphis District, Corps of Engineers: On the design and construction of the Wappapello Dam, 1936-1944.

6. Denison (Tex.) District, Corps of Engineers: On the design and construction of the Denison Dam; "O. N." has been called the "Father of the Denison Dam." (He was a staunch friend of the Hon. Sam Rayburn, long-time representative of the Fourth Texas Congressional District, in which Denison is located, and Speaker of the House of Representatives since 1940. Mr. Floyd had made extensive preliminary investigations into the feasibility of a dam on the Red River, in Texas and Oklahoma, for the dual purposes of flood control and power production. Mr. Rayburn sought his opinion as to the merit of the project. The reply was that, of all similar projects in the Southwest, the Denison project was the soundest. Mr. Rayburn sponsored legislation which authorized the design and construction of the dam and power plant.)

7. Division Engineer, Corps of Engineers, Omaha, Nebr.: On the location of a dam on the Missouri River near Minot, S. Dak., 1944.

8. Division Engineer, Corps of Engineers, Dallas: On soil erosion control studies in Texas and Oklahoma, 1943-1944.

Public bodies did not make up the entire list of O. N.'s clients, however. He enjoyed to a high degree the confidence of contractors and private utility companies. He served the Callahan Construction Company on numerous occasions in the preparation of bids on construction contracts. The first of these engagements occurred in 1923 and 1924, and involved flood control work at Pueblo, Colo., and a water supply dam at Oklahoma City, Okla. Later, he made a study of the Madden Dam project in the Panama Canal Zone, and continued his connection with the project throughout the construction period. He represented the contractors in all their negotiations with the Corps of Engineers relating to the construction of the John Martin Dam on the Arkansas River in Colorado. In 1940 he was the sole arbitrator of disputed claims between Dodds and Wedegartner, contractors, and the Willacy County Water Improvement District No. 1, Raymondville, Tex. In 1944 he made a trip to Alaska, inspected the Canol project, and prepared a full report to the contractors.

The complete confidence which Mr. Floyd enjoyed from cities, state and federal agencies, utility corporations and construction contractors gives a fair measure of his absolute honesty and recognized ability. Most men would consider themselves fortunate to earn the respect and confidence of one or two of these groups of clients. O. N. Floyd had so impressed all of them with his fairness, professional integrity, and technical mastery, that all trusted him and sought his advice. He was one of the outstanding authorities of the United States in the fields of water conservation, flood control, soil erosion, hydroelectric power production, and the construction of large works to make effective these purposes. He frequently was called on by contractors to design their plants for heavy construction, and was considered an authority on earth-moving equipment and concrete-manufacturing equipment. Mr. Floyd was the author of two articles on the construction of earth dams.[2, 3]

Mr. Floyd was a man of unimpeachable character who took a keen interest in helping those in need. He was chairman of the Board of Elders of the Central Christian Church of Dallas, and a director of the Young Men's Christian Association (Y. M. C. A.) of Dallas. As a member of the Camp Committee of the "Y," he sponsored the construction of a swimming pool for boys at Camp Crockett, near Dallas. He made the plans for this small operation with his own hands, with the same meticulous care he gave to the multimillion dollar projects of the TVA; he was also a member of the Property Committee, to which he gave much of his time. His church work and Y. M. C. A. work were labors of love for him, and some measure of his character could be estimated through hearing the glowing tribute paid to his memory by his pastor and the general secretary of the Dallas Y. M. C. A.

O. N. Floyd was married on February 22, 1917, at Cleveland, Ohio, to Alice Cornelia Hofrichter, who survives him. Their only child is Lois Jean Floyd.

Mr. Floyd was an expert marksman with all types of small arms and was a life member of the National Rifle Association. He was also a member of the Technical Club of Dallas; the Texas Society of Professional Engineers; the American Association of Engineers; and the Conservancy Lodge No. 661, Free and Accepted Masons, of Dayton.

An active member of the American Society of Civil Engineers, Mr. Floyd participated in sectional and general activities; he was a member of the Executive Committee of the Construction Division; chairman of the Subcommittee on Cut-Offs and Embankment Slope of the Committee on Earth Dams and Embankments, Soil Mechanics and Foundations Division; and Chairman of the Committee on the State of Art and Science of Hydraulics of the Hydraulics Division. He was a serious student of technological advancement, and greatly enjoyed his work with the Technical Division Committee. Also, he was a member of the Texas Section and of the Dallas Branch, and attended all the Monday monthly luncheons which his busy travel schedules would permit.

Mr. Floyd was elected an Associate Member of the American Society of Civil Engineers on September 3, 1913, and a Member on September 12, 1921.

ALBERT WEBSTER GALBREATH, M. ASCE[1]

DIED OCTOBER 15, 1944

Albert Webster Galbreath was born in Wilmot, Ohio, on October 29, 1883, the son of Charles Burleigh and Ida (Kelley) Galbreath. The families of both father and mother were interested in educational work in the field of literature

---

[2] *Civil Engineering*, August, 1940, p. 487.

[3] *Ibid.*, September, 1940, p. 586.

[1] Memoir prepared by H. D. Bruning and Clarence D. Bowser, Members, ASCE.

and the liberal arts. Being of a mechanical turn of mind, Albert, from his early school days, applied himself to scientific matters and chose the engineering profession for his life work.

Mr. Galbreath received his early education in East Palestine, Ohio. In 1896, the family moved to Columbus, Ohio, where Albert entered the Central High School; he spent one year in Otterbein University at Westerville, Ohio. In 1899, he entered the Ohio State University, at Columbus, as a student in civil engineering, which course he pursued into 1904, spending the summer months on surveys and construction work with Wilber A. Ginn, chief engineer of the Columbus, Urbana and Western Traction Company. It was this experience that led him into the field of railroad engineering which he followed up to the time of his retirement, in 1934, on account of a physical ailment.

In January, 1905, he entered the service of the Pennsylvania Railroad Company, at Cincinnati, Ohio. He was connected with this company and its affiliated lines until May, 1917, when he voluntarily entered the service of his country during World War I, receiving his honorable discharge on May 28, 1919. During the aforesaid service on the Pennsylvania Railroad he was engaged as assistant on maintenance and construction. From June 1, 1909, to March 1, 1911, he was in responsible charge of the construction of about twenty-two miles of second main track on the St. Louis Division of the Vandalia Railroad Company between Montrose and Altamont, Ill., including the construction of eleven permanent bridges. The entire work was performed under traffic at a cost of approximately $900,000. After this he was assistant engineer with the Vandalia Railroad in charge of the drafting room of the chief engineer of Maintenance and Way, checking all estimates, preparing plans and specifications of special structures, and doing valuation work. In July, 1919, he resumed his work with the Pennsylvania Railroad as assistant engineer on valuation. In August, 1920, he was appointed valuation engineer on the Missouri, Kansas and Texas Lines with headquarters at Parsons, Kans. This position he held until 1932, when the final report to the Interstate Commerce Commission was accepted and the work of valuation completed. He then followed a private consulting practice in St. Louis, Mo., in railroad work until his retirement.

During World War I, he was stationed in France as First Lieutenant and Captain of the 12th Regiment Railway Engineers on construction, maintenance, and operation of light railways, and some construction of standard-gage lines.

Mr. Galbreath had many friends in both his civilian life and his professional life. He was always sincere in his friendships, and all who knew him and worked with him had the utmost respect for him. Honesty, loyalty, self-sacrifice, and belief in fair play were his outstanding characteristics. He was generous and always willing to help a friend and associate in time of need. He was very active in the Boy Scout movement. As a member of the Parsons Boy Scout Council he was its representative on the National Council at the National Council meeting in New York, N. Y., in 1927.

Mr. Galbreath was a member of the American Railway Engineering Association; the Engineers Club of St. Louis; Circle Club of St. Louis; and the

Engineers Club of Columbus. He was a member of the Masonic Order in Effingham, Ill.

His marriage to Stella Snow occurred on October 14, 1907, in Columbus. He is survived by his widow and his mother.

His recreations were mostly outdoor life and gardening. He had a great interest in photography and in the national game of baseball.

Mr. Galbreath was elected an Associate Member of the American Society of Civil Engineers on April 17, 1917, and a Member on December 3, 1926.

ARTHUR FRANKLIN GORDON, M. ASCE[1]

Died January 29, 1942

Arthur Franklin Gordon was born in Terre Haute, Ind., on October 16, 1875. He was the son of James McClelland and Caroline (Melcher) Gordon. He received his technical training at Rose Polytechnic Institute in Terre Haute, being graduated in 1897 with the degree of Bachelor of Science.

From July, 1897, to June, 1919, he held the following positions:

June to October, 1897—engineer for Townley Brothers in Terre Haute on electrical construction work.

October, 1897, to February, 1899—office engineer for the Standard Wheel Company in Terre Haute.

February, 1899, to March, 1900—rodman and assistant resident engineer on the location of a railroad extension from Marion, Ill., to the Mississippi River, and later electrician in charge of the electrical plant at the Danville (Ill.) shops of the Chicago and Eastern Illinois Railroad Company.

March, 1900, to February, 1902—draftsman with structural engineering firms in Pittsburgh, Pa.

February, 1902, to July, 1907—engineer in charge of a drafting room squad for the McClintic-Marshall Construction Company at Pittsburgh (except for a period as construction engineer in charge of field erection work).

July, 1907, to June, 1911—draftsman, checker, or engineer for various structural engineering firms in Pittsburgh, Pa., Cincinnati, Ohio, Terre Haute, Ind., Chicago, Ill., and Rochester, Pa.

June, 1911, to April, 1912—checker in the drafting office of the American Bridge Company at Ambridge, Pa.

April, 1912, to April, 1916—designer in the Bureau of Bridges of the City of Pittsburgh on the design of the Bloomfield Bridge and numerous other important structures in Pittsburgh.

April, 1916, to October, 1918—assistant chief engineer of the Bureau of Building Inspection, Pittsburgh, in charge of the review and approval of structural work.

---

[1] Memoir prepared by the Rev. R. Paul Schearrer, Pastor, Presbyterian Church, Takoma Park, Md., and A. E. McClure, Senior Highway Engr., Public Roads Administration, Washington, D. C.

October, 1918, to January, 1919—concrete designer for the munition plant at Neville Island near Pittsburgh.

January, 1919, to June, 1919—structural engineer in charge of design of mill buildings and concrete work for the plant of the Weirton Steel Company at Weirton, W. Va.

From June, 1919, until his death, Mr. Gordon was with the U. S. Bureau of Public Roads (later the Public Roads Administration) as senior highway bridge engineer in immediate charge of the Bridge Division of District Ten which at that time embraced the states of Ohio, Pennsylvania, Maryland, Delaware, Virginia, North Carolina, and West Virginia, and later the District of Columbia. He had immediate responsibility for supervision of building all federal-aid highway bridges in this district until his death.

During his forty-five years of service in his chosen profession, Mr. Gordon always contributed unselfishly his time, energy, and talent toward the development of local social and civic projects. Mr. Gordon was an active member of the Takoma Park Presbyterian Church. He was elected to serve as an Elder on January 4, 1920, and continued in this service without interruption until April 2, 1936. As a member of the Session, he served as treasurer of benevolences. He was also superintendent of the Senior Department of the Church School. He was a high type of Christian man who lived and practiced the teachings of his religious faith. He was a devoted husband and father. He was also an ardent lover of nature and derived much pleasure from working around his trees, shrubbery, and beautiful flowers. For many years Mr. Gordon lived in Takoma Park, Md., a suburb of Washington, D. C., which was founded by a relative, Benjamin F. Gilbert.

On August 14, 1900, Mr. Gordon was married to Bertha E. Miller, daughter of James B. and Catherine M. Miller. Besides his widow, he is survived by a son, James Miller Gordon (Major, U. S. Army), and three grandchildren, James Miller, Jr., Franklin Lee, and Nancy Ellen.

Mr. Gordon was elected a Member of the American Society of Civil Engineers on December 15, 1924.

LYMAN GRISWOLD, M. ASCE[1]

DIED MAY 10, 1944

Lyman Griswold was born on March 27, 1880, at Fandon, Ill., the son of Dr. John and Zura (Thompson) Griswold.

In January, 1882, the family left Fandon, moving to Helix, Ore., and here Lyman grew to manhood. He acquired his elementary education in the public school at Helix. Gifted with unusual ability and exceptional perseverance, he acquired his technical education from correspondence courses, long and diligent home study, and actual experience.

---

[1] Memoir prepared by Harold A. Rands, M. ASCE.

At the age of twenty four he joined the staff of the Oregon Land and Water Company at Irrigon, Ore., as assistant manager. During his connection with that company he made irrigation surveys covering 42,000 acres of company-owned lands. He turned next to railroad engineering, and until March, 1913, he played an active and creditable part in the closing years of the memorable era when the United States was crossed and recrossed by transcontinental and branch-line railroads. His record for this period is as follows:

December, 1905, to December, 1906—resident engineer, Spokane, Portland and Seattle Railroad Company, Spokane and Inland Empire Railway Company, and Spokane International Railway Company;

January, 1907, to December, 1908—locating and resident engineer, Chicago, Milwaukee, St. Paul and Pacific Railroad Company; and

July, 1909, to March, 1913—district and division engineer, Oregon Trunk Railway and Oregon Electric Railway, both subsidiaries of the Great Northern-Northern Pacific System.

Mr. Griswold served the Chicago, Milwaukee, St. Paul and Pacific Railroad Company on the extension of the main line west to Puget Sound. Concerning Mr. Griswold's work on this project, an associate on the same work writes as follows:

> "My first meeting with Lyman Griswold occurred in the summer of 1908. At that time he was Resident Engineer for the Chicago, Milwaukee & St. Paul Railway on a four-mile section of the main line construction just west of the Taft Tunnel, which pierces the main Bitter Root Range at that point. This section comprised some very heavy grading and some high timber trestles, and was considered to include some of the heaviest construction on the entire line."

From September, 1913, to October, 1915, Mr. Griswold was Assistant State Highway Engineer for the State of Oregon. During this period, in addition to assisting in the organization of the highway department, he directed the location of 100 miles of the Columbia River highway and 300 miles of other state roads. Thus, after playing an active and creditable part in the closing drama of steam railroad building in the United States, he became a pioneer in the building of roads for motorized traffic—the Columbia River highway from Portland to Astoria being the first stretch of modern highway to be built in the State of Oregon.

In October, 1915, he opened a consulting office in Portland. For the remainder of his life he continued his practice except for the period from September, 1917, to February, 1919, when he served in France, first as Captain, and later as Major, Corps of Engineers. During the war Major Griswold, from headquarters at Tours, France, was engaged in the construction of roads, light railroads, and other military works; in the operation of quarries; and in the design and construction of pontoons.

After his return from France, Mr. Griswold resumed his consulting practice, serving the State of Oregon and most of the large construction companies of the Pacific Northwest on highway work, particularly tunnels. He also advised numerous towns and cities on various matters. He became recognized as an expert witness in controversies concerning classifications of materials in highway and tunnel excavations.

Later, the business of the firm became largely hydraulic in nature, mostly in connection with proposed power developments. During this period Mr. Griswold was called as a consultant by the U. S. Engineers in connection with the Bonneville Power Project in Oregon, the proposed Umatilla Power and Navigation Dam on the Columbia River in Oregon, and seven proposed navigation dams on Snake River between the mouth and Lewiston, Idaho. Possibly, however, his most outstanding work in the field of hydraulics was the thorough investigation of Lewis River (a tributary of the Columbia River in the State of Washington) which he made for the Northwestern Electric Company of Portland. On this project, for the first and possibly the only time, a practical application was made of the "tree-ring" method for determining past precipitation cycles in the Douglas fir area of the Pacific Northwest. So thorough and satisfactory was Mr. Griswold's work that the power company, as a result of his investigations and recommendations, proceeded with the construction of the Ariel Power Plant. Throughout the construction of this development, Mr. Griswold was retained as consulting engineer and, in addition, had full charge of a material-delivery highway from Woodlawn, Wash., to the site of the plant. Probably, if the federal government had not constructed the large Bonneville and Grand Coulee power plants, one or more of the other sites investigated by Mr. Griswold on Lewis River would have been selected for development. His studies of plant location developed the complete regulation of the annual flow on that river.

The diversion of water for irrigation and the utilization of water for the generation of power were not, however, the only reasons for his interest in the streams of the Pacific Northwest. These were professional reasons. Fishing was his hobby. He gave to this sport the same energy, application, and persistence which enabled him, without benefit of college degree, to win and hold the confidence of great corporations, and to carry through as a Major in France—as is evidenced by the facts that his library contained more than one hundred volumes on fish and fishing; that he tied his own flies; and that his fishing tackle included fly rods of the most approved types and sizes for landing any fish from the "just within limits" brook trout to the largest and strongest Chinook salmon.

By one of those unusual coincidences which occasionally occur in real life, Lyman Griswold's hobby of fishing developed a part of his professional career which became of practical application. His knowledge of the habits of the Columbia River salmon became of real engineering value when he was called upon to solve the problem of caring for the salmon runs which from time immemorial had ascended the Lewis River to spawn in the headwaters. These runs would be destroyed by the building of a dam nearly 200 ft high. Under Mr. Griswold's supervision, a hatchery and accessory facilities were provided —to the satisfaction of the United States and of the authorities on fish in the State of Washington—which have proved to be highly successful. His design of the methods of trapping the adult salmon at the base of the dam and holding them in retaining ponds for artificial spawning proved a model for later problems.

Mr. Griswold was a Past-President of the Oregon Section of the Society. He belonged to the Society of American Military Engineers (first president of the local post) and the Professional Engineers of Oregon. He was also a Mason, and a past-president of the following: The Portland Yacht Club; the Portland Industries Finance Service; and the Meadow Lake Club.

On September 3, 1910, at Portland, he was married to Anna Hansman Aiken, who survives him. He also is survived by his mother; a brother, James Griswold (First Lieutenant, U. S. Army); and a sister, Laura (Mrs. Seymour Doolin).

Mr. Griswold was elected a Member of the American Society of Civil Engineers on October 10, 1921.

FRANK WILLARD HANNA, M. ASCE[1]

Died January 26, 1944

Frank Willard Hanna was born on September 16, 1867, near Geneseo, Ill., the son of James Steel Hanna and Harriet Louise (Hunt) Hanna. He spent his early years at farming, and thus he earned the money that enabled him to attend Highland Park College (later known as Des Moines University) at Des Moines, Iowa, from which he received the following degrees: Bachelor of Science in 1893, Bachelor of Civil Engineering in 1894, Master of Science in 1898, and Civil Engineer in 1902.

He began his professional career as a teacher and dean of mathematics and civil engineering at Highland Park College in 1895, and served there until 1903. During the summer of 1900, he traveled in Europe making studies of schools and of engineering structures for the Governor of Iowa. From 1903 to 1905, he served as hydrographer in the U. S. Geological Survey with headquarters in Chicago, Ill., where he was responsible for stream gaging and power investigations for the government in the upper Mississippi Valley and Great Lakes region. In 1905 he joined the U. S. Reclamation Service and worked, respectively, as designing, project, supervising, and consulting engineer, until 1921. His work included the design or supervision of design on the major reclamation projects which took place in the United States from 1905 to 1921.

In 1921, Mr. Hanna was called to Canada to become manager for the Canada Land and Irrigation Company at Medicine Hat, Alta. He was administrative head for a $16,000,000 business that had 530,000 acres of land and many head of cattle, horses, sheep, and hogs. He returned to the United States in 1924 to take the position of hydraulic and designing engineer for the East Bay Municipal Utility District at Oakland, Calif. From 1929 to 1934 he was chief engineer and general manager of this large utility which was doing a gross business of $4,700,000 annually. Among the important works connected with this position was the design of the Pardee Dam on the Mokelumne River in California. It is one of the highest dams of its type in the world.

---

[1] Memoir prepared by L. O. Stewart, M. ASCE.

Mr. Hanna retired from active engineering practice in 1934 and moved to Ankeny, Iowa, where he lived quietly, managing his personal agricultural interests. He moved to Webster City, Iowa, in 1942 and lived there until his death.

He was an inventor and an author. His inventions included an angle multisector, irrigation water meter, and automatic stop and relief valves. He was the author of "Logical Methods in Arithmetic," written in 1900; "Tables for Reinforced Concrete," "Measurement of Irrigation Water," "Agriculture by Irrigation," all written in 1913; "The Agricultural Value of Peat Soils," written in 1919; and "The Design of Dams," written in 1931 and revised in 1938. Also, he wrote many articles on engineering subjects for the technical press.

Mr. Hanna was a member of the American Water Works Association, American Concrete Institute, Cosmos Club of Washington, and a life member of the Lions Club. His religious affiliation was Methodist.

On August 28, 1901, he was married to Frances Grace Gore of Pilot Mound, Iowa. Mrs. Hanna and a son, John A. Hanna, survive.

Mr. Hanna was elected a Member of the American Society of Civil Engineers on January 7, 1913.

ANDREW PHILIP HARTMANN, M. ASCE[1]

Died April 18, 1945

Andrew Philip Hartmann was born in New York, N. Y., on August 27, 1868.

From 1883 to 1886, he was student; field assistant and draftsman with Hamilton Ewen who was civil engineer and city surveyor, New York City, part time; and he attended a scientific course at The Cooper Union for the Advancement of Science and Art, in New York City.

Mr. Hartmann was principal assistant, surveyor, and draftsman to Nathan F. Barret, landscape engineer, New York City, in 1886 and 1887.

In July, 1887, and continuing until 1912, he was in private practice as civil engineer and city surveyor on the following:

1888—principal assistant engineer with the late Horace Crosby, M. ASCE, civil engineer, New Rochelle, N. Y.

1889–1890—engineer and surveyor for the Kensico Cemetery Corporation.

1890—prepared extensive topographical surveys at Big Stone Gap, Va.; made surveys to establish a townsite at Kimball, Tenn.; and was on various municipal engineering jobs in New York City and its surburban sections.

---

[1] Memoir prepared by Christopher J. Sheridan, M. ASCE.

1890–1896—engineer for the Yonkers (N. Y.) Park Association.

1893—prepared topographical outline surveys of property of the State Reformatory for Women, near Bedford Station, N. Y.

1895–1896—engineer for the Village of White Plains, N. Y., planning and directing the paving of Railroad Avenue.

1896–1898—engineer to board of trustees of State Reformatory for Women at Bedford Station, designing and supervising sewer system, water supply, and large masonry steam heating conduit.

1900—engineer on preliminary surveys for extension of Riverside Drive from 135th Street to 158th Street in New York City.

1903–1906—engineer in charge of improving Exterior Street, New York City, along the East River from East 64th Street to East 82d Street, including heavy retaining walls.

1903—engineer in charge (under construction engineer) of field work on construction of Riverside Drive Extension from 135th Street to 158th Street (total construction cost was approximately $4,200,000).

1906—engineer on preliminary survey and laying out routes for the extension of Riverside Drive from 155th Street to Spuyten Duyvil.

1908–1909—member of Special Citizen's Commission to deal with settlement of trolley question, and investigate and report on sanitary measures to improve condition of Saw Mill River, in Yonkers.

1910–1911—member of Joint Water Supply Committee to investigate and report on additional water supply for Yonkers.

1911–1912—engineer in charge of construction of a system of private sewers, and of other municipal work of private character in the eastern section of Yonkers; from August, 1911, through 1912, chief engineer of the Bronx Valley Sewer Commission.

In 1920, and until 1922, he was a member of the Zoning Board of Appeals of Yonkers; in 1922 and 1923 he was the city engineer of Yonkers. From January 1, 1924, until his death, Andrew Hartmann was a member of the Zoning Board of Appeals.

Surviving are three children, Walter R. Hartmann, Andrew P. Hartmann, Jr., and Phyllis V. Roe.

Mr. Hartmann was elected a Member of the American Society of Civil Engineers on September 3, 1912.

GEORGE EDWARD HAWTHORN, M. ASCE[1]

Died June 2, 1945

George Edward Hawthorn, the son of Frank and Carrie (Clark) Hawthorn, was born in New Rockford, N. Dak., on November 21, 1889, where he spent his earlier years. The family moved to Seattle, Wash., during his high school days, and he was graduated from the Seattle High School in 1910. In 1915 he received the degree of Bachelor of Science in Civil Engineering from the University of Washington in Seattle and, in 1926, the professional degree of Civil Engineer.

---

[1] Memoir prepared by Robert B. Van Horn, M. ASCE.

After a year of teaching mechanical drawing and mathematics at the Mossyrock (Wash.) High School, he began his professional career with the Washington State Highway Department at Olympia, Wash., serving this department from 1917 to 1924, and passing through the positions of draftsman, senior draftsman, chief draftsman, and resident engineer. In October, 1924, he resigned his position with the highway department to accept the appointment of instructor in general engineering at the University of Washington. In 1928 he was appointed assistant professor of civil engineering and, in 1937, associate professor, which rank he held at the time of his death. While in the civil engineering department, Professor Hawthorn was in charge of all courses in highway and railway engineering, and he maintained close contact with the State Highway Department and the problems pertaining to the highway field. During the summers of 1926, 1927, and 1929, he returned to that department serving as assistant resident engineer.

In his twenty-one years of service at the University of Washington, Professor Hawthorn contributed greatly to the advancement of the Department of Civil Engineering, and he was directly responsible for the development of its highway and bituminous laboratories. He gave unstintingly of his time and energy to the various problems submitted by individuals and concerns of the state, and he won the high regard of his students and colleagues as a teacher and organizer of courses. He wrote "Highway and Railway Economics"[2] and "Introduction to Transportation Engineering,"[3] used by the Department of Civil Engineering, and "A Method of Designing Non-Rigid Highway Surfaces,"[4] which brought widespread favorable comment.

On August 16, 1916, he was married to Anne E. Lawson and he is survived by his widow and two daughters, Ruth (Mrs. D. J. Gjesdahl) and Frances (Mrs. Joseph Di Gregorio).

Professor Hawthorn was elected an Associate Member of the American Society of Civil Engineers on October 12, 1925, and a Member on October 20, 1936.

GEORGE TERRY HORTON, M. ASCE[1]

DIED MARCH 19, 1945

George Terry Horton, eldest son of Horace E. Horton,[2] M. ASCE, and Emma (Babcock) Horton, was born in Waupun, Wis., on August 25, 1873, and died in Chicago, Ill., from injuries received in an automobile accident on March 19, 1945.

---

[2] "Highway and Railway Economics," by George E. Hawthorn, Univ. Book Store, 1938.

[3] "Introduction to Transportation Engineering," by George E. Hawthorn, Univ. Book Store, 1934.

[4] *Bulletin No. 83,* Eng. Experiment Station, Univ. of Washington, Seattle, Wash.

[1] Memoir prepared by T. L. Condron, I. F. Stern, and Ralph H. Chambers, Members ASCE.

[2] For memoir, see *Transactions,* ASCE, Vol. LXXVI, 1913, p. 2221.

He was a direct descendant of Barnabas Horton of Lancaster, England, who migrated to America in 1665, landing at Hampton, Long Island, N. Y. Barnabas Horton was several times a member of the General Courts of New Haven and Hartford, Conn. Hiram T. Horton, of the sixth generation of Hortons in America, was a carpenter and contractor. He migrated west, first to Ohio and later to Rochester, Minn. His son, Horace E. Horton, was born in Norway, Herkimer County, N. Y., in 1843, but grew up and attended school in Rochester. He later attended Fairfield Academy in Herkimer County for two years. In 1871 he was married to Emma Babcock in Waupun. She was born in Wheeling, Ill., and was a direct descendant of James Babcock, who was born in England in 1612, and settled in Portsmouth, R. I. She was directly descended from the famous Pilgrim, William Bradford, who was baptized in Yorkshire, England, in 1589, and came to Plymouth, Mass., in 1620 on the *Mayflower*. Emily Brown, of the seventh generation of descendants of Governor Bradford, was married to George Babcock. She was the mother of Emma Babcock and grandmother of George Terry Horton.

Horace E. Horton acquired his engineering education and knowledge by personal application and study. Unquestionably he had an engineering and inventive mind, for, when only twenty-three years old, he designed and directed the construction of a timber arch bridge (186-ft span) over the Orinoco River in Minnesota. Later he designed and built the famous iron cantilever bridge over the Mississippi River, at Dubuque, Iowa, and scores of other bridges, including eleven spanning the Mississippi River. By 1887 he had established an enviable reputation as a designer and builder of bridges. His great success in this field, during the twenty-three years he operated from Rochester, was proof of his ingenuity and engineering talent, as well as his business ability. In 1889 he combined his engineering and contracting business with that of the Kansas City Bridge and Iron Company; and established in Chicago, Ill., the Chicago Bridge and Iron Company, to which his sons succeeded.

This same year, 1889, his son George entered Rensselaer Polytechnic Institute at Troy, N. Y., from which he was graduated in 1893 with the degree of Civil Engineer. Immediately following his graduation, George became an employee of the Chicago Bridge and Iron Company, remaining with that company as employee and officer the remainder of his life, nearly fifty-two years.

Like his father, George Horton was a great engineer; he was proud of his profession and delighted in its problems. He had an inventive mind, and he was always striving to improve upon previous designs and methods of construction, applying his unusual originality and imagination with boldness, unconventionality, and skill in the design of steel structures.

He was convinced that any design could be improved. Custom was to him a challenge. He once said, "Standardization is stagnation." "Never, if you can help it, build the same type of structure twice." "There is nothing so good that you can't improve on it."

He had been about a year in the employ of the Chicago Bridge and Iron Company, when, in looking over a book on metal structures,[3] he saw an illustration of a new type of elevated water tank with a hemispherical bottom. He called his father's attention to this and suggested that they build it. At that time the commercial attractiveness of bridge building was at low ebb, and the company was therefore receptive to new ideas. George Horton made some changes to simplify the illustrated design and some experiments on the dishing of plates, and determined to go ahead. The first such elevated tank was built at Fort Dodge, Iowa, in 1904, by the Chicago Bridge and Iron Company. This was the start of the tank business, which grew to great proportions.

Some time later George T. Horton was made chief engineer of the company. In 1912 Horace E. Horton died and George T. Horton was made president. In 1910 the business had grown to such extent that a New York, N. Y., office was warranted, and in the same year a second plant was built at Greenville, Pa., near Pittsburgh, Pa. In 1914 a Canadian plant was built at Fort Erie, Ont., and in 1930 a southern plant at Birmingham, Ala., was purchased. Following World War I, the company withdrew from the construction of bridges and gave its entire attention to tanks and similar structures.

George T. Horton directed the research and development department of his company, where his creative and scientific mind could show its best expression. Under his leadership the Hortonsphere and the Hortonspheroid were developed, as well as a modification of the latter, named the Watersphere, which consists of a spherical tank supported at the top of a tapering cylindrical column, so designed as to give a striking and pleasing appearance. A total of forty-four patents, fifteen of which are design patents, were issued in his name; in addition to these, many other patents have been taken out in the names of his associates working under his jurisdiction.

He was among the first to become interested in, and to make practical application of, electric welding. This opened new opportunities for his creative genius. With the introduction of the coated rod, about 1930, it became possible to build entire structures of steel by welding, and he promptly adopted such welding for all steel storage tank construction designed and built by his company. Although his company had just equipped its plants with the most modern riveting machines, his faith in the future of welding was so great that he did not hesitate to declare this equipment obsolete and proceed with designing for, and fabricating by, welding methods. He was an active supporter of the American Welding Society.

After he became interested in welding, through his influence and benefactions a welding research laboratory was established at the Rensselaer Polytechnic Institute. Before this he had established five permanent scholarships at the Institute, one for graduate study, and four which are available to sons and relatives of employees of his company.

Although the Chicago Bridge and Iron Company was principally engaged in designing and building tanks for the storage of liquids and gases, it broadened its field at the time of World War I, and Mr. Horton interested himself in shipbuilding. His contribution to "winning the war" was to speed up production by developing and prefabricating entire sections of ships to be assembled on launching ways. As assistant general manager of the Submarine Boat Corporation, he was responsible for securing contracts for furnishing of fabricated parts for cargo vessels constructed by that company at its Port Newark, N. J., shipyard.

---

[3] "Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, John Wiley & Sons, Inc., New York, N. Y., 1st Ed., 1893; also illustrated description in *Engineering News*, August, 1891.

At the beginning of World War II, he responded to the call of the Navy Department that his company come to the aid of the naval construction program. A shipyard was hurriedly constructed at Seneca, Ill., on the Illinois River for the building and launching of "LST's" (landing ship tanks), and these were launched at the rate of one every five days. Also, other shipyards were established by his company at Newburgh, N. Y., Morgan City, La., and Eureka, Calif., for the building of floating dry docks.

It was natural for one of his active and forward-looking mind to become interested in and participate in aviation. He not only owned his own cabin plane, but he was a licensed pilot. However, in later years he depended upon a professional pilot for operating his plane. When he decided to give up using a private plane, he gave his plane and two additional engines to the aeronautical department of the Rensselaer Polytechnic Institute.

George T. Horton was an unusual looking man of towering height—six feet, four inches. He inherited his heroic figure and his exceptional engineering talent from his father, and from his mother, who was a strikingly beautiful and gracious lady, his handsome appearance and attractive personality. His characteristics were humility, modesty, consideration, generosity, kindness, fearlessness, and basic honesty in thought and deed. His door was always open to employees of the company, to discuss their personal and business problems. His brother, Horace B. Horton, treasurer of the company, said that he was "a great man in intellect and above all in friendship and human sympathy." "No man ever loved his company and his employees more." To this should be added that no man was ever more loved and respected by the employees of the company. His associates talk about the human qualities of the company, as "one big family," and the fixed goal was "doing a better job next time than it did the last."

George T. Horton was philanthropic and civic-minded, and responded to many appeals. He was chairman of the Chicago Plan Commission from June, 1940, to January, 1944. He was a life trustee, from 1925, of the Rensselaer Polytechnic Institute. He was a retired Lieutenant Commander of the Civil Engineering Corps, United States Naval Reserve. He was a member of the New England Historic Genealogical Society, the Chicago Historical Society, the Art Institute of Chicago, the Chicago Galleries Association, the South Shore Country Club, the University Club, the Commercial Club of Chicago, the New York Engineers Club, and an Honorary Member of the Chicago Engineers Club. He was also a member of the Delta Kappa Epsilon fraternity.

He was a member of many professional societies, including the Western Society of Engineers (honorary member, 1944), the American Society for Testing Materials, the American Welding Society (president, 1939-1940), the

Society of Naval Architects and Marine Engineers, the American Water Works Association, the American Petroleum Institute, and the Society of American Military Engineers.

George T. Horton was married to Hazel Hamilton Heath on November 27, 1907. She survives him. Two children were born to them—a son, Ernest Heath Horton, who died on November 1, 1921, and a daughter, Heath (Mrs. Arnold Gillatt). He is survived also by a sister, Susie Mary (Mrs. Robert H. Murray), and two brothers, Horace B. Horton and Hiram T. Horton.

Mr. Horton was elected a Member of the American Society of Civil Engineers on April 6, 1904.

EUGENE CHRISTIAN HULTMAN, M. ASCE[1]

Died April 22, 1945

Eugene Christian Hultman was born in Boston, Mass., on July 13, 1875, the son of Eugene N. and Lydia Crocker (Bacon) Hultman. He received his early education in Adams Academy, Quincy, Mass., and in Thayer Academy, in Braintree, Mass.

He studied civil engineering at the Massachusetts Institute of Technology, then in Boston, and was graduated with the degree of Bachelor of Science in 1896. The first six months after graduation he was engaged on topographic surveys for the United States Geological Survey.

During the next year, until March, 1898, he served as a rodman, transitman, and designer for the West End Street Railway Company and for the Boston Elevated Railway Company. For the next eighteen months, until September, 1899, he was assistant chief engineer of the Barbour Stockwell Company on the design and installation of special street railway work. He continued for several years to do consulting work for this company, and was also engineer for the Board of Directors of the West End Street Railway Company. Then, for four years, ending in 1904, he was engineer and special auditor for the Board of Directors of the Fitchburg Railroad Company. For the next thirteen years, until 1918, he was consulting engineer for the Boston Elevated Railway Company on the design and construction of the Cambridge Subway.

He became interested in politics, and after serving as a member of the Quincy City Council and chairman of a Republican Ward Committee he was elected to the Massachusetts House of Representatives in 1905, 1906, and 1907, serving on its committees on Water Supply and on Public Lighting. He then served two terms in the Massachusetts Senate, on some of its most important committees: On Rules, on Ways and Means, and on Public Lighting. He was made chairman of the Committee on Public Lighting.

In the difficult days of adjustment and equitable distribution of goods following World War I he held a number of important state positions. On

---

[1] Memoir prepared by Karl R. Kennison, M. ASCE.

August 4, 1920, Calvin Coolidge then Governor of Massachusetts, appointed him as Commissioner of Necessaries of Life, and later as Fuel Administrator.

He served the City of Boston in many capacities. As Fire Commissioner for about four years beginning July 6, 1926, he modernized the department by installing smoke blowers, searchlights for illumination of fire escapes and alleys in the rear of burning buildings, radio equipment, and small specially equipped one-man boats for fighting fires beneath wharves, by changing drill methods, and by special attention to fire prevention. He served the city for four months early in 1930 as Building Commissioner, and revised the City Building Code. Probably his most notable service to the City of Boston was as Police Commissioner, being appointed by Frank G. Allen, then Governor of Massachusetts, on May 7, 1930. He undertook to reorganize the department and to install a complete coordinated system of records, including a modern fingerprint system in lieu of the obsolete system then in use. The efficiency of the Bureau of Records was greatly increased by the installation of complete and thoroughly modern criminal identification equipment. The signal system was readjusted with flashing lights on the police boxes for prompt contacts with the officer personnel and reliable assistance was available to the public by a system of citizens' alarms. He established a Police School to instruct officers in court procedure, regulations, ordinances, and statutes that they are called on to enforce. He made many radical changes in the organization of Police departments, all in the interest of efficiency and economy. He also discontinued the practice of detaining and confining women prisoners in cells at station houses. With the cooperation of Joseph B. Ely, then Governor of Massachusetts, he established the first two-way police radio in the United States, by the organization on July 11, 1934, of a Bureau of Operations handling all calls for assistance through radio, telephone, teletype, and telegraph.

On December 27, 1934, he resigned to accept an appointment as chairman of the Metropolitan District Commission. As such he was the executive head of the organizations. He maintained and operated the Metropolitan Water District, the Metropolitan Sewerage Districts, the Metropolitan Police Force, and activities in the vast system of Metropolitan Parks. By virtue of this office he was also ex officio chairman of the Metropolitan District Water Supply Commission, a special construction commission which was engaged in extending the sources of metropolitan water supply and which was authorized, during his incumbency, to construct extensions to the Metropolitan Sewerage Works. In this service he gave his best to the state. Following his death, the Metropolitan District Water Supply Commission gave the name of Hultman Aqueduct to the new pressure aqueduct which he had done so much to help construct. This aqueduct extends from the Wachusett Aqueduct terminal chamber of the old Wachusett Aqueduct to the center of distribution at Chestnut Hill, varying in diameter from 11 ft 6 in. to 14 ft, and constructed in tunnel and cut-and-cover pre-cast pipe. At the time of his death the aqueduct was completed except for about five miles of tunnel at the easterly end.

On January 15, 1907, Eugene C. Hultman was married to Elizabeth Blake in Chestnut Hill, Mass. She survives him.

Mr. Hultman was a man of strict probity, he had a keen sense of humor and much political sagacity. He was a man of strong likes and dislikes, and ready at all times to fight for a principle.

In 1935 ouster proceedings were brought against him by James M. Curley, then Governor of Massachusetts. The trial was before the Governor and Council. The contest was a grueling one. There were some one hundred witnesses but none of them was able to produce anything against his character or official conduct. The result was a complete vindication for Mr. Hultman and a severe rebuff to his accusers.

Quoting from a Memorial which was spread upon the records of the Metropolitan Water Supply Commission at the time of Mr. Hultman's death:

> "The Chairman was a man well qualified for the varied duties that he was called to perform. Trained as a civil engineer, proven by active service in the field, he had seasoned experience in construction work which was of great value in the many different problems occasioned by the construction of Winsor Dam, Quabbin Reservoir, and the incidental works. With his experience as an administrator, as Police Commissioner and Fire Commissioner of the City of Boston, he possessed the ability to choose and build up the proper personnel to carry out the multitudinous details of such an extensive project. Honest in his opinions, straightforward in his talk and direct in action, yet he was gentle and sympathetic toward those whose property and lives were necessarily affected by the carrying out of the work. He brought a friendliness and genuineness that never failed to impress the most casual acquaintance."

His readiness to fight for a principle is well illustrated by his carrying to the Supreme Court, in the face of adverse preliminary decisions, two suits brought by the contractors who built the two large hydraulic fill dams of Quabbin Reservoir (Massachusetts). He thus established important legal principles affecting the liabilities of the contractor and the rights of the engineer. The Supreme Court's ruling in the Winsor Dam (Massachusetts) case is well summarized by its decision that the court cannot impose its lay opinion upon the expert opinion of the engineer.

Mr. Hultman was elected a Member of the American Society of Civil Engineers on August 28, 1922.

JOHN PATRICK HURLEY, M. ASCE[1]

DIED DECEMBER 30, 1944

John Patrick Hurley was born in New York, N. Y., on September 15, 1878. He was the son of Michael Hurley and Mary (O'Neill) Hurley.

Following attendance at private schools in Ireland, he entered Cornell University, Ithaca, N. Y., where he received the degree of Civil Engineer in June, 1907. In addition, he studied at St. Kierans College, Kilkenny; Blackrock College, Dublin; and Queen's College, Belfast, Ireland.

---

[1] Memoir prepared by Philip T. Coffey, Captain, U. S. Army (Retired), New York, N. Y.

Mr. Hurley was a professional engineer, a military man, and a diplomat.

His first engineering work was in 1907 with the New York State Barge Canal. Shortly thereafter he entered the employ of the New York City Board of Water Supply, where he designed various road crossings, and a street railway bridge. Also, he made working drawings for the proposed Catskill Aqueduct. Later he had charge of the field party of a five-mile section of the Newburgh (N. Y.) Division.

From 1909 to 1915, Mr. Hurley was an assistant engineer with the Bureau of Highways, Borough of Brooklyn, N. Y. During that period he supervised methods of construction of pavements, bulkheads, street railways, retaining walls, etc. From 1915 to 1916, he was an engineer with the Board of Rapid Transit in charge of field work for the construction of a section of the Culver Line Extension of the Brooklyn-Manhattan Transit Division, New York.

From June, 1916, to March, 1917, he served as a Captain in the 69th Regiment of the New York National Guard on the Mexican border. During this tour of military duty, he laid out the regimental camp, supervised the water and sanitary facilities, and instructed in military engineering. Subsequently, he returned to civilian life for four months. He was recalled to active military duty with the 69th Regiment, later known as the 165th United States Infantry Regiment.

His regiment was ordered overseas in December, 1917, and he served with it throughout the Champagne-Marne and Aisne-Marne offensives. He was wounded during the latter action and received the Purple Heart and the Distinguished Service Cross. The citation follows:

> "John Patrick Hurley, Captain, 165th Infantry, 42nd Division. For extraordinary heroism in action at Villers-sur-Fere, France, July 28, 1918. His company having reached its objective he ordered several patrols forward to silence several enemy machine guns which were causing heavy casualties in his own and other companies of his battalion. The patrols meeting heavy casualties from intense enemy fire, Captain Hurley himself organized a patrol, led it forward. While temporarily checked by intense fire he crawled forward and rescued a wounded officer, carrying him to a place of shelter. Resuming the advance of the patrol Captain Hurley was severely wounded, but continued to direct the movement of his men, who, inspired by the great courage and fortitude of their leader, pushed forward and captured the machine-gun nest, killing or capturing the crews thereof."

Shortly after he returned from overseas, he entered the Consular Service; and he was appointed Consul to Reval, Estonia, in September, 1919. The following year he was assigned to Riga, Latvia, where he was stationed for five years. In 1925, he was transferred to Vienna, Austria, and in 1929, after four years of service in that city, he returned to Riga. Two years later he was assigned to Nassau, Bahama Islands; and in 1934 he was appointed Consul General at Marseilles, France, where he was made Dean of the Consular Corps. In 1940 he was assigned to the State Department for special work. He retired in 1942.

Mr. Hurley was a great student of higher mathematics and advanced engineering problems. In his personal relations he was a delightful gentleman. His success in the consular field was a tribute not only to his engineering ability but to his knack of cooperating with other officials. He was a "career man" in every sense of the word.

He was married to Marie Teresa Henry on October 12, 1912. He is survived by his widow.

Mr. Hurley was elected a Member of the American Society of Civil Engineers on July 31, 1933.

JOSEPH FREDERICK JACKSON, M. ASCE[1]

Died February 8, 1945

Joseph Frederick Jackson was born on July 4, 1871, the son of George and Elizabeth (Gallagher) Jackson of New Haven, Conn.

He was graduated from the Sheffield Scientific School of Yale University at New Haven, in 1895, with the degree of Bachelor of Philosophy. For three years prior to graduation, he was employed in the engineering department of the New York, New Haven, and Hartford Railroad Company.

Upon graduation, he was employed in structural drafting for elevated railways of New York, N. Y. From 1896 to 1933, he was principally occupied in sanitary engineering, serving as engineer, consultant, and commissioner for various municipalities, industrial concerns, and the Connecticut State Department of Health. He was an authority in this field and wrote many papers on the subject.

Mr. Jackson was a member of the Engineering Advisory Commission of the War Council of the State of Connecticut and a member of the Evacuation Committee. He had a great interest in engineers in war service. As chairman of the War Effort Committee of the Connecticut Society of Civil Engineers, he advocated, and put into effect, many ideas to bring cheer and encouragement to fellow members in the armed forces. He was an active member of many engineering societies: Member of the New England Water Works Association; fellow and member of the executive committee of the American Public Health Association; member of the New England Sewage Works Association; honorary member, former president, director, and secretary-treasurer of the Connecticut Society of Civil Engineers; and member of the executive committee of the State Sanitary Engineers.

Mr. Jackson served in various capacities, including resident engineer, engineer examiner, and chief engineer for the Rhode Island and the Connecticut region of the Public Works Administration. He was active as an engineer up to the time of his death, being engaged, in 1944, by the City Plan Commission of New Haven to study and report on a six-year, postwar program of capital improvements. In 1944 he read a paper on this subject before the Connecticut Society of Civil Engineers.

Fred Jackson was a credit to the Society and sought to live up to its ideals and to raise, if possible, the standard of its aims. He was ever willing to give his advice and experience. He was one of the organizers and a member of the first executive committee of the Sanitary Division of the Society.

---

[1] Memoir prepared by W. Vincent Barry, M. ASCE.

His activities extended beyond the engineering field. He was a member of the Graduates Club of New Haven and of the Meadowbrook Country Club of Hamden, Conn. He was much interested in athletics, especially golfing and swimming. He was president of the Young Men's Institute of New Haven (private circulating library) and president of the Hamden Historical Society.

In religion, Mr. Jackson was a Roman Catholic and was active in many charitable pursuits, being secretary of Highland Heights (a Catholic Orphan Asylum), secretary of the Catholic Cemetery Associations, and trustee of Our Lady of Mount Carmel parish.

On February 3, 1897, he was married to Agnes L. Spencer, daughter of John R. Spencer and Mary O'Holleran Spencer. He is survived by his widow; his daughter, Mary (Mrs. Edward Cowan); and his granddaughter, Maureen Cowan.

Mr. Jackson was elected an Associate Member of the American Society of Civil Engineers on September 3, 1913, and a Member on June 24, 1916.

RUDOLPH GUSTAV KASEL, M. ASCE[1]

DIED JUNE 14, 1945

Rudolph Gustav Kasel was born in St. Louis, Mo., on October 15, 1899, the son of Carl August and Antonia (Ritter) Kasel.

He received his preparatory education in the public schools of New Haven, Mo., and entered the University of Missouri School of Mines and Metallurgy at Rolla, in 1917. After one year his education was interrupted by his enlistment in the Navy during World War I, where he served on the *USS Graf Waldersee* and at Great Lakes Naval Training Station, Great Lakes, Ill. Discharged from active service in 1919, he resumed his studies in January, 1920, at the Missouri School of Mines and Metallurgy. He was graduated with the degree of Bachelor of Science in Civil Engineering in 1923.

Before graduation he obtained practical experience on mine surveying in several mines in Missouri and during his summer vacation, in 1922, he was employed as a draftsman by the Western Electric Company, Chicago, Ill., on automatic telephone switchboard layouts. After graduation he worked for several months as instrumentman and draftsman for the Southern Carbon Company, Fairbanks, La., on plant layout, pipe-line surveys, and townsite maps. From October, 1923, to April, 1924, he was draftsman and computer for the Missouri State Highway Department, Division 10, Sikeston, Mo.

Mr. Kasel was with the U. S. Geological Survey, Water Resources Branch, from April, 1924, until his death on June 14, 1945. He served on numerous and varied assignments, beginning with that of resident engineer at Colorado River gaging stations in the Tucson, Ariz., district. From July, 1925, until March, 1928, he was in the Columbus, Ohio, district on stream measurements, construction of gaging stations, and office computations for gaging stations in Ohio, Indiana, Michigan, and Kentucky. From April, 1928, until September, 1932, he was engaged in the design, construction, and installation of gaging stations and stream-gaging equipment in Idaho, Montana, and British Columbia with headquarters at Boise, Idaho. During this period he was also engaged on special investigations in Kootenai Valley, Idaho, in connection with surface-water and ground-water problems. In October, 1932, he was placed in charge of the district office at Iowa City, Iowa, as acting district engineer, becoming district engineer in 1933. In addition to his duties as district engineer, he also served on the Water Resources Committee of the Iowa State Planning Board and on the staff of the Iowa Institute of Hydraulic Research, University of Iowa, in Iowa City. On April 29, 1940, he was transferred to Washington, D. C., as acting chief, Division of Surface Water, Water Resources Branch, U. S. Geological Survey. He became chief of that division on May 1, 1941.

---

[1] Memoir prepared by Charles H. Pierce, M. ASCE.

He was the author of "Water Resources of Iowa, 1873–1932,"[2] and coauthor of numerous Geological Survey water-supply papers and technical reports. He was a member of Sigma Xi fraternity, the Iowa Engineering Society, and various fraternal and civic organizations. Hunting and fishing were his principal hobbies, and his brief vacations were mainly spent in the open.

On December 20, 1926, he was married to Adele Louise Muench of Washington, Mo. He is survived by his widow; a daughter, Helen Louise; and a brother, Archibald Kasel.

Mr. Kasel was gifted as an engineer and possessed exceptional administrative and technical abilities. His clear understanding of the many intricate details of the highly specialized branch of his chosen profession, together with his ability as an organizer and a leader, gave him an enviable record in all his undertakings.

Mr. Kasel was elected a Junior of the American Society of Civil Engineers on December 15, 1924; an Associate Member on May 12, 1930; and a Member on October 17, 1938.

HENRY JAMES KESNER, M. ASCE[1]

Died February 10, 1945

Henry James Kesner was born on October 30, 1883, near the town of Aurora, Ont., Canada. He was the son of Edgar Euryas and Dorcas Ann

---

[2] "Water Resources of Iowa, 1873–1932," by R. G. Kasel, Iowa State Planning Board, 1935.

[1] Memoir prepared by Roy M. Green, M. ASCE.

(Hortop) Kesner, who were both teachers by profession. Mr. Kesner studied both broadly and deeply. After obtaining his early education in the public schools of Fairplay, Boulder, and Salida, Colo., he attended the University of Colorado in Boulder from which he received the degrees of Bachelor of Arts in 1905, Bachelor of Science in Civil Engineering in 1907, and Civil Engineer in 1911.

Immediately after graduation in 1907, Mr. Kesner began working for the U. S. Reclamation Service as hydrographer on the Uncompahgre Project. In September, 1907, he accepted a position as an instructor in structural engineering at the University of Minnesota, in Minneapolis.

In June, 1908, he left the teaching profession to become junior engineer in the Technologic Branch of the United States Geological Survey at Pittsburgh, Pa. In March, 1909, he became a draftsman for the Minneapolis Steel and Machinery Company at Minneapolis. In 1909 he returned to teaching, serving from August, 1909, to May, 1913, at the University of California in Berkeley as instructor and later as assistant professor of civil engineering. During the summer of 1912 he acted as director of the Summer School of Surveying at that institution.

From September, 1915, until his death, each academic year Professor Kesner taught in some school of engineering in the United States. During this period he served on the faculty of Purdue University in Lafayette, Ind., from September, 1915, to June, 1921, as instructor, assistant professor, and later as associate professor of structural engineering. From September, 1921, to June, 1923, he was associate professor of civil engineering at Armour Institute of Technology in Chicago, Ill. In September, 1923, he joined the staff of the department of civil engineering at the University of Nebraska in Lincoln. At that institution he held, successively, the ranks of assistant professor, associate professor, and in 1927 professor of civil engineering. From 1925 until his death, he had charge of the courses in structural engineering at the University of Nebraska.

During summer vacations, Professor Kesner worked for the following organizations: From 1910 to 1914, for Charles Derleth, Jr., M. ASCE, consulting engineer, and for Haviland and Tibbets, consulting engineers of San Francisco, Calif.; in 1916 for the Chicago, Burlington and Quincy Railroad Company; in 1917 for the Interstate Commerce Commission in Chicago on valuations; in 1918 for the Foundation Company of New York, N. Y., as a designer; in 1919 and 1921 for the Indiana State Highway Commission as a designer; in 1920 for the Wyoming State Highway Commission on the supervision of concrete bridge construction; in 1922 for H. S. Crocker, Past-President and Hon. M. ASCE, consulting engineer of Denver, Colo., as a designer; in 1923 for the South Park Commission of Chicago as structural engineer; in 1924 for the Chicago Bridge and Iron Works; and in 1926 for W. H. Adams, M. ASCE, consulting engineer of Detroit, Mich., as designer.

In addition to the Society, Professor Kesner was a member of the Society for the Promotion of Engineering Education and the American Association of University Professors. He was a registered structural engineer in the State of Illinois and a registered professional engineer in the State of Nebraska

Besides his professional affiliations, Professor Kesner belonged to Sigma Xi, Phi Beta Kappa, Sigma Tau, Tau Beta Pi, Theta Tau, and Beta Theta Pi fraternities. He was also an active member of the Lincoln chapter of the Interprofessional Institute and served as president in 1943.

On September 3, 1921, Professor Kesner was married to Mary Downer of Denver. He is survived by his widow.

Intensely individualistic, thoroughly competent, habitually studious, and strictly ethical, Professor Kesner was a born teacher who exerted a permanent influence upon the lives of a long line of engineering students.

Professor Kesner was elected a Junior of the American Society of Civil Engineers on December 6, 1910; an Associate Member on March 4, 1913; and a Member on October 10, 1927.

ROBERT VOLANT LABARRE, M. ASCE[1]

DIED SEPTEMBER 27, 1944

Robert Volant Labarre, the son of Clement Labarre and Rosa (Bouligny) Labarre, was born at Gretna, La., on October 20, 1873, at the plantation of his paternal grandparents, who were planters of the old South. In his early youth he was subjected to the hardships of the reconstruction period in New Orleans, La. His education, in the parochial schools at New Orleans and the Jesuit School at Quebec, Que., Canada, with two years at Tulane University in New Orleans, was interrupted by the death of his father. While still in his teens, Robert Labarre entered the employ of the City of New Orleans as draftsman. Later, he worked for the Orleans Levee Board as rodman and draftsman, becoming assistant engineer in 1895. As topographer with a survey party of the U. S. Engineer Department, he did map work on the Mississippi delta region.

Moving to Shreveport, La., in 1901, he was engaged in mechanical design and construction for the Lake End Cotton Mills and the J. L. Means Machinery Company. He was employed on design by the Fred A. Jones Building Company of Houston, Tex., later becoming superintendent of construction on office, apartment, and industrial buildings in Houston, Tex., Birmingham, Ala., and Atlanta, Ga. He then entered the contracting business for himself and erected a number of schools and industrial buildings throughout the South.

During World War I he served as Captain of Engineers, commanding Company F, 606th Engineers, and then Company B, 211th Engineers. After the war, he was employed by the Foundation Company of New York, N. Y., on industrial construction in the Detroit (Mich.) area. He was in charge of port sanitation south of Lima, Peru, and later worked for the Vanadium Corporation in the Andes Mountains in South America. On his return to the

---

[1] Memoir prepared by Harry W. Dennis and Charles T. Leeds, Members, ASCE, in collaboration with Mrs. Robert V. Labarre.

United States in 1921, he was employed by the Realty Construction Company on industrial design and construction in Michigan.

Moving to Los Angeles, Calif., in 1923, he worked for the Schofield Engineering Company, and for the P. J. Walker Company on the engineering problems of foundation and underpinning projects, a type of work for which he was well fitted, not only because of his early experience, but also because of his keen ingenuity and ability to reduce the most complex problems to simple elemental concepts. These contractors built the foundations under the Broadway Department Store Building, the Subway Terminal Building and Tunnels, the Southern California Edison Building, the Stock Exchange Building, and Bullocks department stores.

At this time Captain Labarre began to realize that adequate scientific study and thought were not being applied to the structural values of foundation materials—that huge projects were financed and built with little apparent concern for the physical characteristics of the ground to be used as a foundation. Realizing the need for definite knowledge of soil as a structural foundation material, he began to specialize in that field. In 1928 he established a research and consulting foundation engineering office in Los Angeles. Thus, he was one of the pioneers on the West Coast in the consideration of foundation engineering and soil mechanics as a separate and requisite field of engineering. Alert to the necessity of establishing soil mechanics on a scientific basis, he conducted field and laboratory tests on soils, made extensive experiments on the bearing value of various types of piles, and designed and built equipment and apparatus for his experiments, as his knowledge of soil mechanics progressed. His firm continued to practice, constantly enlarging its field of research, until Captain Labarre's retirement because of illness in the latter part of 1942—from 1933 to 1936, with Frederick J. Converse, Assoc. M. ASCE, as associate; and, from 1940 until Captain Labarre's retirement, with William F. Swiger, Jun. ASCE, as associate. During this time, Captain Labarre was foundation consultant for the State of California, municipalities, public utilities, industrial corporations, architects, and engineers. Many jobs of outstanding importance and complexity were brought to him. Among them were the stabilization of the foundations of the Southwest Museum (which, being located upon a high hill of interbedded shale and sandstone, was threatening to slide); the exploration of the foundation material along the Second Boulder-Chino Transmission Line for the Southern California Edison Company; the design of cast-in-place reinforced concrete tower footings; the foundations for the Harbor Steam Plant of the Los Angeles Bureau of Power and Light;[2] a very detailed and comprehensive study and report on the concrete aggregate of the Santa Clara River (which also involved a comprehensive investigation and study of the concrete in which this and other aggregate had been used); facilities for the port of Oakland (Calif.); and foundations of the Geneva Plant of the Columbia Steel Company Defense Plant Corporation at Provo, Utah. He also served as one of the consultants for the Southern California Edison Company on certain problems at the Long Beach (Calif.) steam plant caused by unwatering operations at the near-by U. S. Naval Fleet Operating Base.[2]

---

[2] "Foundation Tests for Los Angeles Steam Plant," by W. F. Swiger, *Civil Engineering*, December, 1941, p. 711.

Concurrently with his development of soil mechanics research, Captain Labarre became intensely interested in seismology. About 1930 the United States Coast and Geodetic Survey began a program of measuring both the earth movements during destructive earthquakes and the periods of vibration of buildings and other structures. Captain Labarre cooperated with Frank Neumann, seismologist of the Coast and Geodetic Survey in the development of a vibration meter to measure structural and ground vibrations. Captain Labarre took a very active part in organizing conferences to perfect plans, and especially in creating sentiment in favor of the survey's program. He persuaded building owners to provide sites for instruments and secured permission to make vibration measurements. Largely because of such cooperation, extremely valuable records of the Long Beach earthquake of March 10, 1933, were obtained. Subsequent to this earthquake, several local technical groups and other interested bodies began to make investigations independently. The necessity of correlating these efforts was soon recognized and a permanent committee known as "Joint Technical Committee on Earthquake Protection" was formed under the chairmanship of Robert A. Millikan of the California Institute of Technology at Pasadena. Seven technical groups were represented on the committee, and Captain Labarre was one of the members acting on behalf of the Society. In 1934, while Captain Labarre was president of the Structural Engineers Association of California, his dominant interest in seismology helped to bring the influence of the association to bear on the California Legislature, resulting in the adoption of a revised State Building Code Relating to the Construction of Schools. His also was the driving force which resulted in the Society's Joint Committee on Seismology, organized on July 13, 1936. He was the committee's first chairman, and this committee was well on the way to important accomplishments, when the war, and then Captain Labarre's illness and death, intervened. His accomplishments in the field of seismology are important, especially when it is recalled that his prime interest lay in only one phase of the problem—foundations.

Possessing judgment, ingenuity, and executive ability beyond the average, Captain Labarre accomplished much by his vivid and engaging personality and forcefulness, both in private life and as a member of professional societies. He was affectionately known as "Cap" among his many friends. A fluent speaker, a capable organizer, and a leader, he served on numerous committees for organization as well as on local and national committees of the Society and was Vice-President of the Los Angeles Section of the Society in 1939.

He was a member of the Executive Committee of the Soil Mechanics and Foundations Division from 1937 to 1941, inclusive. He was most active in division affairs and was a member of the Committee on Glossary of Terms and Definitions and on Soil Classification from 1937 to 1944, inclusive; chairman of the Committee to Cooperate with Committee D-18 on Soils for Engineering Purposes of the American Society for Testing Materials in 1938; and chairman of the Joint Committee on Seismology from 1941 to 1944, inclusive. He belonged to the American Society of Mechanical Engineers from 1923 to 1942, American Society for Testing Materials, Engineers Club of San Francisco (Calif.), Engineers Club of New York, University Club of Los Angeles, and the Seismological Society of America. He was a registered civil engineer in the State of California.

---

[2] "Novel Construction Plan for Graving Dock Suggested by Soil Studies" (a Symposium), *Civil Engineering*, August, 1944, p. 323.

Captain Labarre keenly enjoyed life. He had many friends and many and diversified interests beyond technical fields. A devotee of music, history, and travel, he also especially liked motoring through the country, driving to many meetings of the Society in his own car. He never tired of seeking out old landmarks of the hardy pioneers, especially in the old mining districts and in Indian country of the Southwest. He was never without an absorbing hobby, which changed along with the years and times. At his home he had a complete machine shop, where he spent many leisure hours. He had keen joy in, and unbounded enthusiasm for, his professional work.

Because of the nature of last illness, he was compelled to retire from active work in the latter part of 1942. He spent his last year in Arizona in and around the haunts of the rugged historical characters with whom he was so familiar. He died at Wickenburg, Ariz. His monument is found in the lives and works of the many younger engineers trained and taught by him with patience and with a deep wisdom of the world and men.

He was married twice—on February 17, 1897, to Alice Lang of New Orleans, and on January 5, 1923, to Gertrude Ward of Los Angeles. He is survived by his widow; a sister, Margaret (Mrs. S. E. Ingles); and three daughters by his first marriage, Anna (Mrs. A. L. Ferguson), Marcelle (Mrs. Laurence Pace), and Gladys (Mrs. George Stewart).

Captain Labarre was elected an Associate Member of the American Society of Civil Engineers on August 9, 1920, and a Member on October 26, 1931.

JOHN ROBERT LAMBERT, M. ASCE[1]

DIED NOVEMBER 12, 1944

John Robert Lambert was born on January 8, 1884, in Niles, Mich. His mother, whose maiden name was Juliette Smith, was a member of one of the numerous families that migrated from New York State to Michigan about the middle of the nineteenth century. His father came from a prominent Virginia family.

John Lambert was graduated from the high school in Niles in 1901, and during the following year worked for a local paper manufacturing and lithographing company. He entered Michigan State College at East Lansing in the fall of 1902, led his class all through college, and had the honor of being valedictorian. He was the first member of his class to be elected to Tau Beta Pi, the engineering honorary fraternity.

---

[1] Memoir prepared by Scott B. Lilly, M. ASCE.

His entire professional career was spent in the employ of the Phoenix Bridge Company at Phoenixville, Pa. In 1906, when he began work in the drafting room, the company was engaged in completing the details for the first Quebec Bridge. In August, 1907, the Quebec Bridge collapsed during erection—a failure of an outstanding engineering structure and one that affected engineering design profoundly. The cause of the failure was due partly to inadequate details used in the latticing of the columns, and partly to the use of too high stresses in compression. The weakest members in the bridge were the two anchor-arm bottom-chord sections, one in each truss, adjacent to the main shoes.

The effect of this failure on John Lambert was to intensify his natural inclination to examine everything carefully, to test every conclusion, and to prove every computation.

A succession of important structures passed through the drawing room of the Phoenix Bridge Company, and John Lambert acquired not only an intimate knowledge of design and detail, but he gained a thorough intimate knowledge of shop and erection practice. For years he had a large part of the responsibility for estimating the costs of bridges and buildings.

He remained a student all his life. He was keenly interested in the design, construction, and operation of movable bridges. During this period his company built many such structures, and Mr. Lambert studied the design of every one that was available to him. There was a 320–ft bridge for the New York, New Haven and Hartford Railroad over the Taunton River in Massachusetts. This was a 1,500–ton double track drawbridge. His company built: Scherzer rolling lift bridges over the Seekonk River in Rhode Island and over the Savannah River in Georgia; Strauss trunnion bascule bridges such as that over Bayou Plaquemine, Louisiana, that at Jacksonville, Fla., over St. John's River; the Arlington Memorial Bridge, double-leaf 2,200-ton, central span at Washington, D.C.; vertical lift bridges such as the 341-ft span over the Hudson River near Troy, N.Y.; the 544-ft, 5,000-ton bridge at Buzzards Bay over the Cape Cod Canal, Massachusetts; the Piscataqua River double deck, 224-ft span at Portsmouth, N.H.; and the 240-ft, 2,800-ton bridge over the Reserve Basin at League Island Navy Yard, Philadelphia, Pa.

Then there were cantilever bridges such as the 3,400-ton Smith Street Bridge with a 420-ft main span at Rochester, N.Y.; the 765-ft highway bridge of 990 tons over the Grasse River at Massena, N.Y.; and the 2,400-ft 18,000-ton length of the Pulaski Skyway. There was the 3,400-ton continuous-type truss structure for the Gill-Montague Bridge over the Connecticut River, in Massachusetts; the 1,600-ton Deer Isle suspension bridge over Eggemoggin Reach at Sedgwick, Me., with its 1,080-ft main span; the 540-ft tied arch span of the Chesapeake and Delaware Canal, 7,400-ton crossing at St. Georges, Del. These structures and many others were of absorbing interest to Mr. Lambert. There was something of him in each one of them.

In 1923 he was transferred to the contracting department; in 1926 he became chief engineer; and in March of 1944 he was made general manager, which position he held at the time of his death. He was a director of the Phoenix Bridge Company and also of the Phoenix Iron Company.

Until the last few years of his life, Mr. Lambert gave freely of his time to the young engineers who joined his company. He had classes in structural design, and in the various phases of bridge building, at his home at night. In this way, he not only encouraged these young men to improve their knowledge of structures, but gave them, by his excellent teaching, more than they would have been able to secure in many colleges.

Throughout this time, he was interested in mathematics and developed a method of solving equations of a high order by the use of recurring series. In 1933 he rediscovered a solution of equations by this method; and in 1935 he distributed a monograph covering his solution. In this monograph he had derived sample equations solving, among others, equations of the seventh degree.

He had many other hobbies. He was an enthusiastic stamp collector and was interested in book binding and sun dials. He was interested in the many covered bridges of Pennsylvania, and spent many happy days driving over this part of the state with his wife taking photographs of those that still remained. For years he was an enthusiastic golfer; he competed as a member of the team from his club with similar groups from neighboring courses.

For years, he served on the Board of Health of Phoenixville, and for a much longer period, on the Library Board. He was fond of pictures, music, and books. His outstanding characteristics were his interest in people, his loyalty to his friends, his lifelong conviction of never saying or doing anything that would injure anyone.

In 1936, he was married to Esther Wetherall of Taunton, Mass., who survives him.

Mr. Lambert was elected an Associate Member of the American Society of Civil Engineers on April 19, 1920, and a Member on January 14, 1924.

WILLIAM BARKER LANDRETH, M. ASCE[1]

Died December 9, 1941

William Barker Landreth, the son of the Rev. James Landreth and Sarah (Barker) Landreth, was born in Rushville, N. Y., on August 3, 1857. He was graduated from Union College, Schenectady, N. Y., in 1881, with the degrees of Bachelor of Arts and Civil Engineer. In 1931, the honorary degree of Doctor of Science was conferred on him by his alma mater. He was a member of Sigma Xi and Beta Theta Pi fraternities.

---

[1] Memoir prepared by Roy G. Finch, M. ASCE.

Following graduation he was engaged in railroad work in Mexico for several years. Upon his return to New York State he did pioneer work in the construction of sewers and sewage disposal plants in Schenectady, Amsterdam, Tonawanda, White Plains, Jamestown, Cortland, Port Jervis, and other localities. In 1897 he became identified with the Office of State Engineer of New York State, and served in various capacities in that office until 1922 with the exception of four years (1911–1914) when he was engaged in private practice. He served one year (1914) as city engineer of Schenectady. Upon his retirement in 1922 from the State Engineer's office he again engaged in private practice, and continued until he died in 1941.

Professionally his outstanding work was performed during his twenty-two years of state service. He was affectionately known as "Uncle Billie" by hundreds of engineers, many of them youngsters starting on their careers, who were granted the privilege of serving with and under this capable engineer and gentleman. His words of advice and professional guidance will always be gratefully remembered by those fortunate enough to have been associated with him during this period.

There was no one more familiar with, or who played a more important part in, the planning and construction of the New York State Barge Canal than Mr. Landreth. His first experience on canal work was in the deepening of the old system which was the last improvement undertaken prior to the construction of the Barge Canal. Under his direction the first surveys for the Barge Canal were made. The location of the canal was based, in a large measure, on the results of his studies and recommendations. The involved hydraulic computations necessary in providing an adequate water supply for canal operation came under his supervision. Practically all the plans for this great undertaking were prepared under his direction; and the construction of the major part of the system was completed under his general supervision. The history of the Barge Canal reveals the names of many able and distinguished engineers who were identified with the project; but, from its inception to its completion, no one man contributed more to the undertaking than did Mr. Landreth. He believed in the canal, and never doubted that ultimately it would prove its worth and fully justify the expenditure made for its construction.

Mr. Landreth was a friendly man and never lost touch with his former associates of the canal days. After his retirement in 1922, it was his custom to make frequent trips to Albany, N. Y., solely for the purpose of renewing the old friendships with his former associates. These periodical visits were looked forward to by those whom he termed "his boys."

In the death of this kindly and respected gentleman, the profession suffered a great loss.

In 1881 he married Amelia Theresa Fitzgerald who died in 1923. He is survived by two daughters, Mary (Mrs. Thomas S. Bailey) and Grace Louise (Mrs. Elmer L. Anderson), and two grandchildren, the Rev. William L. Bailey and Dorothy L. Anderson (Mrs. James M. Shaw). One daughter, Adeline Sarah Bailey Landreth, died in 1916.

He was a member of the Society of Engineers of Eastern New York, Albany Society of Engineers, Rensselaer Society of Engineers, International Congress of Navigation, Sapphire Masonic Lodge of Camillus, N. Y., and St. George's Church of Schenectady. He served as a Director of the Society from 1905 to 1907.

Mr. Landreth was elected a Member of the American Society of Civil Engineers on October 3, 1888. He became a Life Member in 1923.

ENGBERT A. LEE, M. ASCE[1]

DIED JUNE 7, 1945

Engbert A. Lee was born in Louis Valley, La Crosse County, Wis., on January 29, 1870, the son of Anders Lee and Peronella Lee, who migrated from Norway to Louis Valley in 1869. From there they moved to Minnesota and settled on a farm near Grand Meadow in 1875.

Mr. Lee's preparatory education was obtained in the public schools of Grand Meadow, Decorah, Iowa, and St. Olaf College in Northfield, Minn. He then entered the University of Minnesota in Minneapolis, where he received the degree of Bachelor of Science in Civil Engineering on June 3, 1897. At that time, because of his excellent scholarship, he was awarded the key of Sigma Xi.

After graduation Mr. Lee was employed by the Gillette-Herzog Manufacturing Company in Minneapolis. In January, 1899, he was made assistant engineer of its Denver, Colo., office, which position he held until this company was absorbed by the American Bridge Company in 1900. He was retained by the American Bridge Company until the summer of 1903 at which time he resigned his position to enter private practice in Denver.

In 1905 Mr. Lee was employed by the American Smelting and Refining Company. During this employment he was located in the Denver office as assistant engineer until 1911 and then he was sent to the Perth Amboy plant in New Jersey. He remained there until the end of 1912 when he was transferred to El Paso, Tex. The following year he returned to Denver where he became chief engineer of the Colorado Division. In 1928 he was loaned to the Amarillo, Tex., plant and remained there until his retirement in 1930.

From October, 1935, to July, 1937, Mr. Lee was employed by the Denver Board of Water Commissioners as draftsman engaged in the designing of structural details for the Transmountain Water Diversion from the Frazer River to the City of Denver. Following this and until his death, Mr. Lee was a valued employee of the Climax Molybdenum Company engaged in metallurgical plant design.

---

[1] Memoir prepared by Herbert S. Crocker, Past-President and Hon. M. ASCE, and Maynard C. Allen, Mech. Engr., Eng. Dept., Climax Molybdenum Co., Golden, Colo.

Throughout his life Mr. Lee was greatly interested in music, both instrumental and vocal, and enjoyed working in choral societies. With a farming background it is natural that he should be a great lover of the wonders of outdoor life which he enjoyed recording with his camera. Mr. Lee was a man of modest demeanor. His life was purposeful and he was admired for his fine character, competence as an engineer, and loyalty to his employers and his associates. He was a man of whom his family can be justly proud. Would that there were more like him!

In 1911 Mr. Lee was married to Essie R. Lindell of Chicago, Ill., who, with a son, Alfred R., and a daughter, Martha Ann (Mrs. Gerald G. Christensen), survives him.

Mr. Lee was elected an Associate Member of the American Society of Civil Engineers on October 7, 1903, and a Member on October 11, 1920. He became a Life Member in 1938.

HENRY ALEXANDER LEEUW, M. ASCE[1]

Died October 18, 1945

Henry Alexander Leeuw, the son of Charles Richard and Henrietta (Jungman) Leeuw, was born in New York, N. Y., on November 5, 1882. His early education was obtained in the city public schools. In 1901 he entered The Cooper Union for the Advancement of Science and Art, in New York, taking the evening course in general science.

While continuing his evening courses in The Cooper Union, he was engaged during the day in survey work for the Atlantic Avenue improvement, Brooklyn, N. Y., and later in building subaqueous tunnels under the Hudson River; he was made general superintendent of the Washington Street shaft of the Hudson Tunnels in 1908. In 1910 he was superintendent in charge of the construction of five miles of narrow gage railroad for the Degnon Construction Company at New Paltz, N. Y. From 1910 to 1912 he was general superintendent on tunnel work for Glyndon Contracting Company at Yorktown Heights, N. Y., and for Condon Graham and Milner at Tallaluh Falls, Ga.

Because of his experience in building tunnels and placing concrete linings in them, he turned his attention to developing pneumatic methods of placing concrete; and from 1912 to 1915 he was vice-president and general manager of the Pneumatic Concrete Placing Company.

In 1916 he was superintendent for the New York and New Jersey Construction Company building concrete-lined tunnels under Newark Bay for the Passaic Valley Sewerage Commission. From 1916 to 1920 he was general superintendent on the construction of a sewerage disposal plant at Skillman, N. J.; railroad yards at Pittcairn, Pa.; and a dirigible hangar at Lakehurst, N. J. Mr. Leeuw again left the construction field from 1920 to

---

[1] Memoir prepared by F. R. W. Cleverdon, M. ASCE.

1923 to enter the employ of the New Methods Utilities Company of Newark, N. J.; as sales engineer. In 1923 he was engaged by Allen N. Spooner and Son, Inc., as general superintendent on the construction of a tunnel under the Passaic River at Belleville, N. J.; from then until his death, he was associated with that corporation, as construction engineer, and directed innumerable projects in waterfront construction and subaqueous work.

Mr. Leeuw held the unique distinction of having been a member of the small group of engineers (who formally worked with the New York and New Jersey Construction Company) that met at a dinner on October 29, 1936, at the Masonic Club, Jersey City, N. J. At that time he moved that they might be formed into a permanent organization. At a second dinner, on April 29, 1937, he was appointed chairman of a committee to select a name and prepare a set of by-laws for the new organization. At Mr. Leeuw's suggestion the name of "The Moles" was adopted. The first dinner of the organization under the name of "The Moles" was held on January 15, 1938; Mr. Leeuw was elected its first president. From that time until October 1945, a period of seven years, "The Moles" enjoyed the most phenomenal growth, both in members and the quality of membership, ever experienced by any organization of its kind. Its membership, increasing from 26 members, in 1938, to 316 members, in 1945, consisted of the most prominent engineers and contractors in civil life, and the most prominent officers in construction work in both the Army and Navy of the United States.

Mr. Leeuw's death occurred at the peak of his engineering ability and when his qualities of character were well defined. Thoroughness of detail, accurate judgment of men, ability to secure the loyal cooperation of subordinates, absolute devotion to any responsibility he had once accepted—these were the qualities that made him a credit to his profession and an inspiration to all who enjoyed his personal friendship. He died of a heart attack at the Harkness Pavilion, Medical Center in New York City, on October 18, 1945.

On September 22, 1918, in Baltimore, Md., he was married to May V. Bergen. He is survived by his widow and a daughter, Virginia (Mrs. Louis Ragonetti).

Mr. Leeuw was a licensed professional engineer in both New York and New Jersey. He was a member of the National Society of Professional Engineers.

Mr. Leeuw was elected a Member of the American Society of Civil Engineers on August 15, 1938.

OLIVIER ODILON LEFEBVRE, M. ASCE[1]

Died March 25, 1944

Canada has lost a great engineer and above all a good citizen in the death of Olivier Odilon Lefebvre. Mr. Lefebvre was a leader in the field of stream regulation. Largely through his efforts, the primary power output of most of the great water power plants in the Province of Quebec, Canada, has been greatly increased; the output of some has been more than doubled. Mr. Lefebvre interested himself not only in the engineering but in the economic features of these developments. He was largely instrumental in combining public and private interests in such a way that the facilities were paid for in the form of advance rentals by the owners of the existing or possible future plants that benefit by the increased low-water flow, although ownership remained with the province. This plan contrasts favorably with developments elsewhere in which the public have been saddled with the initial costs of plants that compete with existing privately-owned works.

---

[1] Memoir prepared by James H. Brace, M. ASCE.

Olivier Odilon Lefebvre was born at St. Hugues, Bagot County, Que., Canada, on November 14, 1879. His father was Olivier Lefebvre and his mother was Justine (Lefebvre) Lefebvre. He had five brothers and six sisters. His family typified the best in French-Canadian farm life as it existed three quarters of a century ago. He was fond of telling of his early life and stated that the family produced nearly everything it required. Mr Lefebvre was educated in the rural school at St. Hugues and then attended Mount St. Louis College and the École Polytechnique, both in Montreal, Que., Canada. He was graduated with honors from the latter institution in 1902 with the degree of Bachelor of Applied Science in Civil Engineering. In 1929 the University of Montreal at Montreal conferred on him the degree of Doctor of Science.

For eleven years Mr. Lefebvre was employed by the Dominion Government on laboratory work, surveys, and construction work at Ottawa, Ont., and on the west coast in the vicinity of Vancouver, B. C. His real life work began in February, 1913, when he was appointed chief engineer of the Quebec Streams Commission. He continued this work throughout the remainder of his life—as chief engineer of the Streams Commission from 1913 to 1935, as vice-chairman of the Quebec Electricity Commission from 1935 to 1937, as member of the Provincial Electricity Board from 1937 to 1940, and as vice-chairman of the Streams Commission from 1940 until his death in 1944. During this period Mr. Lefebvre was largely responsible, among other projects, for the initiation, design, and construction of the following important works: Gouin Dam and other storage dams on the St. Maurice River by which minimum flow was increased from 6,000 cu ft per sec to 16,000 cu ft per sec and the Mercier Dam, built about 1927, which increased the minimum flow of the Gatineau River from about 2,000 cu ft per sec to 10,000 cu ft per sec. The increased flow made economically practicable the three power developments on the Gatineau River at Chelsea, Farmers Rapids, and Paugan Falls. These plants have an aggregate installed capacity of 504,000 hp. His last large work was the construction of the Cadillac Power Development, on the Ottawa River, completed in 1941.

Mr. Lefebvre was a member of the Joint Board of Engineers on the St. Lawrence Waterways Project which reported in 1927. He represented Canada at the World Power Conference in Berlin, Germany, in 1930 and again at Washington, D. C., in 1936. At the time of his death he was a member of the Canadian Temporary Great Lakes-St. Lawrence Basin Committee. In

1933 and 1934, as chief engineer, he had charge of the construction of the Mercier Bridge over the St. Lawrence River near Montreal.

Throughout his entire professional career, Mr. Lefebvre took an active interest in the Engineering Institute of Canada, serving as councillor, vice-president, and finally in 1933 as president. He was prominent in the formation of the Corporation of Professional Engineers of the Province of Quebec (president in 1941).

He was also prominent in the educational affairs of the City of Montreal and of the Province of Quebec, having been a member of the administrative board of the École Polytechnique and of the board of administration of the University of Montreal at Montreal. When he died, he was chairman of the Catholic School Board of Outremont. Mr. Lefebvre spent much time in connection with many charitable organizations, among which were the Federation of French Charities, the Red Cross, and the Society for Crippled Children. He was a member of the Rotary Club, the Cercle Universitaire, and the Knights of Columbus. He was fond of reading, greatly enjoyed a game of bridge or billiards, and had a large circle of personal friends. Mr. Lefebvre did more through his personal influence than any other engineer to promote and develop cordial relations between the English-speaking and French-speaking population of Quebec. He possessed in an unusual degree the confidence of those in both groups with whom he came in contact.

On September 5, 1905, at St. Hugues, Mr. Lefebvre was married to Marie-Anna Comtois. He is survived by his widow and two daughters, Louise and Eliane. In fulfilment of a request he had often made, he was buried at his native place, St. Hugues.

Mr. Lefebvre was elected a Member of the American Society of Civil Engineers on April 12, 1926.

THEODORE ALFRED LEISEN, M. ASCE[1]

Died July 18, 1944

Theodore Alfred Leisen was born in Philadelphia, Pa., on February 17, 1864, the son of Charles Francis Leisen and Katherine (Murray) Leisen. After his education was completed, his entire life was spent in the practice of civil and hydraulic engineering. His father was a mechanical engineer and was granted numerous patents on mechanical devices; and his maternal grandfather, John Murray, was an engineer and architect in the British Government Service.

After graduating from a Philadelphia high school Theodore Leisen took special courses in engineering under the guidance of two professors of engineering in the Polytechnic College of Philadelphia. Also during that time he obtained valuable practical experience on general surveys and railway location.

---

[1] Memoir prepared by George H. Fenkell, Hon. M. ASCE, and W. C. Hoad, M. ASCE.

On April 27, 1892, he was married to Sarah G. Watson, of Wilmington, Del. Mrs. Leisen died in 1938.

Mr. Leisen spent the years from 1884 to 1890 in the Republic of Colombia, South America, first on the location and construction of the Ferrocarril de Antioquia, and then as chief engineer of the Barranquilla Railway and Pier Company, Ltd. This work—the building of the first railroads from the coast—was a good beginning for a young engineer, a beginning which aided him through his entire career.

In March, 1890, Mr. Leisen resigned from the office of chief engineer of the railway and pier company and, after spending a vacation of a few months in England and France, returned to the United States to become principal assistant engineer in the Street and Sewer Department of Wilmington. In 1892 he became chief engineer of the Department of Parks at Wilmington, and he served the city, in this capacity, and as consultant to the water department, until 1903. From 1904 to 1908 he was chief engineer of the water department. The Rockford Water Tower, a landmark at Wilmington, was his work.

In 1908 he accepted an offer from the Louisville Water Company, Louisville, Ky., to become its chief engineer and superintendent. In addition to carrying the responsibilities of this position, he was active in civic affairs in Louisville and was an honorary member and past president of the Engineers and Architects Club of that city. During this period also he served as consulting engineer to the water company at Frankfort, Ky. He remained at Louisville until 1914, when he accepted the offer of the Board of Water Commissioners of the City of Detroit, Mich., to become chief engineer and general manager of that city's expanding water department.

In 1917 Mr. Leisen was commissioned as Major in the Construction Division of the Quartermaster Corps and was assigned to the post of Officer in Charge of Utilities at Camp Custer, Battle Creek, Mich. When it was decided to double the size of Camp Custer, Major Leisen was appointed Constructing Quartermaster and, in addition to his duties as Utilities Officer, was put in charge of the enlargement program and of the construction of a new base hospital. In this assignment he set records for economy and efficiency that were unsurpassed in the Construction Division.

In 1919, immediately after his release from the United States Army, he returned to Detroit as consulting engineer to the Board of Water Commissioners and had entire charge of the design and construction of Detroit's first filtration plant. At the time of its completion, in 1923, this was the largest filtration plant in the world.

While in Detroit Mr. Leisen organized the Detroit Local Section of the Society and was its president. He was awarded a life membership in 1932. From 1936 to 1940 he was a member of its Board of Direction. He was also an honorary member and past president of the American Water Works Association.

In November, 1923, Mr. Leisen was appointed general manager of the Metropolitan Utilities District of Omaha, Nebr., in charge of the water, gas, and municipal ice plants. For some time previous to this appointment he had served the District as consultant on the design and construction of its filtration plant. Here again he established records of economy and efficiency which were outstanding. In Omaha he was also active in the movement to improve the Missouri River. He held this post until his retirement from active professional work at the end of 1940.

After his retirement he resided with his son, Frederic, in Detroit. He spent the winters in Florida, where he was able to indulge in his favorite recreation of golfing.

He maintained an active interest in military affairs, remaining in the Reserve Corps after the end of the World War I. In 1924 he was commissioned a Colonel in this organization and he held that rank in the inactive Reserve at the time of his death.

He is survived by two sons, Theodore A. Leisen, Jr., and Frederic A. Leisen.

Theodore Alfred Leisen's name among engineers is chiefly associated with the design, construction, and operating management of public water supply systems. His eminence in that field will always be recognized. He also devoted much of his time and energy to other and related civic problems in the communities, and to the interests of young engineers. There are many men in responsible posts throughout the United States who will always remember his friendly and helpful counsel.

Mr. Leisen was elected a Member of the American Society of Civil Engineers on June 2, 1897. He became a Life Member in January, 1932.

LEON RODERICK MACKENZIE, M. ASCE[1]

DIED JUNE 26, 1944

Deeply rooted in the formative period of the West, the traditions of Leon Roderick MacKenzie stem from the poineer era of Omaha, Nebr., of which townsite his grandfather, William David Brown, was the original owner, registering his claim in 1853. Although in later years Mr. MacKenzie became identified with activities which took him far afield, the commencement and broadening of his career lay within the western regions which were his lifelong attachments. Without doubt, the qualities of fairness and resourcefulness in his professional life, as well as his habitual energy and refusal of discouragement, were inherited from his pioneer forbears and were the result of his western environment.

Born on April 23, 1883, at Omaha, Leon MacKenzie was the second child of Alexander F. MacKenzie, a native of Gairlock, Scotland, and Emma N. (Brown) MacKenzie of Omaha. He received his fundamental education in the public schools of Omaha and acquired his technical training through instruction by, and association with, the well-known engineers by whom he was employed. Continuous application to study in the fields he had selected provided the basis for a comprehensive technical knowledge, utilized in later life in the particularized practices in which he became engaged.

---

[1] Memoir prepared by Norman D. Dean, Assoc. M. ASCE.

His first assignment, in 1900, found him a member of field parties of the Union Pacific Railroad Company and the Choctaw, Oklahoma and Gulf Railway Company in Wyoming, Oklahoma, and Texas. After two years in these activities, he decided to prepare for entry into the United States Military Academy at West Point, N. Y., and months were devoted to study. Toward the end of 1904 he abandoned this in favor of the career he had so auspiciously begun. The possibilities of the Cheesman Dam in Colorado appeared sufficiently compelling, and he became assistant to the construction engineer and, later, assistant superintendent of maintenance on the project. After about a year and a half on this project, he went to Mexico as assistant superintendent and engineer of surface operations for the Coahuila Coal Company at Hondo, Coahuila.

In 1907 he returned to Omaha as construction engineer for the Union Telephone Construction Company on the erection of exchange buildings and conduit installations. This work led to his employment by a prominent Omaha organization which was engaged in municipal engineering and construction.

Thus far, the young man had followed the not unusual path of many who enter the realm of engineering and are forced by circumstance, or desire for change, to seek other and greener fields. At the beginning of 1912, however, he organized his own business, under the firm name of Jackson and MacKenzie, consulting and contracting engineers, in Omaha. A year later he went to Chicago, Ill., to carry out research in street paving materials and methods. This led to the position of manager, and, soon after, chief engineer, of the California Brick Company at San Francisco, Calif., the largest paving brick plant on the West Coast.

The years from 1915 to shortly after the commencement of World War I were devoted to Mr. MacKenzie's well-developed specialization—street and highway pavements, research, development, and materials. As field and consulting engineer for firms of national repute in the uses of concrete and asphalt pavements, his activities were distributed throughout the United States. These abruptly ended when he became commissioned a Captain of Engineers in the National Army in 1918, and he was assigned to the engineering staff of the Commanding General of the Port of Embarkation at Newport News, Va.

The end of the war brought new ideas and stimulated new efforts, but also created delays and necessitated adjustments. Various surety companies, at this time, had discovered the desirability of utilizing engineers in contract completion, and in providing data prior to the issuance of surety bonds on important works to be undertaken. In the capacity of surety engineer, Mr. MacKenzie assumed charge for the Southern Surety Company of Iowa at Des Moines. This company had broad interests in many states. During tenure of this office he introduced many original procedures and practices still in use. He tendered his resignation in 1922.

By then, the years of application in the fields of street and highway paving materials and methods brought results. The uses of concrete for surfaces had increased steadily and were given added impulse following the war. After much experiment in the effects of vibration on concrete, he, with old friends and associates, founded the American Vibrolithic Corporation of Des Moines, Iowa, an organization which, by the end of a few years, had become nation-wide, extending its activities to Cuba and its patents to other foreign states. For ten years, as president of the corporation, Mr. MacKenzie became a well-known figure among engineers and contractors, and in municipalities all through the United States.

Concurrent with his work in the perfecting of vibrated concrete techniques, he commenced long and exhaustive experiment and research in the development of asphalt emulsions. The laboratory at Des Moines and work in the field, at last, yielded a product which added much to the advancement of asphaltic surfaces, resulting in the creation of his own organization, L. R. MacKenzie, Inc., at Des Moines. He was president of this organization until his death. In 1934 he was invited by the Soviet government to partake in a series of conferences in Moscow, U.S.S.R., concerned with highway planning and organization. In preparation for this event, he consumed months in study and gathering data calculated to be of practical value to the Russian government. His ideas and organizational plans were highly regarded by the Russians, who, at that time, were intent upon modernization of their road system, and upon the establishment of a road network which could be economically built and adapted to the vast road mileages involved. The mission to Moscow allowed Mr. MacKenzie the opportunity to visit Poland, Finland, France, and England in the interest of his patents.

Through a lifetime of activity he ran the gamut of struggle, progress, disappointment, and eventual success. In later years, although engaged in highly competitive production, he never relaxed his staunch principles of professional ethics and fair dealing. In private life he was recognized for his kindness and unfailing willingness to help others. He disliked display, or any manner of ostentation, preferring his rewards in the form of successful accomplishment. From Mexico to Canada he was fondly known as "Mac" and by his Russian friends as "Mr. Macansky." His hobby was his family of which there remain his widow, Ann (Amundson) MacKenzie; one daughter, Margaret Ann (Mrs. Robert B. Ash); a granddaughter, Margaret Randall Ash; his mother, Mrs. Alexander MacKenzie; a sister, Norma MacKenzie; and a brother, Lyle MacKenzie.

Mr. MacKenzie was elected an Associate Member of the American Society of Civil Engineers on September 12, 1916, and a Member on March 9, 1920.

LESTER CHIPMAN McCANDLISS, M. ASCE[1]

Died October 31, 1945

Lester Chipman McCandliss, the son of Harry E. and Harriet (Barr) McCandliss, was born in Anderson, Ind., on June 16, 1886. He was educated in the Anderson Public Schools and at Purdue University, in Lafayette, Ind., from which he received the degree of Bachelor of Science in Civil Engineering in 1909.

His first engineering experience was acquired with the Chicago, Burlington and Quincy Railroad. He then was employed by the Carmichael Construction Company of Akron, Ohio, and as office building superintendent.

In 1912 he joined the faculty of the School of Engineering of the University of Pittsburgh in Pittsburgh, Pa., and thus began his long career as an educator. He became assistant professor in 1915 and in 1931 was made professor and head of the department of civil engineering of the University, which position he held at the time of his death. During this period, at various times he taught most of the courses included in the civil engineering curriculum, including mechanics, strength of materials, geodetic surveying, and hydraulics.

For more than twenty-five years Professor McCandliss was in charge of the summer engineering camp maintained by the University of Pittsburgh at Windber, Pa., where he supervised the development of an outstanding surveying camp and the design and erection of an unique hydraulics laboratory. He was also largely responsible for the design and construction of the highway and automotive laboratory of the University on the campus.

During the operation of the service and management war training classes at the University before and during World War II, Professor McCandliss had charge of the engineering drawing and civil engineering classes in which several thousand men were trained.

During World War I, from May, 1917, to April, 1919, Professor McCandliss served as First Lieutenant and Captain of the Fifteenth Engineers, United States Army, spending twenty months in France in responsible charge of construction of railroads, warehouses, barracks, and highways. He had the unique distinction of leading the first company of armed American soldiers ever to set foot on British soil in wartime.

Professor McCandliss was active in the civic affairs of the community, being a member of the Pittsburgh Better Traffic Committee and at the time of his death, president of the Pittsburgh Motor Club. He was past-president of the Pitt Faculty Club and had served as Director of the Pittsburgh Section of the Society. He was a member of the Society for the Promotion of Engineering Education, Society of Military Engineers, and of the following fraternities: Scabbard and Blade, Phi Gamma Delta, and Signa Tau. He also belonged to the Bellefield Lodge, F. and A.M., and the Pennsylvania Consistory. He was a registered engineer in the State of Pennsylvania.

---

[1] Memoir prepared by Lewis W. McIntyre and John M. Rice, Members, ASCE, and Donald McNeil, Assoc. M. ASCE.

Professor McCandliss' outstanding characteristic was his devotion to his family and students. Although his main concern during the greater part of his active professional life was the development and improvement of the technique of teaching civil engineering subjects, he had a deep conviction that guidance in character building was of equal importance if the engineer graduate was to assume his place in society properly. The impression of his own high character and the earnestness of his teaching upon the thousands of his students made them not only good engineers, but also better men. The high plane of friendliness in student relations which he achieved is best illustrated by the affectionate title of "Cappy" with which he was universally greeted on the campus. Most of all, his hundreds of past and present students loved him. His office door was always open to them; and, if they were in trouble, they always left with a feeling of new courage and determination after having talked with him. He believed that every man and every student, if properly adjusted, would give out the best that was in him. His departmental faculty respected and recognized him as a leader. In the words of a prominent alumnus, "He was a great teacher." His kindly nature, loyal friendship, and judicious counsel endeared him in the highest degree to his colleagues, associates, friends, and students. All have suffered an irreparable loss by his death.

He was married, in Anderson, on October 12, 1910, to Abby W. McNamee. He is survived by his widow; two sons, John Henry and Alfred Neal McCandliss; and two brothers, Bernard B. McCandliss and Donald A. McCandliss.

Professor McCandliss was elected an Associate Member of the American Society of Civil Engineers on November 28, 1916, and a Member on September 9, 1935.

RALPH STECK McCORMICK, M. ASCE[1]

DIED MARCH 18, 1946

Ralph Steck McCormick, the son of Franklin S. and Elizabeth (Moore) McCormick, was born in Quaker City, Guernsey County, Ohio, on June 22, 1873. The family moved to Saginaw, Mich. (about 1883) where Ralph was graduated from high school. He attended the University of Michigan at Ann Arbor, for two years.

On leaving the University he was employed by the Pere Marquette Railway, from 1890 to 1894, as assistant engineer in Saginaw. Then, in 1894, he became draftsman and assistant engineer for the Grand Trunk Railroad at Battle Creek and Detroit, Mich., until 1900, when he went with the Algoma Central and Hudson Bay Railway at Sault Ste. Marie, Ont., Canada, as locating engineer. In 1903, Mr. McCormick returned to the Pere Marquette Railway, at Saginaw, as division engineer. In 1905, he became construction engineer for the New York Barge Canal at Rochester, N. Y.; and from 1905 to 1909 he was construction and locating engineer for the Grand Trunk Railroad (later the Canadian National Railway), at Fort William, Ont., Canada. In 1909, as chief engineer and general superintendent, he returned to the Algoma Central Railroad at Sault Ste. Marie. From 1916 until he retired, in 1945, he was general superintendent and chief engineer for the Algoma Central.

---

[1] Memoir prepared by L. C. Maxwell, Esq., Engr. Maintenance of Way (Retired), Algoma Central R.R., Sault Ste. Marie, Minn.

Ralph McCormick belonged to the American Railway Engineering Association, the Engineering Institute of Canada, and the Toronto Railway Club. He was a member of the Presbyterian Church (president of the board of trustees for several years), the Boy Scout Council, and the Masons.

On June 21, 1921, he was married to Eva Maxwell. They had four children: Two sons, Harry and Ralph McCormick, and two daughters, Gene and Dorothy Ann McCormick. He is survived by his widow and children.

He was a devoted husband, and, as a father, took a keen interest in the education and welfare of his children.

Mr. McCormick was elected a Member of the American Society of Civil Engineers on October 3, 1911.

JOHN GILMORE McMILLAN, M. ASCE[1]

DIED FEBRUARY 14, 1935

John Gilmore McMillan was born in Bristol, R. I., on July 11, 1851. He was the son of William Wallace McMillan and Sarah (McCaughy) McMillan, the second child in a family of four sons and two daughters. His father first arrived in California in 1849 and engaged in mining in Butte County, at Union Bar on the Feather River. After returning to Rhode Island, he again went to California by way of Cape Horn. Mrs. McMillan and two small boys crossed the Isthmus of Panama early in 1856, proceeding to San Francisco, Calif., by sailboat—an arduous journey. They were finally met by an ox team which conveyed them to the mines.

After the mine at Union Bar was worked out, the family moved to Hurleton, Calif., in the Feather River section of the Mother Lode country. Mr. McMillan and his elder brother were sent to a school held in a little cabin—a walk of six miles through the rough wooded country. With the benefit of the tutelage of his father, a graduate of the University of Glasgow in Glasgow, Scotland, and with the encouragement of the late Smith Hurles, Mr. McMillan extended his studies far beyond the curriculum of the remote country school; and, at the age of sixteen, he was teaching. His aptitude for mathematics, together with the influence of his contact with the mining activities of the Mother Lode country, led him to devote his spare hours to the study of civil engineering.

His cousin, the late Sarah Daley, wrote of the early life of Mr. McMillan:

---

[1] Memoir prepared by Earl C. Thomas, Assoc. M. ASCE.

> "His childhood days * * * were not made of luxuries, as so much depended upon the mines. He was always a good studious boy and the pride and joy of a good mother's heart * * *. He won the admiration of not only his own relatives but very many friends who yet remember him."

In an old scrapbook Mr. McMillan cited an extract from a letter written by his father just after leaving home:

> "I will allow nothing on the outside to draw my attention from my daily duties, my firm resolution is to go slow, be modest, agreeable and dignified and avoid affectation in reading, speaking or acting. Be natural now and forever, it is much easier to be what we would like to appear to be, than to appear to be what we are not. The more we read and the more we see, the more are we inclined to take a common sense view of all that surrounds us and a veneration of all that is above or beyond our comprehension."

Apparently this advice had great influence on the young man since the sense of the quotation comprehends the best description of his character. Mr. McMillan's good judgment, sustained by his mathematical and inherent technical ability, was the groundwork for his engineering achievements.

In 1878 Mr. McMillan was elected county surveyor of Sutter County, California, serving for nearly three years. He was forced to resign because of ill health and then entered the employ of the Southern Pacific Railroad Company. In 1883–1884 he was engaged as assistant construction engineer on the Market Street System of cable railways in San Francisco. The following year he was in Central America, as assistant engineer on the location and construction of the railroad from San José to Guatemala City, Guatemala.

Returning to California he was engaged by a French syndicate, in charge of location and construction of reservoirs and flumes for the development of hydraulic mining in the northeastern part of the state. In 1886 Mr. McMillan was engaged by Leland Stanford, then U. S. Senator from California, as chief engineer for the Stanford Properties. The greater part of his activities was centered at the Palo Alto (Calif.) Farm on the surveys for, and early construction of, Leland Stanford Junior University.

In 1890 Mr. McMillan became county surveyor of Santa Clara County, California. He began his career in the field of highway bridges in 1891 by designing one of the earliest part concrete bridges in the United States over Penetencia Creek. (The plans were adopted by the board of supervisors in that year but work did not commence until 1892.) During this early period, Mr. McMillan was not sure of the action of concrete in an arch and constructed this 36-ft arch of four rowlock brick with concrete side-walls and abutments. In 1896 he built two similar bridges. In the fall of 1897, construction began on a 24-ft concrete arch bridge reinforced with fabricated steel ribs, over Canoas Creek, near San Jose, Calif. A search by the Engineering Societies Library reveals that not more than nine concrete arch highway or railroad bridges were constructed in the United States prior to 1897. Thus, Mr. McMillan was among the pioneers in the design and construction of reinforced concrete bridges.

He continued to specialize in brick arch and fabricated steel reinforced concrete arch bridges until 1903 when he used ⅞-in. rods to reinforce a 40-ft bridge over Los Gatos Creek at Alma, Calif. Notable among the bridges constructed by Mr. McMillan are Long Bridge near Saratoga, Calif. (a two-span arched masonry bridge constructed of native rock) and the municipal bridge at Los Gatos, Calif. In 1910 Mr. McMillan constructed a three-span (one span of 70 ft) bridge over the Coyote River on the highway leading to Oakland, Calif. This bridge was outstanding as an economical type of spandrel construction which later became commonly recognized. All Mr. McMillan's work shows that he was resourceful and inventive. In 1899 he devised a bridge flooring composed of timbers laid on edge longitudinally to form a solid and continuous deck, covered with asphalt. Numerous similar bridge floors were built in California, several of which were covered with concrete instead of asphalt. Descriptions of this type of construction have recently reappeared in engineering literature.

During his tenure of office and during his residence in San Jose until his death, Mr. McMillan was engaged in various engineering consultation and construction, including the location and construction of the San Jose and Alum Rock Railroad, many sewer and sewage disposal plants, water works, and other municipal projects.

Mr. McMillan was married in 1887 to Elizabeth D. Weisshaar. He is survived by his widow; two sons, W. Bruce McMillan, M. ASCE, and Percy W. McMillan; and a daughter, Doris A. McMillan.

He became a Mason in Forbestown Lodge No. 50 (Butte County) in 1872. He subsequently joined the Knights Templar and the Scottish Rite. He was also a member of several other fraternal organizations, the Technical Society of the Pacific Coast, and the Sons and Daughters of Pioneers.

Mr. McMillan was elected a Member of the American Society of Civil Engineers on October 5, 1909. He became a Life Member in January, 1934.

LEON SOLOMON MOISSEIFF, M. ASCE[1]

Died September 3, 1943

With the death of Leon S. Moisseiff, the engineering profession lost a man of great knowledge, who had a keen analytical mind, professional honesty, and moral integrity. His knowledge of languages, combined with his intellectual curiosity, made him one of the best informed of engineers. He placed the foundation of his professional career when the engineering science as it is known today was still in its infancy and he grew with engineering science, always remaining abreast of it.

Leon Solomon Moisseiff, the son of Solomon and Anna (Bloch) Moisseiff, was born in Riga, Russia, on November 10, 1872. He studied at the Emperor

---

[1] Memoir prepared by O. H. Ammann and Frederick Lienhard, Members, ASCE.

Alexander Gymnasium and the Baltic Polytechnic Institute in Riga. His activities in liberal groups forced him to leave Russia in 1891. On his arrival in the United States he worked as a draftsman in New York, N. Y., until he entered Columbia University in 1892. In 1895 he was graduated with the degree of Civil Engineer. During his college studies he was privately employed by W. H. Burr,[2] M. ASCE, one of his professors.

In those early days the public's conception of an engineer was an outdoor man in puttees. A college degree was not part of this picture and subtracted from, rather than added to, the concept. After two years of holding modest positions with private concerns, in 1897 Mr. Moisseiff entered the service of the City of New York, remaining for the next eighteen years. He began as draftsman and bridge engineer in the Borough of the Bronx, but was soon transferred to the Department of Bridges of the Borough of Manhattan and became chief draftsman in 1900. About this time he began to work on designs for the Manhattan Bridge and the Queensborough Bridge, as well as on reports for the projected reconstruction of the Brooklyn Bridge. He was the first to recognize the significance of the deflection theory, which had been outlined by J. Melan in 1888.[3] Mr. Moisseiff proved that this theory allows important savings in material. His complete development and application of the deflection theory became a standard work of reference for later designers of suspension bridges.[4]

Mr. Moisseiff was put in charge of the Williamsburgh Bridge investigation in 1909. His studies led to reinforcing the main span and strengthening the side spans. Two years later he was charged with the design of the proposed Hudson Memorial Bridge across the Harlem River. Because of lack of funds, this reinforced concrete arch with an unprecedented span of 725 ft was not built. In 1910 the City of New York established a Division of Design of which Mr. Moisseiff became head, with the title of engineer of design.

In 1915 he left the service of the City of New York and opened an office as consulting engineer. He did little professionally for the next few years. World War I caused a cessation of bridge building, and the use of the automobile had not reached the proportions which were to demand the building of large bridges. The first large suspension bridge to be built after the war was the Delaware River Bridge connecting Philadelphia, Pa., with Camden, N. J. In 1920 Mr. Moisseiff was appointed engineer of design for this structure.

From that time until his death he was actively engaged in the design of most of the large bridges in the United States—The Ambassador Bridge at Detroit, Mich.; the Maumee River Bridge at Toledo, Ohio; the Golden Gate and the San Francisco-Oakland Bay bridges at San Francisco, Calif.; the Triborough, the Bayonne Arch across the Kill Van Kull, the Bronx-Whitestone, and the George Washington bridges at New York, N. Y.; and the Tacoma Narrows Bridge at Tacoma, Wash.

[3] "Theorie der eisernen Bogenbruecken und der Haengebruecken," by J. Melan, 2d Ed., 1888.

[4] "Report to the City of New York, Department of Bridges, 'Manhattan Bridge," by Ralph Modjeski, 1909.

In addition, Mr. Moisseiff was retained by the Commissariat of Railroads of the Union of Soviet Socialist Republics for two and one-half years, from 1929 to 1932. The work involved engineering advice in the broadest sense on existing bridges as well as on standards for new structures. The studies necessitated an extensive trip in Russia. Two years later his advice was again sought for a design audit of the proposed Palace of Soviets in Moscow.

The planners of the Chicago (Ill.) World's Fair (1933) will remember Mr. Moisseiff as the responsible designer of the Travel and Transport Building. The basic conception for this structure was like that of a suspension bridge, the main sustaining members being cables.

In 1935 the City of New York requested a complete investigation of its East River crossings—the Manhattan, Williamsburgh, and Queensborough bridges—with recommendations for strengthening the structures as a whole and improving the roadways. Mr. Moisseiff was a member of a two-man board and all work was conducted in his office.

From 1937 to 1940 the Aluminum Company of America engaged Mr. Moisseiff to make a thorough study of aluminum as a structural material for bridges. The results of his investigations are summarized in "Design Specifications for Bridges and Structures of Aluminum Alloy 27S-T."[5] This research may, in due time, contribute to rewriting present specifications for steel.

In 1939 the Edward G. Budd Manufacturing Company of Philadelphia requested Mr. Moisseiff to make a study of stainless steel—particularly of its application to passenger railway cars. In addition, Mr. Moisseiff was active on many projects which did not materialize, notably the Mackinac Straits Bridge in Michigan. His activities in recent years may be summarized by the statement that Mr. Moisseiff was a consultant to consulting and executive engineers.

Throughout his career Mr. Moisseiff was very active in professional societies. He reviewed many papers, took part in discussions, and prepared a number of notable papers including "The Deflection Theory as Applied to Suspension Bridges with Suspended Trusses,"[6] "The Towers, Cables and Stiffening Trusses of the Bridge Over the Delaware River Between Philadelphia and Camden,"[7] "Manufacture and Use of High Strength Structural Steel for Bridges,"[8] "George Washington Bridge: Design of the Towers,"[9] "The Design, Materials and Erection of the Kill Van Kull (Bayonne) Arch,"[10] "Investigation of Cold Drawn Bridge Wire,"[11] and "Evolution of High-Strength Steels Used in Structural Engineering."[12] In collaboration with Frederick Lienhard, M. ASCE, Mr. Moisseiff wrote "Suspension Bridges Under Action of Lateral Forces,"[13] and "Theory of Elastic Stability Applied to Structural Design."[14] In collaboration with E. C. Hartmann and R. L. Moore, Assoc. M. ASCE, Mr. Moisseiff wrote "Riveted and Pin-Connected Joints of Steel and Aluminum Alloys."[15]

[12] *Transactions,* ASCE, Vol. 102, 1937, p. 1333.

[13] *Ibid.,* Vol. 98, 1933, p. 1080.

Mr. Moisseiff received the Norman Medal and the James Laurie Prize from the Society, the Egleston Medal from Columbia University, and the Modern Pioneer Award from the National Association of Manufacturers. He was on many committees of the Society and gave freely of his time and experience. He was a member of the American Society for Testing Materials, American Railway Engineering Association, and American Welding Society, serving in an executive capacity and on committees for some of these organizations. He belonged to Sigma Xi and Zeta Beta Tau fraternities.

Mr. Moisseiff was married to Ida Assinovski in 1894 in New York City. Surviving are his widow; a son, Siegfried Moisseiff; and two daughters, Mrs. Liberty Weiss and Mrs. Grace Smith.

Mr. Moisseiff was elected a Junior of the American Society of Civil Engineers on December 3, 1895; an Associate Member on September 5, 1900; and a Member on December 3, 1907.

PHILLIPS BATHURST MOTLEY, M. ASCE[1]

Died January 13, 1946

Phillips Bathurst Motley was born in Calcutta, India, on March 22, 1871. His parents were John Phillips Motley, a shipmaster in the East India Company, and Annie Eliza Carey, granddaughter of the great Dr. William Carey. Dr. Carey, who lived from 1761 to 1834, was the first missionary to India, and worked in the then hostile land for forty years. He translated the Bible into forty languages and was instrumental in abolishing the custom of "suttee," the burning to death of widows.

Phillips Motley received his early education in England, notably at Padcroft School, West Drayton, London. He received his engineering training at the School of Practical Engineering, Sydenham, England, and then worked for one year (1891) for a firm of mining engineers in London, as draftsman and engineer.

Mr. Motley left England for Montreal, Que., Canada, in 1892, to join the engineering department of the Canadian Pacific Railway, and he was instrumental in the construction of many of the large bridges built in the Rockies, along the north shore of Lake Superior, and in the Maritime Provinces. Among them were: Lethbridge Viaduct; Edmonton High Level Bridge; Stoney Creek Arch Bridge in the Rockies; the cantilever bridge at Saint John, N. B., Canada; the double-leaf bascule bridge at Fort William, Ont., Canada; and the double-track bridge over the St. Lawrence River between Ville LaSalle and Caughnawaga, Que., Canada.

---

[14] *Transactions*, ASCE, Vol. 106, 1941, p. 1052.

[15] *Ibid.*, Vol. 109, 1944, p. 1359.

[1] Memoir prepared by Press Relations Dept., Canadian Pacific Ry., Montreal, Que., Canada.

In his forty-five years with the Canadian Pacific, Mr. Motley, successively, occupied the positions of draftsman, bridge inspector, assistant engineer, and assistant engineer of bridges before becoming engineer of bridges for the entire system, in 1911—overseeing all design, construction, and supervision of bridges from the Atlantic to the Pacific.

He was married on December 24, 1901, to Mary Helena Scott, daughter of William Scott, picture and fine art dealer of Montreal. He is survived by his widow and a son, Phillips C. Motley.

He was a life member of the Engineering Institute of Canada; and a member of the American Railway Engineering Association, the Institution of Civil Engineers of Great Britain, and the Professional Engineers of the Province of Quebec.

Accurate and conscientious to a degree, Mr. Motley carried the weight of great responsibility which his position involved with consistent faithfulness and success. On his retirement he was able to follow his many hobbies, chiefly photography and the collection and repairing of antique clocks and furniture, and other wide interests.

Mr. Motley was elected a Member of the American Society of Civil Engineers on April 7, 1915. He became a Life Member in January, 1942.

EVERETT BODMAN MURRAY, M. ASCE[1]

DIED JULY 10, 1945

Everett Bodman Murray, the son of Emma (Atkins) and Albert D. Murray, was born in Chicago, Ill., on September 26, 1885. He was graduated from the University of Illinois at Urbana, with the degree of Bachelor of Science in Civil Engineering in 1908. He was a member of Phi Gamma Delta fraternity.

While still attending school, he worked part time from 1902 to 1908, including three summers (1904–1907), as a rodman and instrumentman for the Chicago, Milwaukee and St. Paul Railway Company. From 1908 to 1909 he was in charge of a survey party for the Tallahatchie Drainage District in Mississippi. From 1909 to 1910 he was field superintendent on drainage, reinforced concrete, and power-plant construction work for the Harmon Engineering Company of Peoria, Ill. From 1910 to 1911 he was field superintendent of construction for the Federal Engineering Company of Milwaukee, Wis. From 1911 to 1912, he was chief engineer for the Kaw Valley Drainage District at Kansas City, Kans. From 1912 to 1917 he engaged in private practice—E. B. Murray and Company in Kansas City, Mo.—as consulting engineer on drainage, water works, sewerage, pumping plants, water purification, sewage disposal, etc.

With the entrance of the United States into World War I in 1917, Mr. Murray was appointed a Captain in the Corps of Engineers, U. S. Army, and served in France with the Three Hundred and Fourteenth Engineers, attaining the rank of Major. In 1924 he resigned from the regular army and returned to private practice as consulting engineer on management of income producing properties, office buildings, etc. He was president of E. B. Murray and Company, Inc., at the time of his death.

---

[1] Memoir prepared by E. A. Blanpied and G. H. Frieling, Assoc. Members, ASCE.

Mr. Murray, familiarly known to his friends as "Mike," made building management his profession but was deeply interested in the human side of business and civic affairs connected with his real estate and housing projects. His contagious interest in life brought him a host of friends and his counsel and leadership in civic affairs made him one of Kansas City's most valued citizens.

He was president of the Missouri Bank and Trust Company, a director of the Missouri Land and Loan Company, and national president of the National Association of Building Owners and Managers. He belonged to the American Association of Engineers, American Society of Mechanical Engineers, and National Real Estate Board. Mr. Murray's civic activities were numerous, including service as the chairman of the Kansas City Housing Authority and of the Jackson County Citizens Reassessment Committee. For two years he was president of the University Club of Kansas City, Mo.

In 1910 he was married in Kansas City, Mo., to Clara Lee Webb. She died in 1943. He is survived by a son, Everett W. Murray; his father, A. D. Murray; and a brother, Donald Murray.

Mr. Murray was elected an Associate Member of the American Society of Civil Engineers on April 2, 1913, and a Member on October 3, 1922.

EGBERT STEPHEN NEEDHAM, M. ASCE[1]

Died March 13, 1945

Egbert Stephen Needham, the son of an American father and an Irish mother, was born on April 11, 1887, at St. Paul, Minn., and attended high school there.

At the age of seventeen, he took his first job, as a draftsman in the mechanical and engineering departments of the Chicago Great Western Railroad Company. Here he was engaged on bridge plans, starting an association with bridge work which he was destined to follow almost uninterruptedly for the next quarter of a century. After five years with the Chicago Great Western Railroad Company, he joined the bridge department of the Northern Pacific Railway Company, in 1909, as a designing draftsman; he remained there until 1913. This period included approximately a year with the Strauss Bascule Bridge Company of Chicago, Ill., in a similar capacity. From 1913 to 1915 he was a designer in the departments of the Engineer of Structures and Grand Central Terminal Improvements of the New York Central Railroad Company;

---

[1] Memoir prepared by Leroy A. Beaufoy, King's College, London Univ., London, England.

then, in 1915, he went to the West Indies as resident engineer to the Department of Public Works, Santo Domingo, Dominican Republic, where he had charge of the construction of the Ozama River Highway Bridge, 700 ft long. When this job was finished, in 1917, he rejoined the Northern Pacific Railway Company as an assistant engineer supervising bridge reconstruction. In 1918 he joined the Army as a private in the 43d Engineer Corps, 20th Engineers, and spent a year in France with the American Expeditionary Force.

After World War I he remained in Europe. On July 26, 1923, he was married at Folkestone, England, to an English girl, Ivy Maud Dexter, the daughter of an Admiralty official stationed at Devonport, England. For a short period immediately after the war he was in private practice as a structural engineer in London, England, working on the design of a railway bridge over the Santa Lucia River in Montevideo, Uruguay. He entered the civil engineering and contracting department of Sir W. G. Armstrong Whitworth and Company, Ltd., general contractors, Westminster, London, in 1921, and was soon at work on an arch design of the accepted type for the Sydney Harbour Bridge, Australia, together with details and weights sufficient for a preliminary price. He also reported on the port works at Valencia, Spain. Then he was sent by the firm to Ireland, the land of his mother's birth, on the design and construction of the Bann River Bridge for the London, Midland and Scottish Railway at Coleraine. The opening span of the bridge is a Strauss trunnion bascule with underhung counterweight. It was probably the first of its type in the United Kingdom, and doubtless reflected his earlier experience with the Strauss Bascule Bridge Company at Chicago. Mr. Needham subsequently prepared a report on this work for the technical press.[2]

In 1925, his firm sent him to South America as their engineer and agent in charge of the construction, for the Colombian National Railways, of the Girardot Bridge over the Magdalena River. Shortly after he had settled down in Colombia, Mr. Needham was joined by his wife, who traveled from England with their infant son and made the last stage of the journey from Barranquilla, on the Atlantic side of Colombia, to Girardot, 700 miles up the Magdalena River, by plane. The Girardot Bridge, the largest bridge in Colombia, is of the cantilever type, 1,530 ft long, and the river span between centers of main piers is 426 ft. The work involved heavy foundations and anchorages, and construction under severe tropical conditions. Transport also was difficult. By the successful termination of this assignment in 1930, Mr. Needham displayed his ability to work in harmony with governmental bodies.

There followed a short engagement on harbor works and water supply problems in the Near East. During the slump period (1932–1933) in Great Britain, Mr. Needham took the examinations of the Institution of Civil Engineers, London, and began a special study of electric welding and its structural applications. This led to his being engaged (1933–1935) by Messrs. Murex, Ltd. on the design and construction of extensions to their works at Rainham, Essex, England. This work involved heavily reinforced-concrete raft foundations on piles, and steel-framed, all-welded factory buildings. He also designed the first all-welded Vierendeel truss to be erected in the United Kingdom, and was joint author of a paper[3] on the subject presented to the Institution of Civil Engineers in London. In 1936 he transferred to Messrs. Murex Welding Processes, Ltd. and, as their construction engineer, was responsible for the design and construction of new factory buildings at Freezywater, Waltham Cross, Herts, England, the main building alone being a 1,000-ton, all-welded structure covering four and one half acres. This work inspired two papers presented by him to the Institute of Welding.[4,5] The Freezywater factory finished, Mr. Needham, in 1939, opened a private practice in London as consulting engineer for structural welding; with the imminence of World War II, the occasion was not favorable. He was, however, invited to inquire into the then recent collapse of the Hasselt Bridge over the Albert Canal in Belgium, an all-welded structure of the Vierendeel type; and, in an article in *Engineering*,[6] he gave a critical review of the known facts and made an examination of the design of the bridge.

---

[2] "Strauss Bascule Bridge over the Bann River, Ireland," by E. S. Needham, *Engineering* (London), Vol. 118, 1924, pp. 758–759.

In 1940 he went to Turkey to represent Sir Alexander Gibb and Partners, Consulting Engineers, Westminster, London, and he remained there on fortification works in the Dardanelles until 1943. On his return to England, he was for a short time in charge of a Ministry of Supply establishment for training welders, of which the country was then in great need. Then, in 1944, with the invasion of Europe by the allied forces impending, he accepted a post with the U. S. Army as a civilian engineer with the assimilated rank of Major. After a brief period at U. S. Army headquarters in London, he moved over to France shortly after the allied invasion began, and was concerned in the restoration of port facilities, and later with Rhine bridging problems. The strain, however, proved to be great and toward the end of the year he was invalided back to England. Soon, as was usual with him on his return from trips overseas, he plunged into the professional activities of the engineering societies in London, and it was actually while he was making a contribution to the discussion of a paper at the Institution of Civil Engineers, London, that he suddenly collapsed and shortly afterward died without regaining consciousness. He thus died "in harness," as doubtless he would have wished had the choice been his, for he was exceptionally devoted to his profession, and was a frequent contributor to the discussions at meetings of the leading institutions. It was perhaps fitting that his last act should have been that of contributing to a paper on bridge construction, a subject in which he was well versed.

He always maintained close contact with his Colombian friends, some of whom visited at his home. Those who were privileged to join his family circle were charmed by it. Mr. Needham always seemed to fit into it, on his return from a trip abroad, just as though he had never been away.

---

[3] "Analysis of a Vierendeel Truss by Moment Distribution and Deformeter Methods," by E. S. Needham and L. A. Beaufoy, *Journal*, Inst. C. E., Vol. 10, 1939, pp. 253–272.

[4] "Design and Construction of a Large All-Welded Factory," *Transactions*, Inst. of Welding, Vol. I, 1938, pp. 139–186.

[5] "Design of Knee Joints for Portal Frames," paper presented to the North Eastern (Teesside) Branch of the Inst. of Welding, London, on April 17, 1940.

[6] "The Hasselt Bridge Collapse," *Engineering* (London), Vol. 147, 1939, pp. 395–397.

His stay in Turkey, during World War II, had endeared him to it. He thought it a country of great promise, and was looking forward to going back after the war to open a practice there. On his return from Turkey he enthusiastically availed himself of courses in the Turkish language given under Turkish Government auspices at the Turk Halkevi in London.

He was a remarkably self-contained man and in general would go out on a social occasion only if there were a scientific or engineering flavor to it. Then he would welcome and enjoy it. He was keen on the game of patience, a habit probably acquired during his trips abroad, and was a competent pianist who sought and found intense pleasure in the relaxation that music provides.

He is survived by his widow; two children, James Christopher and Alicia Margaret (Néna); a brother, John; and a sister, Eleanor.

In addition to his membership in the Society, Mr. Needham was a member of the Institution of Civil Engineers and the Institute of Welding, both in London.

Mr. Needham was elected an Associate Member of the American Society of Civil Engineers on November 27, 1917, and a Member on July 6, 1931.

CHARLES MARSHALL NEELD, M. ASCE[1]

Died December 23, 1945

Charles Marshall Neeld was born on December 8, 1875, at Banksville, near Pittsburgh, Pa., the son of Capt. John R. and Harriett (Robinson) Neeld. After preparation in the public schools and the Pittsburgh Academy, he entered the Western University of Pennsylvania (later the University of Pittsburgh) in Pittsburgh, from which he received the "degree in Civil Engineering" in 1896.

For the next two years he was draftsman and designer with the Fort Pitt Bridge Works in Pittsburgh, after which he was sales engineer, designer, and vice-president with the Columbia Bridge Company of Pittsburgh (later the Columbia Steel Shafting Company).

In 1902 Mr. Neeld was married to Alice McNeilly, to whom three children were born—Charles R., Alice (Mrs. H. D. McMurray), and Ruth (Mrs. A. W. Baisler). Mrs. Neeld died in 1923 and two years later Mr. Neeld was married to her sister, Roberta, who, with his son and two daughters, survives him.

From 1900 to 1911 he was with McClintic-Marshall Construction Company of Pittsburgh, as, successively, designer and estimator, manager of erection, superintendent of shops, contract manager, and, for five or six years, general manager of the Pittsburgh plant which had a capacity of 8,000 tons of fabricated steel per month. The Pittsburgh and Lake Erie Railroad bridge over the Ohio River at Beaver, Pa., and the Panama Canal lock gates, together with hundreds of important and similar projects, were constructed under his direction.

---

[1] Memoir prepared by a Committee of the Pittsburgh Section, consisting of Vernon R. Covell, Clarke K. Harvey, and James C. Jordan, Members, ASCE.

From 1911 to 1934 he was engaged in the construction business as president of the C. M. Neeld Construction Company (later the Neeld Construction Company) of Pittsburgh. The company designed and constructed many bridges, reservoirs, and buildings, and conducted coal stripping operations. Outstanding examples of his work were the relining of the Eden Park Reservoir at Cincinnati, Ohio; the construction of a reinforced concrete bridge in Wilkes Barre, Pa., spanning three important railroad yards and many tracks, at a cost of $300,000; the reconstruction and double-decking of the Havre de Grace (Md.) highway bridge over the Susquehanna River (approximately a mile long, involving change of elevation of spans to make the runoffs, the reconstruction of the draw span and change of the machinery—all without interfering with traffic at a cost of $450,000); the reconstruction of the Chester-East Liverpool interstate highway bridge spanning the Ohio River at East Liverpool, Ohio, with a new, lightweight, permanent floor, designed and patented by Mr. Neeld; the reconstruction of the West Penn Railways bridges at Wheeling, W. Va.; and the reconstruction of fifteen bridges of the Pittsburgh Railways Company under traffic.

In 1934 Mr. Neeld entered consulting work and later often served as an expert witness in cases involving bridge design, construction, and maintenance. Some of his more important contributions were revision of the layout of the three plants of the Dominion Bridge Company in Montreal, Canada; design and construction of bridges for the State of Maryland; and many engagements with the Pennsylvania Railroad Company.

Mr. Neeld was a lifelong member of the Mount Lebanon United Presbyterian Church in the South Hills of Pittsburgh, and for many years was superintendent of the Sabbath School and an Elder in the church. He always stood for his high ideals and unflinchingly for what he believed to be right.

He was a registered professional engineer in Pennsylvania.

Mr. Neeld was elected a Member of the American Society of Civil Engineers on October 7, 1908.

JAMES CLARENCE OGDEN, M. ASCE[1]

DIED SEPTEMBER 10, 1945

James Clarence Ogden, the son of John W. Ogden and Susanna (Rhoads) Ogden, was born at Springfield, Pa., on September 21, 1867. He took a special course in civil engineering followed by one year of postgraduate work at the University of Pennsylvania, Philadelphia.

Following completion of his college course, in 1887, he was assistant to the superintendent of construction of the Atlantic Refining Company, Philadelphia, where from June, 1887, to November, 1888, he was in charge of laying out and constructing pipe lines—designing and in charge of erecting buildings, tanks, and stills. From November, 1888, to May, 1889, he was engineer in charge of field surveys with Joseph Young, engineer and contractor. From May, 1889, to March, 1893, he was mill and shop inspector for the Pittsburgh Testing Laboratory, part of the time in Philadelphia checking details of bridges. In March, 1893, Mr. Ogden entered the employment of the Robert W. Hunt Company. From 1893 to 1902 he was mill and shop inspector in charge of the Philadelphia District. From 1902 to 1923 he was manager of the New York office in charge of mill, shop, and erection inspection, preparation of specifications, and design and inspection of safe deposit vaults. On June 28, 1923, when the company was incorporated, Mr. Ogden was elected a director. On July 24, 1930, he became vice-president; and, on March 25, 1935, he was elected president of the company. On April 17, 1945, he was made chairman of the board and held that position to the time of his death.

---

[1] Memoir prepared by W. L. Cooper, Pres., Robert W. Hunt Co., New York, N. Y.

During 1914 to 1918 Mr. Ogden directed the inspection of large quantities of ordnance and materials of all kinds for war purposes used by the Allied Nations.

He had extensive experience with foreign engineering contracts and made several visits to Europe in that connection.

Throughout his career he played an important part in obtaining improvements in specifications and methods of production and construction of engineering materials and equipment.

Mr. Ogden had high standards of personal integrity and retained the respect and loyalty of all who came in contact with him.

He was a member of the American Society for Testing Materials, the American Society of Metals, the Union League Club of Chicago, the Bankers Club of New York, and the Plainfield Country Club. He was, for many years, a resident of Plainfield, N. J.

On June 1, 1893, Mr. Ogden was married to Elizabeth Morton Lewis who died on February 24, 1930. He is survived by his daughters, Edith (Mrs. Monroe H. Long) and Elizabeth (Mrs. Will McLain); and by four grandchildren

Mr. Ogden was elected a Member of the American Society of Civil Engineers on October 3, 1911. He became a Life Member in January, 1938.

ARTHUR KERSHAW OLSEN, M. ASCE[1]

Died November 17, 1944

Arthur Kershaw Olsen was born at Salt Lake City, Utah, on February 17, 1904. He was the son of Haakon Kershaw Olsen and Fredricca (Rystrom) Olsen. After his early education in the public schools of Salt Lake City, he attended the University of Utah also in Salt Lake City, from which he was graduated in June, 1929, with the degree of Bachelor of Science in Civil Engineering. In 1935 he was awarded the degree of Bachelor of Laws by the LaSalle Extension University in Chicago, Ill.

---

[1] Memoir prepared by A. Diefendorf, M. ASCE.

Prior to his graduation, from July, 1925, to May, 1926, he was employed as a rodman in the division engineer's office, Chicago, Milwaukee, St. Paul and Pacific Railroad Company, at Deer Lodge, Mont., on service, acting as instrumentman on a four-man party. From May, 1926, until May, 1929, he was with the Iowa Highway Commission in Ames, Iowa, on construction of approximately fifty miles of concrete paving (including grading, culverts, and bridges) as instrumentman and inspector, responsible to the resident engineer for proportioning, mixing, and placing concrete for paving slabs and structures.

After he completed his engineering course, Mr. Olsen was employed for four years (from 1929 to 1935) as county highway engineer for Union County at Creston, Iowa, on construction and maintenance of a 750-mile highway system (expenditures, $130,000 annually, supplemented by grants of funds, material, labor, and equipment from the Public Works Administration and the Works Progress Administration). He had full charge of administration and engineering (under him were from 50 to 400 men), and was responsible to a board of supervisors and the State Highway Commission for surface design, construction, and maintenance. In 1930 he reorganized the county highway department to conform to the new highway law.

From February, 1935, to December, 1941, Mr. Olsen served as general manager and engineer, for the Creston (Iowa) city water works, on the rehabilitation and reorganization of the water system. He was engineer in charge of design and construction of a $200,000 improvement program, involving earth dams, concrete reservoirs, modernization of the filtration plant, an elevated tank, and extensive main replacement. He was also general manager in charge of operation and maintenance, responsible to the board of trustees for administration (including the payment of interest and the retirement of $269,000 worth of bonds).

In December, 1941, he was made assistant chief of operations, Construction Section, Special Engineering Division, Panama Canal, on the construction of a third set of locks (estimated to cost $350,000,000). He was responsible to the chief engineer for coordination of all construction operations, procurement and delivery of materials, cost estimates, engineering reports, construction planning, review of all plans and specifications, and the supervision of safety.

In August, 1943, he joined the United States Army and was commissioned a Captain, serving as a public works and utilities specialist in the division of military government. He first reported to Camp Custer, Mich., and then went to Yale University in New Haven, Conn., for military government training. He was sent overseas in January, 1944. When he died, he was in Alsdorf, Germany, installing a sanitary water system.

Concerning his work, Maj.-Gen. L. S. Hobbs said the following of Captain Olsen in awarding him, posthumously, the Bronze Star Medal:

> "Captain Olsen distinguished himself by outstanding performance of duty as a public utilities specialist during a difficult period of military operations. His soldierly attributes and demonstrated fortitude in the face of handicaps have been decided factors in successfully accomplishing in a superior manner all tasks assigned him. His coolness under fire, de-

> votion to duty, and loyalty to his leaders have contributed to the combat achievements of his unit and are worthy of emulation by his associates."

Captain Olsen also received the Purple Heart on January 22, 1944.

On August 7, 1926, in Iowa City, Iowa, he was married to Lora Bernice Duncan. He is survived by his widow; a son, Arthur K. Olsen, Jr.; his mother; and a sister, Mrs. Lucy Augustson.

Captain Olsen had the faculty of drawing people around him. He had a great sense of humor and was well liked by every one who met him. The men who worked with him had a great deal of admiration and respect for him and they found him always ready and willing to listen to their problems and help out wherever he was able.

While Captain Olsen resided at Creston, he was president of the Rotary Club and the Chamber of Commerce, chairman of civilian defense, district leader of the Boy Scouts, and a member of the First Presbyterian Church. He belonged to Scabbard and Blade, Theta Tau, and Phi Alpha Upsilon.

Captain Olsen was elected a Member of the American Society of Civil Engineers on May 18, 1943.

SHEPARD BROWN PALMER, M. ASCE[1]

Died August 17, 1945

Shepard Brown Palmer, the son of Benjamin H. and Eliza (Brown) Palmer, was born in Norwich, Conn., on January 23, 1871. He went to the local schools and was graduated from the Norwich Free Academy. He attended Worcester Polytechnic Institute at Worcester, Mass., being graduated in June, 1894, with the degree of Bachelor of Science in Civil Engineering.

Following his graduation he was employed by Charles E. Chandler of Norwich, in a general engineering capacity. In 1897, the firm of Chandler and Palmer was formed; he was a partner in the firm until the time of his death. In the early days of the firm, Mr. Palmer had charge of design and construction of sewer systems for Taftville, Jewett City, Danielson, and Wauregan—all in Connecticut. He also made preliminary surveys for trolley lines from Norwich to Jewett City and from Norwich to Westerly, R. I. For many years he acted as engineer for the Water Department of Norwich; and under his direction the dam and pipe line to Stony Brook reservoir was constructed in 1909. In 1926, the Deep River reservoir and pipe line was constructed for the department; this represented an investment of about $1,000,000. As city engineer for many years he had charge of important municipal work including the widening of many important and congested city streets.

During World War I, Mr. Palmer acted as engineer for a Federal Housing Project at Newport and at Jamestown, in Rhode Island.

---

[1] Memoir prepared by Benjamin H. Palmer, M. ASCE.

He was considered an authority in the hydraulic field, and he served the state of Connecticut for many years as a member of the board having supervision of dams and structures. All dams and hydraulic structures in eastern Connecticut were inspected and approved, as to detail, by him.

A man with many civic, as well as business interests, Mr. Palmer gave much time to outside affairs. He served as director and chairman of the board of The Dime Savings Bank. He was a member of the Advisory Board of The Hartford-Connecticut Trust Company, director of The Norwich Water Power Company, and president of The New London County Mutual Fire Insurance Company.

Mr. Palmer served as president of The Norwich Free Academy Board for fifteen years, member of the Backus Hospital Advisory Board, and president of The Johnson Home. He was elected a member of the Connecticut Society of Civil Engineers in 1895, was president in 1910, and made an honorary member in 1935. He was a member of the Central Baptist Church of Norwich.

He is survived by his widow; two daughters, Sybil C. Palmer (Mrs. George P. Bellos) and Clara Palmer (Mrs. Harold Kranz); and a son, Shephard B. Palmer, who is also an engineer.

Mr. Palmer was elected a Member of the American Society of Civil Engineers on April 4, 1911. He became a Life Member in January, 1942.

HARRY THOMAS PATERSON, M. ASCE[1]

Died January 1, 1943

Harry Thomas Paterson was born in Newport, Ky., on September 7, 1874. He was the son of William Alexander and Alice (Clemens) Paterson. After graduation from high school in his native city he studied engineering from 1892 to 1895 at Rose Polytechnic Institute in Terre Haute, Ind., where he became a charter member of the Beta Upsilon Chapter of the Sigma Nu fraternity. Ill health forced him to leave college before graduation, but in 1896–1897 he took a special course at the Missouri School of Mines and Metallurgy at Rolla, Mo. From November, 1895, to January, 1898, with exception of the period spent at Rolla, he was employed in Colorado Springs, Colo. Here Mr. Paterson worked in the office of E. A. Sawyer, city engineer, first as draftsman (November, 1895, to March, 1896) and then as superintendent of construction on eighteen miles of ditch for placer mining (May, 1896, to November, 1896). From May, 1897, to December, 1900, he was principal assistant, assistant engineer, assistant superintendent, and chief engineer of the Colorado Springs Rapid Transit Railway Company. From January 1, 1901, to January 1, 1902, he was deputy county surveyor, El Paso County, Colorado, and from February, 1902, to October, 1902, draftsman, leveler, and transitman for the Denver and Rio Grande Railroad Company.

---

[1] Memoir prepared by George H. Maurice, M. ASCE.

In October, 1902, he entered the United States Government Service, and remained in government employment, under various departments, until his death. His first assignment, under the U. S. Reclamation Service, was as assistant engineer, afterward as topographer until May, 1903. During this time he traveled more than two hundred miles along the Colorado River in a row boat, from a point near the present Boulder Dam, in Arizona-Nevada, to Yuma, Ariz. Mr. Paterson was also in charge of parties on surveys near the towns of Reno and Fallon in Nevada, and from May to October, 1904, of road construction in Shoeshone Canyon, Wyoming. From November, 1904, to January, 1907, he was resident engineer in charge of location and construction of 114 miles of laterals and ditches and the construction of Hondo Reservoir, New Mexico. Mr. Paterson had the responsibility for the completion of the Hondo Reservoir after May, 1905, and design and construction of three headgates and takeouts on the distribution system. The month of January, 1907, and subsequent winter months he spent in a tent camp near Malta and Great Falls, Mont., with the thremometer frequently reaching 30° below zero. He decided to seek a warmer climate, and in July, 1907, obtained a transfer to the U. S. Engineer Department with headquarters at Wilmington, N. C. His first assignment was the survey and construction of the Inland Waterway from Neuse River to Beaufort Harbor, including triangulation, survey, location, plans, estimates, and specifications for the waterway and a steel drawspan highway bridge. In 1910 he was placed in charge of eleven river and harbor works in the northern portion of the district, with headquarters at New Bern, N. C. With the closing of the New Bern office in 1932, he was recalled to the Wilmington office, and resided in Wilmington until his death on January 1, 1943.

On December 11, 1909, he was married to Loula Burroughs McConchie, of Fredericksburg, Va. Mr. Paterson had three sons, Harry T., Jr., William Alexander, II, and Robert Clemens, who, with Mrs. Paterson, survive him.

The outstanding feature of Mr. Paterson's nonprofessional life was his love of fraternal activities and the resulting associations and interests. His brilliant Masonic career began on November 10, 1900, when he became a member of El Paso Lodge No. 13, F. and A. M., at Colorado Springs, Colo. His early work in sparsely settled sections of the West prevented much activity in Masonry until he moved to North Carolina in 1907. Since then he had advanced through all degrees to the Thirty Third having filled many honorable offices in all of them, and was Grand Master in North Carolina in 1938. He became a member of Oasis Temple in 1911 and was a charter member of Sudan Temple in 1914. He was also active in the Benevolent and Protective Order of Elks which he joined in 1901, and was past president of the North Carolina State Elks Association. He was a member of the North Carolina Society of Engineers, which he joined in 1939, and a member of the Wilmington Engineers Club.

Among his associates he was known as a man of wide experience, marked ability, and high integrity. He was modest and retiring and of a cheerful disposition, making friends easily. He was a Presbyterian and had long been a member of the First Church in Wilmington. His early religious training was influenced by his paternal grandmother who had been a childhood playmate of David Livingston, the great Scottish explorer and missionary.

Mr. Paterson was elected an Associate Member of the American Society of Civil Engineers on February 3, 1904, and a Member on May 4, 1909.

JASPER MARION PHILLIPS, M. ASCE[1]

Died December 22, 1944

Jasper Marion Phillips was one of a family of nine children. He was the son of Thomas Wiley and Quintinia (Lane) Phillips and was born in St. Clair, Hawkins County, Tenn., on September 25, 1863. He received his high school education at St. Clair, and was graduated in 1880. He attended the military academy at Knoxville, Tenn., in 1881 and the Tusculum College at Jonesboro, Tenn., in 1882.

He then spent a year wandering about in the western states doing miscellaneous work, and, in 1884, he returned to Tusculum, entering the employ of the city engineer. About a year later he was appointed city engineer. In 1886 he worked for the Charleston, Cincinnati and Chicago Railway, first as leveler, then as transitman, and, in 1888, in charge of some location and construction. In 1889 he entered private practice in Johnson City, Tenn. Then from 1890 to 1892 he was with the Embreeville (Tenn.) Freehold Land and Iron Company. He left the Embreeville Freehold Land and Iron Company to serve with various southern and midwestern railways and, from 1899 to 1902, inclusive, he was chief engineer of the Louisiana Railway and Navigation Company. During this period he was in charge of the construction of 160 miles of railway. He then served on location and reconnaissance, and was in charge of construction on the Chicago Great Western, The Tidewater, and the Alberta and Great Western railways. He was employed by the Great Northern Railway in 1909, remaining most of the time until May, 1913. During this period he was engaged on location, construction, and reconnaissance, including surveys for extensive line revisions. Before and after working with the Great Northern Railway he was, at various times, with the firms of Waddell and Hendrick, and Howard and Ash. In 1915 he was engaged in exploration and reconnaissance for a railway in the Dominican Republic and Haiti, and then did miscellaneous railway work in the south and west. In 1920 he practically retired to make his home with his father and mother in Wichita, Kans.

During the next few years he worked at a number of short jobs but spent most of the time with his parents. He was extremely fond of them and devoted his time to them until they died in 1928 and 1929. In 1930 he moved to Port Isabel, Tex., where he lived until just before his death. During his residence in Port Isabel he did some local work, but his health was failing to such an extent that he lived in practical retirement.

---

[1] Memoir prepared by Oscar S. Bowen, M. ASCE.

Mr. Phillips spent a roving life. He was passionately fond of the out of doors, and a large part of his active life was spent in camp, mainly on railway work. In his wanderings he covered a good part of the United States. He was a great reader, had a splendid memory, was very fond of people, made friends wherever he was, and, with his wide travel experience, he was a most interesting companion. He contributed liberally to the training of younger men working under his supervision. He took a great interest in, and was very popular with, young people, enjoyed associating with them and helping them with their problems. Mr. Phillips never married and is survived by only one near relative, a brother, H. G. Phillips. He was a Thirty-Second Degree Mason and was very active in the lodge.

Mr. Phillips was elected a Member of the American Society of Civil Engineers on July 2, 1913.

STEUART PURCELL, M. ASCE[1]

Died April 18, 1946

Steuart Purcell, the son of William H. Purcell of Dublin, Ireland, and Mary Steuart Purcell of "Holly Hill," Anne Arundel County, Maryland, was born in Dublin on February 22, 1878. Although his father was Irish, through his mother, he was a direct descendant of the Lords Baltimore. When he was three years old, his parents came to the United States and settled in Baltimore, Md. He was educated in the public schools of Baltimore, being graduated from Baltimore City College in 1897. In 1901 he received the degree of Civil Engineer from Cornell University in Ithaca, N. Y.

Shortly after graduation, he entered the employ of the Factory Mutual Fire Insurance Company of Boston, Mass., where he remained for approximately one year. Subsequently, he was employed as office engineer by the S. D. Brady Engineering Company, mining engineers of Clarksburg, W. Va., where he remained for a few months. In the early part of 1903 he entered the employ of the Pennsylvania Railroad Company, which was at that time just beginning its improvement program in Washington, D. C. He served as levelman, transitman, and as assistant to the resident engineer on the construction of tunnels, bridges, freight yards, and brick and steel warehouses until the completion of this program in 1910. In November, 1910, he entered the employ of the City of Baltimore, where he was employed in various capacities, from draftsman to chief engineer. His service to the City of Baltimore covered a total of thirteen years.

Just prior to World War I, he served as superintendent of assembly for the Gathmann Ammunition Plant in Texas, Md. In June, 1917, he enlisted in the U. S. Army Engineers, serving for two years as Captain. After the war, he was in the Reserve Officers Corps, earning his commission as Major.

In 1927 he was appointed a member of the Public Service Commission of Maryland, on which he remained until his death—for the last five years as chairman. No other member of the Maryland commission ever served for such a length of time.

---

[1] Memoir prepared by Paul L. Holland, M. ASCE.

Few men have been appointed to regulatory commissions who have had more varied and suitable engineering training than had Steuart Purcell, who was known throughout the state as "Major." Few men have enjoyed greater respect and esteem from utilities and their customers alike.

On September 14, 1901, in Baltimore, Major Purcell was married to Julia Eichelberger. He is survived by his widow; two daughters, Penelope Purcell and Mary (Mrs. G. Richard Purdy); two sisters, Eleanor Purcell and Mary Steuart Purcell; and a granddaughter, Cary Glenn Bruton. A daughter, Hannah Cary (Mrs. C. Glenn Bruton), died in 1929, and a son, William H. Purcell, died in 1945.

Mr. Purcell was elected an Associate Member of the American Society of Civil Engineers on October 10, 1916, and a Member on October 21, 1924.

RAMON RAMOS CASELLAS, M. ASCE[1]

Died August 3, 1944

Ramon Ramos Casellas was born on October 6, 1880, at Manati, Puerto Rico. He was the son of Judge Juan Ramon Ramos and Rosa (Casellas) Ramos. He attended local schools and later the Institute of Secondary Education of Puerto Rico at San Juan, Puerto Rico, from which he was graduated with the degree of Bachelor of Arts in 1898.

Since Puerto Rico had become a possession of the United States in 1898 as a result of the Spanish-American War, to become proficient in the language of his new country, Mr. Ramos attended Matawan Military Institute at Matawan, N. J., during 1900 and 1901, where he studied special subjects in the English language. In 1905 he received the degree of Civil Engineer from Rensselaer Polytechnic Institute at Troy, N. Y.

Soon after graduation he was appointed city engineer of Arecibo, Puerto Rico, continuing in this position until 1915. For that city he built the first concrete streets in Puerto Rico. In 1915 Mr. Ramos became connected with the Insular Department of the Interior where he was, successively, resident engineer in charge of road maintenance for the district of Arecibo, chief of the Division of Roads and Bridges, and chief of the Division of Municipal Works.

His executive ability in government service attracted attention; and, in 1920, he was asked to take charge, as general manager, of the interests of Mario Mercado e Hijos, an association owning a sugar mill, Central Rufina, and a large area of some of the best sugar cane lands in the southern part of Puerto Rico. During his management, which lasted until 1927, the organization prospered considerably. From 1927 to 1930 he was general manager for Benitez Sugar Company and J. J. Benitez e Hijos, two concerns owning and operating a sugar mill and an extensive sugar cane estate in Vieques, a small island just east of the main island of Puerto Rico.

---

[1] Memoir prepared by Rafael A. González, M. ASCE.

Management of the two mills and the attached cane lands gave Mr. Ramos the opportunity to acquire a thorough knowledge of the sugar industry. This, coupled with his intense devotion to the interests confided to him, no doubt led to his selection as secretary of the Association of Sugar Producers of Puerto Rico, which has as members most of the sugar mill owners of the island. He held this position from 1930 until his death. During this period the sugar industry, by far the most important source of income to Puerto Rico, was attacked strongly by a large section of the public and became subject to increasing restrictive legislation aimed at obtaining an equitable distribution of the sugar income between the mill owner, the cane planter, and the laborer and, thus, at helping to solve the distressing economic situation of the great mass of the people. In 1941 the movement culminated in the passage by the legislature of the "Land Law of Puerto Rico," whereby the ownership by a sugar mill of more than 500 acres of land was declared illegal. It became Mr. Ramos' duty to present the case and to argue in favor of the sugar industry, in the press, at public hearings, before the insular government, and in Washington, D. C. This he did nobly, with intense loyalty, great courage, and thorough knowledge of the economic and operating phases of the industry as well as of its relative position in the economic and social structure of the island. However, his was a losing battle, as the wave of social and economic reforms moved forward. A prolonged illness gradually undermined his health during the last few years.

Mr. Ramos was noted for his personal honesty and straightforwardness. He was kind to his fellow engineers, particularly to the young members of the profession whom he liked to encourage.

He was a member of the Sigma Xi and Phi Sigma Alpha fraternities, Sociedad de Ingenieros de Puerto Rico, American Chemical Society, Society of American Military Engineers, American Society for the Advancement of Science, International Association of Sugar Technologists, and Association of Sugar Technologists of Puerto Rico.

In October, 1906, he was married to Mary Alice Plunkett, who survives him, together with a son, Ramon. Another son, Jorge Eduardo, died on February, 24, 1934.

Mr. Ramos was elected a Member of the American Society of Civil Engineers on October 10, 1927.

JOHN MARSHALL RIBBLE, M. ASCE[1]

DIED JUNE 23, 1945

John Marshall Ribble was born at Culpepper, Va., on May 9, 1900. He was the son of Dr. Frederick Goodwin Ribble, Dean of the Bishop Payne Divinity School, and Caroline Stribling (Marshall) Ribble, great-granddaughter of Chief Justice John Marshall of the United States Supreme Court. The antecedents of both families came to America before the Revolutionary War and, in both instances, settled in Virginia.

---

[1] Memoir prepared by Howard L. King, M. ASCE.

John Ribble received his grammar school and high school education in Virginia. He attended Virginia Military Institute at Lexington and was graduated with the degree of Bachelor of Science in 1921. He received the degree of Civil Engineer in 1928, after completion of the requirements for the practice of engineering and after the submission of a thesis based on the subway construction on which he had been engaged.

His first five years after leaving college were spent on highway construction in his native state where he worked first as a laborer, then as an instrumentman with the State Highway Department, and, later, as junior highway bridge engineer with the United States Bureau of Public Roads. Turning from employment under a state or federal body, he took a position as engineer and concrete superintendent with the Robert Martin Company, a Virginia railroad contractor, thereby acquiring some knowledge of the contractor's viewpoint as distinguished from that of the owner.

At Virginia Military Institute, John Ribble had been a classmate of Sam A. Mason, a nephew of Silas B. Mason, the head of a company that had done much construction in Virginia, West Virginia, and Kentucky. Sam Mason later became president of the Silas Mason Company and, in 1926, invited Mr. Ribble to come to New York, N. Y., to take a position as field engineer on a contract to build a section of the new city subway, deep in the rock of upper Manhattan Island.

At the time that this work was nearing completion, the Silas Mason Company and its affiliate, the Mason and Hanger Company, were starting the construction of two subway tubes from the vicinity of St. Paul's Churchyard in lower Manhattan, east on Fulton Street to the river, under the East River and east on Cranberry Street, Brooklyn, to Borough Hall. This was a $22,000,000 contract; much of the work was to be done by the shield method under compressed air. The scope, hazard, and difficulty of the undertaking called for contracting ability and courage. The contractors chose John Ribble as field engineer on the Brooklyn half of the work.

The underriver part of the work was done under compressed air, and, in accordance with the custom of subaqueous work, it was prosecuted twenty-four hours a day, six days a week. The challenge of the magnitude of the work and the exacting standards of engineering and construction that were necessary to secure safety in the work and permanence and quality in the completed structure appealed to John Ribble and he gave his best to the job. He reported directly to George B. Montgomery—he could have had no better teacher. From the early and primitive days of the Hudson and Manhattan tubes, Mr. Montgomery had been a foreman or superintendent on nearly every subaqueous tunnel job under the Hudson River or the East River—he knew the way of a shield as few men ever have.

A construction engineer has to move to new locations as new work presents itself. John Ribble's next task was as superintendent on the construction of a large sewer tunnel in the city of Philadelphia, Pa.—also a compressed-air job. After this, he went to Boston, Mass., where the Silas Mason Company had obtained a contract to build a vehicular tunnel under the harbor connecting the north end of the City of Boston with the City of East Boston, Mass. On this work, he stepped over from the field of engineering to that of actual supervision of the construction force; he was the superintendent on one of the three shifts, this job, like most tunnel jobs, having been carried through all the hours of the day. Each tunnel job has its own peculiar quality; the Boston-East Boston tube is the only compressed-air tunnel job on record where the excavated material was conveyed on a belt from the face back through the locks to the construction shaft.

In 1933 and 1934, there was an interlude in tunnel work and Mr. Ribble returned to Virginia as chief engineer for the state on the program of the Civil Works Administration, working with Dean James A. Anderson, M. ASCE, of Virginia Military Institute, who was on leave from the Institute to guide the state's participation in the federal government's program.

Returning to New York in 1934, Mr. Ribble rejoined the Mason and Hanger Company. This company was about to build the south tube of the Lincoln Tunnel through the silt that underlies the Hudson River. When the excavation of this tunnel was completed, he went to work as chief engineer for the Rosoff Tunnel Corporation on the construction of six miles of the Wards Island Sewer.

In 1939, he returned to the employ of Mason and Hanger. The company was just beginning work on the construction of Merriman Dam near Ellenville, N. Y., an important part of the new Delaware Aqueduct project of the Board of Water Supply of the City of New York. The Merriman Dam undertaking included a rock shaft, one thousand feet deep, two miles of rock tunnel, and a long line of concrete caissons to be sunk under compressed air to form a cutoff wall under the rolled earth dam. Mr. Ribble began as job engineer and was later advanced to the position of job manager. After the attack on Pearl Harbor, Hawaii, on December 7, 1941, the construction of the dam was slowed down and later stopped altogether to give preference and priority to war projects. In September, 1942, Mr. Ribble who had had a commission in the Reserve joined the Army as a Captain of Engineers. In June, 1943, he was promoted to the rank of Major and in September, 1944, he was made a Lieutenant Colonel.

Captain Ribble was assigned to the Army base in Anchorage, Alaska, where he was Assistant to the Chief of Operations and was concerned with the building of airfields, docks, and other facilities for the use of the rapidly increasing armed forces in Alaska and the Aleutians. The secrecy of these undertakings forbade his writing home much about his activities. Ordinarily a good letter writer, he was restrained from telling much of a story. The long winter darkness and the incessant fog were more of a hardship than the cold. In March, 1945, he was assigned to the Office of the Chief of Engineers in Washington, D. C., where he was engaged in the handling of engineering equipment for lend-lease to our allies. Colonel Ribble died suddenly on June 23, 1945, at Glendale, Markham, Va.

John M. Ribble's engineering career did not encompass many years but he played a leading part on a number of large contracts. Probably his highest ability lay in supervising the work of others in actual construction. When he went into the Army, he had already acquired something of a reputation as a tunnel superintendent. He commanded the respect of those who worked under him because he was courageous and forceful by nature and straightforward in his dealings. He had learned the fundamentals of his chosen field by many years of intimate contact and association with the men who actually did construction work; from their fund of experience he was always ready to learn. He was the possessor of a playful and unobtrusive sense of humor that did not invite attention to itself but made him a good companion.

John Ribble was married to Anne Jeter in Jacksonville, Fla., on September 26, 1941. He is survived by his widow; his brother, Frederick Deane Goodwin Ribble; and four sisters, Mildred S. Ribble, Frances Le B. Ribble, Elsie Sylvester Ribble (Mrs. J. D. McCarty), and Caroline Marshall Ribble (Mrs. J. R. Green).

Mr. Ribble was elected an Associate Member of the American Society of Civil Engineers on November 15, 1926, and a Member on February 13, 1945.

HOLTON DUNCAN ROBINSON, M. ASCE[1]

Died May 7, 1945

Holton Duncan Robinson, the son of Ichabod Harvey and Isabelle (McLeod) Robinson, was born on February 7, 1863, at Massena, N. Y., of Scotch-English ancestry. One of his ancestors was Sir Alexander Mackenzie, a pioneer Canadian explorer, for whom the Mackenzie River was named. The Robinson farm was on the shore of Robinson Bay in the St. Lawrence River. In the bitter winters of the "North Country," with their icy winds and the resulting frozen ears, the boy developed a wiry physique and a hardihood to physical exposure. His one difficulty was a shyness in meeting people; in his childhood days, when his cousins came to visit him, he would hide under the bed. He was outstandingly shy, modest, and retiring; and he carried these characteristics through life.

Following country schooling in the district school and high school at Massena, he studied hard to pass the entrance examinations for St. Lawrence University at Canton, N. Y., from which he was graduated with the degree of Bachelor of Science in 1886. He always retained a certain modesty about his college education, because he specialized in liberal arts and sciences and not strictly in engineering. However, he obtained a sound foundation for his later career.

Mr. Robinson received his start and his direction in engineering through his uncle, George W. McNulty, bridge builder, who was associated with Leffert L. Buck,[2] both Members, ASCE. These men in turn had received their start and training under Col. Washington Roebling on the construction of the Brooklyn Bridge in New York, N. Y. In August, 1886, directly after graduation, young Robinson entered the employ of Buck and McNulty, civil engineers, in New York, as a chainman and rodman, and began studying engineering at home. Until July, 1887, he was employed on the construction of ferry terminals, docks, elevated railroad extensions, etc. He was then sent by his employers, Buck and McNulty, to the Rochester Bridge and Iron Works, at Rochester, N. Y., to learn shop inspection and to inspect the shopwork on a ten-span bridge for the Northern Pacific Railway Company (Columbia River Bridge at Pasco, Wash.). While at Rochester, young Robinson also inspected the shopwork on the Niagara Falls (N. Y.) and Clifton Highway Suspension Bridge (erected in 1888).

---

[1] Memoir prepared by D. B. Steinman, M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXIII, September, 1911, p. 493.

He returned to New York City in May, 1888, and entered the employ of Mr. Buck—the association of Buck and McNulty having been terminated. He was employed on computations and drawings for various bridges, including the plans for the Driving Park Avenue Bridge over the Genesee River at Rochester. This bridge (still standing after fifty-six years) included a main spandrel-braced, three-hinged arch of 416-ft span. In July, 1889, he went to Rochester for Mr. Buck and took charge of construction of the arch bridge as assistant engineer. His duties included masonry inspection and shop inspection of the structural work at the Rochester Bridge and Iron Works. Mr. Robinson returned to New York in March, 1890, and was employed on the design of bridges and other structures until the end of that year. Then he was sent to Suspension Bridge (near Niagara Falls), N. Y., to take charge of repairs on the stiffening truss of the Niagara Railway Suspension Bridge built by John A. Roebling,[3] M. ASCE, and opened to traffic in 1855. He served about six weeks on the repairs and then, in February, 1891, he returned to New York City and entered the employ of the Broadway and Seventh Avenue Cable Railway Company, on surveys and design of special trackwork under Mr. McNulty, who was chief engineer. In September, 1891, Mr. Robinson was offered a position as draftsman and assistant engineer in the bridge department of the chief engineer's office of the New York Central and Hudson River Railroad Company. In August, 1895, he resigned to accept a position as chief draftsman, under Mr. Buck (the chief engineer), on the New East River Bridge Commission, preparing the plans for the Williamsburg Bridge in New York.

In 1899 he was appointed assistant engineer in charge of cable construction on the Williamsburg Bridge, and remained in that position until July, 1903, when he was appointed engineer in charge of all construction work on the bridge by the Commissioner of Bridges for the Greater City of New York, Gustav Lindenthal,[4] Hon. M. ASCE. Mr. Robinson remained in charge of the construction of the Williamsburg Bridge until it was opened for highway traffic in December, 1903, and thereafter until March, 1904, when he was transferred and placed in charge of design and construction of the Manhattan Bridge, reporting to the chief engineer of the Department of Bridges of the City of New

---

[3] For memoir, see *Transactions*, ASCE, Vol. 98, 1933, p. 1614.

[4] For memoir, *ibid.*, Vol. 105, 1940, p. 1790.

York, O. F. Nichols,[5] and his consulting engineer, R. S. Buck, both Members, ASCE. He remained in charge of this work until July, 1907, when he resigned to accept the position as chief engineer of the Glyndon Contracting Company, a subsidiary of the Carbon Steel Company, contractor for the construction of the main cables of the Manhattan Bridge in New York. He designed the footbridge, machinery, and plant used in the construction of the four 21-in. cables, which were larger than any previously built.

During the three years with the Glyndon Contracting Company, Mr. Robinson made a proposed suspension bridge design for the crossing at Quebec, Que., Canada, working for the Dominion Bridge Company of Montreal, Que., Canada. He made plans for a combined aqueduct and highway suspension bridge for the proposed crossing of the Hudson River at Storm King, and also was employed part of the time (for the contractors) on the construction of a section of the new Catskill Aqueduct, including one rock and earth tunnel, 6,150 ft long and a rock tunnel, 400 ft long.

He resigned as chief engineer of the Glyndon Contracting Company in June, 1910, and took the contract on his own design to build a highway suspension bridge with a main span of 400 ft and side spans of 100 ft each for his native town, over the Grasse River at Massena Center, N. Y. When the lowest bid was $60,000, Mr. Robinson stated that he could build the bridge himself for $40,000—and he did it. He completed this work in January, 1911, and returned to New York. In 1911 and 1912 he estimated and bid for various contracts, and received the contract for the installation of nine miles of 1,000,000-cm weather-proofed feeder cable and accessories on the Manhattan Bridge; this work was completed in the summer of 1912.

In October, 1912, he entered the employ of Mackenzie and Mann as engineer of design of the Mount Royal Tunnel and Terminal Company. In the spring of 1913 he was also appointed consulting bridge engineer of the Canadian Northern Railway Company on the Eastern Lines from Port Arthur, Ont., to St. Johns, Que., Canada. He resigned from the service of Mackenzie and Mann in the spring of 1914 to take charge of the work of third-tracking and other improvements for the contractor on the Manhattan Elevated Railway in New York City. This work included the replacement of the old Harlem River double-track bridge by a new four-track, double-deck bridge, all floated into place on scows and lowered by sand jacks devised by Mr. Robinson—a method that had never before been used. He completed this work at the end of 1916.

During World War I, in October, 1917, Mr. Robinson entered the employ of the Bureau of Yards and Docks, U. S. Navy, as a supervising engineer on plant extension work for war purposes, and remained with the department until December, 1919.

In the spring of 1920, when the writer was head of the engineering school at the College of the City of New York, he received a telephone call from a man who modestly introduced himself as H. D. Robinson. In the subsequent conference, Mr. Robinson invited the writer to join him in preparing a competitive design (in a world-wide competition) for the proposed bridge at Florianópolis, Brazil. This joint effort, which later (1926) culminated in successful achievement, was the beginning of an association that lasted through the years. With no agreement in writing, the simple and flexible relationship developed into a lasting friendship and partnership, based on mutual confidence and esteem.

---

[5] For memoir, see *Transactions*, ASCE, Vol. LXI, December, 1908, p. 564.

In 1920 Mr. Robinson prepared for Daniel E. Moran,[6] and William H. Yates, both Members, ASCE, the plans for a 705-ft suspension bridge over the Rondout River, at Kingston, N. Y. This was the first suspension bridge designed to carry a concrete floor and to have continuous (hingeless) stiffening trusses. The writer was retained independently by Mr. Yates to calculate the stresses and the sections. In 1920 and 1921 Mr. Robinson was in charge of construction as consulting engineer to the contractor on this work.

During 1921 the writer opened his own engineering office and, subsequently, invited Mr. Robinson to share it. Previously Mr. Robinson's office had consisted of a drafting table in his home, where he did all computing and drafting himself. He would solve difficult three-span catenary problems by suspending a fine chain against the wall and measuring the ordinates.

Effective July, 1922, Mr. Robinson was appointed consulting engineer on cable construction by the Joint Commission on the Delaware River Bridge (between Camden, N. J., and Philadelphia, Pa.). He was asked whether it would be possible to build cables 30 in. in diameter so the construction could be simplified from a four-cable layout to a two-cable design. The largest cables (on the Manhattan Bridge) previously built had been only 21 in. in diameter. Mr. Robinson replied that 30-in. cables could be built and that he was prepared to build them. In August, 1923, after the plans were completed, he resigned to work for the contractors, the Keystone State Construction Company, first on the preparation of the bid and then as consulting engineer on the construction of the cables. All the equipment for the cable construction (including the footbridges, storm cables, spinning machinery, squeezing machines, and wrapping machines) was designed in the Robinson and Steinman office. On this job were used, for the first time, the "flat-band seizings" invented by Mr. Robinson to shorten the time required for the construction of large bridge cables. In March, 1926, at a joint meeting of the Franklin Institute and the Philadelphia Section of the Society, he presented a paper on "Construction of the Cables of the Delaware River Bridge."[7] This was Mr. Robinson's first technical paper; he suffered excruciatingly from stage fright and the experience so unnerved him that he vowed he would never repeat it.

From 1923 to 1924 Mr. Robinson was retained as consulting engineer on the cable construction of the Bear Mountain Bridge at Bear Mountain, N. Y., and on the preliminary plans (by Ralph Modjeski,[8] M. ASCE, and Mr. Moran) for the Mid-Hudson Bridge at Poughkeepsie, N. Y.

Beginning in 1920, the firm of Robinson and Steinman completed many interesting and notable bridge engagements during the twenty-five years of partnership, including the design and construction of the Florianópolis Bridge in Brazil; the General U. S. Grant Bridge over the Ohio River at Portsmouth, Ohio; the Mount Hope Bridge in Rhode Island; the Sparrows Point (bascule) Bridge in Baltimore, Md.; the bridges of the Cochabamba-Santa Cruz Railway in Bolivia; the Bayhead (movable draw) Bridge at Point Pleasant, N. J.; the Grande Mère Bridge across the St. Maurice River in Quebec Province, Canada; the Waldo-Hancock Bridge across the Penobscot River in Maine; the Verona Island Bridge in Maine; the St. Johns Bridge in Portland, Ore.; the Sky Ride and Observation Towers at Chicago, Ill.; the Henry Hudson Bridge in New York, N. Y.; the Thousand Islands International Bridge (five bridges) over the St. Lawrence River; the Sullivan-Hutsonville Bridge over the Wabash River between Indiana and Illinois; the Madison Avenue Bridge at Elmira, N. Y.; the Marine Parkway Bridge (continuous truss approach spans) at Rockaway, N. Y.; the Paerdegat Basin Bridge in Brooklyn, New York; the Deer Isle Bridge in Maine; and the Charter Oak Bridge over the Connecticut River at Hartford, Conn. The firm was engaged on the strengthening or reconstruction of the Steubenville Bridge, the East Liverpool Bridge, the Wheeling Bridge, the Marietta Bridge, and other bridges over the Ohio River; the Hackensack River Bridge in New Jersey; the Southside Bridge over the Kanawha River at Charlestown, W. Va.; the McGregor Bridge at Manchester, N. H.; and many others. It was also retained on the construction of the Ambassador Bridge at Detroit, Mich.; the Triborough, the George Washington, and the Bronx-Whitestone bridges at New York, N. Y.; the Rip Van Winkle Bridge over the Hudson River at Catskill, N.Y.; the Transbay Bridge at San Francisco, Calif.; the Lions' Gate Bridge at Vancouver, B. C., Canada; the Maumee River Bridge at Toledo, Ohio; the Ile d'Orleans Bridge over the St. Lawrence River in Canada; and others. In 1923–1924 the firm was retained to prepare an alternate design for the Sydney Harbor Bridge in Australia; in 1927 for the Cologne-Mühlheim Bridge over the Rhine River in Germany; and in 1928, for the Lillebaelt Bridge in Denmark. The firm served as consultants on the design of the Topeka Avenue Bridge in Topeka, Kans.; the Coolidge Memorial Bridge at Northampton, Mass.; and the bascule bridge at Bilbao, Spain. It also had numerous engagements on inspection, strengthening, traffic analysis, and valuation of various bridges.

---

[6] For memoir, see *Transactions,* ASCE, Vol. 103, 1938, p. 1840.

[7] "Construction of the Cables of the Delaware River Bridge," by H. D. Robinson, *Journal of the Franklin Institute,* Vol. 201, January-June, 1926, p. 735.

[8] For memoir, see *Transactions,* ASCE, Vol. 106, 1941, p. 1624.

Mr. Robinson's inventions in the field of suspension bridge construction include the (hydraulically-operated) cable-squeezing machine, the (electrically-operated) cable-wrapping machine, the flat-band seizings, and a simplified type of cable anchorage. Jointly with the writer, Mr. Robinson developed the Florianópolis type of suspension bridge and a method of preventing aerodynamic instability. As the result of Mr. Robinson's inventions and improvements in the art of cable construction, the time required for building suspension bridges has been enormously reduced. When the Brooklyn Bridge was built, during Mr. Robinson's boyhood, it took twenty-one months to construct the cables. (Each contained only 900 tons of wire.) The required time was progressively reduced, for successively larger cables, to seven months for the Williamsburg Bridge, and four months for the Manhattan Bridge; and in

1939 the Bronx-Whitestone Bridge cables, with 2,000 tons of wire per cable, were completed in only two months.

In 1926 his alma mater, St. Lawrence University, conferred on Mr. Robinson the degree of Doctor of Science, in recognition of his character and achievements. In his modesty, Mr. Robinson always disclaimed this degree as "not earned" and protested when his friends addressed him as "Doctor."

From 1935 to 1937 Mr. Robinson was retained as consultant on the roadway construction for the Williamsburg, Manhattan, and Queensborough bridges over the East River, New York, and during 1944-1945 (to the time of his death) he was consultant on the physical survey of the condition of the Brooklyn Bridge preparatory to its roadway reconstruction.

Even in his last years, Mr. Robinson was active, agile, and fearless in his outdoor work on bridges. He would climb on high steelwork or walk the cables of a suspension bridge with greater ease than most younger engineers. In 1941, during the investigations that followed the Tacoma Narrows (Washington) Bridge disaster, he was retained by the insurance companies, and made a personal examination of the cables of the wrecked structure. Although seventy-eight years old at the time, he calmly walked out over the 17½-in. cables, each 5,900 ft long and 450 ft high at each tower, to examine the condition of the wires and to cut out samples of the wire at midspan. His feat was rendered more difficult and hazardous by the fact that the hand ropes in the main span had been wrecked.

On a bridge construction job, out in the field where the actual erection was being done, Mr. Robinson was happier than anywhere else. He knew the bridgemen and the steel erectors by name, and they knew him. In fact, he felt more at home in their company than in the company of public officials, bankers, and clients. He was thoroughly democratic, and enjoyed the affection and esteem of all who came to know him. He loved his work. A bridge inspection was, to him, a holiday. He would accept such engagements without pay, for the pleasure of doing them; and he would grant the use of his patents for a nominal sum, for the satisfaction of adding another suspension bridge to his list. He was professionally connected with the construction of almost every notable suspension bridge built during his lifetime. This fact was his chief pride.

In 1912, when plans were being prepared for a new suspension bridge over the Rhine River at Cologne, Germany, the authorities called on Mr. Robinson, in the United States, to secure the benefit of his advice and judgment on the most efficient design for that structure, which was completed in 1915. In 1927, when another notable suspension bridge was being planned to cross the Rhine River at Cologne, Robinson and Steinman were retained to prepare a design for that bridge. In 1938 Mr. Robinson made a trip to Sweden to give his consulting services on the construction of an interesting suspension bridge north of the Arctic Circle. The bridge at Florianópolis is the largest bridge in South America and the largest eyebar suspension bridge in the world. The Transbay Bridge connecting San Francisco with Oakland, completed in 1937, at a cost of $78,000,000, the world's greatest bridge achievement, was constructed with the aid of Mr. Robinson's inventions and the firm's consulting services.

Mr. Robinson was enthusiastic about flying. His first air experience was in 1931 when the two partners were taken by Tex Rankin, northwest flying ace, in a stunting plane (with open cockpit) to circle the towers and to fly over and under the newly completed St. Johns Bridge at Portland. This was probably the first time bridge construction received its final inspection from the air, and (on a gusty, rainy day) it was a thrilling experience. Thereafter, Mr. Robinson missed no opportunity to take a plane for his professional trips around the United States. He made numerous transcontinental flying trips in connection with his professional engagements on the Pacific Coast, and he looked forward to them with boyish delight.

Holton Duncan Robinson had many of the finest traits of character, which endeared him to all who had the pleasure of working with him. He was kind, considerate, and generous—almost to a fault. Above all, he was characterized by that genuine innate modesty which is the mark of a truly great man. He was at his office, working, on his eighty-second birthday. The next day he did not feel well—his first illness in a long and active life. Three months later, on May 7, 1945, he passed away.

On June 15, 1893, Mr. Robinson was married to Frank Brown. He is survived by his widow; a daughter, Mary Olivia Robinson; a son, Allan McLeod Robinson; and two granddaughters, Barbara Jean Robinson and Ann Catherine Robinson.

Mr. Robinson was elected a Junior of the American Society of Civil Engineers on March 1, 1892; an Associate Member on January 3, 1894; and a Member on January 7, 1913. He became a Life Member in January, 1929.

ELMER WAYLAND ROSS, M. ASCE[1]

DIED MAY 20, 1944

Elmer Wayland Ross, the son of Erastus Wellington Ross and Hannah (Paine) Ross, was born in Glocester, R. I., on March 3, 1861. His father was a descendant of the Ross family which was one of the early families in Connecticut. His mother was a descendant of Stephen Paine who came to Hingham, Mass., from Great Ellingham, England, on the good ship *Dilligent* in 1638. Later Stephen Paine was one of the men who, under the leadership of Elder Newman, founded Rehoboth, Mass., in 1643.

Erastus Ross was an authority on the subject of weaving and was connected with various textile mills in Rhode Island and Pennsylvania.

Elmer Wayland Ross was educated in the town schools of Warren and Smithfield, R. I., and in the Mowry and Goff Preparatory School in Providence, R. I. He was graduated from the latter school and in June, 1879, entered the City Engineer's Office in Providence as a student engineer.

---

[1] Memoir prepared by Robert L. Bowen, Assoc. M. ASCE.

In March, 1881, Mr. Ross resigned from the City Engineer's Office and was employed by the Conant Thread Company to do engineering work on the construction of a new mill, boilerhouse, and auxiliary buildings by which it was greatly expanding its plant.

In January, 1882, Mr. Ross returned to the City Engineer's Office in Providence where he was destined to spend the remaining years of his professional career. He served in the various departments until May, 1887, when he was appointed assistant engineer in the Bridge Department under William D. Bullock,[2] M. ASCE. He continued in this position for thirty-six years and then in April, 1923, upon the death of Mr. Bullock, he was appointed engineer in charge. Two years later, in April, 1925, he resigned from the City Engineer's Office and retired to private life.

Providence is located at the head of Narragansett Bay. It is bounded on the east by the Seekonk River and is traversed by the Moshassuck and the Woonasquatucket rivers which, flowing together at the center of the city, form the Providence River. These topographic conditions result in a relatively large amount of bridge and harbor work, all of which was designed, constructed, and maintained by the Bridge Department of the City Engineer's Office.

Mr. Ross designed and supervised the construction of twenty fixed-span steel bridges, two swing drawbridges, and two stone arch bridges. A third swing draw span, which he designed, was constructed after he resigned. He also designed considerable lengths of granite masonry river wall, some wharf work, and the first section of the Municipal Dock at Fields Point, which includes a heavy granite quay wall and auxiliary structures.

After retiring to private life Mr. Ross moved to North Foster, R. I., to live on his farm, the ancestral home of the Paine family. Here he took up the work of commercial apple growing and in so doing carried out plans toward which he had been working since boyhood. In this venture he was joined by his son, Donald. They progressively enlarged the orchards which had been started in earlier years, and at the time of Mr. Ross's death were producing, not the largest crops in the state, but some of the finest.

Mr. Ross was in good health, in full possession of all his faculties, and was a delightful companion to the end of his days. He had a keen appreciation of life: He thoroughly enjoyed living and possessed the rare faculty of awakening that enthusiasm in those with whom he was in contact.

In his early days he found time to study art, with particular attention to painting. He was a bicycle enthusiast when the high bicycle was in style and toured many of the eastern states on his "wheel." Genealogy and beekeeping were also among his hobbies.

Mr. Ross was a member of the Boston Society of Civil Engineers, the Roger Williams Association of Rhode Island, and the First Baptist Church in Providence. He was also a member and trustee of the North Foster Baptist Church.

He was married to Adelaide Virginia Drowne, a great, great granddaughter of Dr. Solomon Drowne, famous as a surgeon in the Continental Army during the Revolutionary War and later Professor of Materia Medica and Botany at

---

[2] For memoir, see *Transactions*, ASCE, Vol. 88, 1925, p. 1356.

Brown University in Providence. She died in 1941. Surviving are his daughters, Margaret Drowne (Mrs. Lakes Gill), Esther Winifred (Mrs. William H. Sweetland, Jr.), and Virginia Paine (Mrs. Godfrey Goff); and his son, Elmer Donald Ross.

Elmer Wayland Ross was an able engineer, a good citizen, and above all a true Christian gentleman. His courtesy, his thoughtfulness of others, and his eminent fairness were outstanding characteristics.

Mr. Ross was elected a Junior of the American Society of Civil Engineers on March 5, 1890; an Associate Member on June 1, 1892; and a Member on April 3, 1906.

ARTHUR VALENTINE RUGGLES, M. ASCE[1]

Died October 21, 1945

Arthur Valentine Ruggles was born at Clinton, Mass., on January 23, 1883, the son of Marcus Morton Ruggles and Mary Elizabeth (Burdett) Ruggles. He was a descendent of George Ruggles who was in Boston, Mass., by 1632.

Mr. Ruggles received his early education at Clinton and was graduated from Dartmouth College, Hanover, N.H., in 1902 with the degree of Bachelor of Science.

During his summer vacations from college, Mr. Ruggles received his first engineering experience when he worked as a rodman with the Metropolitan Water Board of Boston on the construction of the Wachusett reservoir. After his graduation from college in 1902, he went to Broklyn, N.Y. From July, 1902, to May, 1904, he served, for short periods of time, as draftsman with the American Bridge Company, E. B. Hyde Company (map publisher), and the Brooklyn Edison Company, all of Brooklyn, and *Engineering News* of New York, N.Y. From May, 1904, until February, 1906, he was associated with Hazen and Whipple, consulting engineers of New York, on the design of filtration plants and on other water supply work.

In March, 1906, Mr. Ruggles became an assistant engineer with the Board of Water Supply, City of New York. His first work with the Board was on the design of the Catskill Aqueduct and Eastview filters. In 1910 he was appointed first assistant to the section engineer on the construction of the Bryn Mawr Steel Pipe Siphon and Yonkers Pressure Tunnel. In December, 1911, he was made assistant engineer for the Department of Water Supply, Gas, and Electricity, City of New York, on the design of a proposed filtration plant at Jerome Park Reservoir for the Croton supply. Mr. Ruggles left the Department of Water Supply, Gas, and Electricity in June, 1913, and for six months was draftsman for the Public Service Commission, 1st District, State of New York.

In January, 1914, Mr. Ruggles went to Cleveland, Ohio, as assistant engineer with the Division of Water, Department of Public Utilities. His first work there was on the design and construction of the $4,000,000 Division Avenue filtration plant and pumping station. Before its completion he was promoted to the position of engineer of construction for this work.

---

[1] Memoir prepared by Ralph E. Boyce, Civ. Engr., Board of Water Supply, City of New York, N. Y.

From September, 1917, to January, 1919, Mr. Ruggles served as Captain in the Engineering Corps of the United States Army. He was with the American Expeditionary Forces in France for one year. For nine months of this time he was first assistant to Maj. J. B. Hawley, in charge of all water supply and sanitation in Base Section 1 at St. Nazaire.

In February, 1919, Mr. Ruggles returned to Cleveland, serving until January, 1925, as engineer of construction and surveys, Division of Water, Department of Public Utilities, and as Commissioner of Water from July, 1922, to February, 1924. During this period as the chief civil engineer he planned, and completed the design and construction of, the Baldwin Fairmount Project (including the 130,000,000 gal covered Baldwin Reservoir, the 165 million gal per day rapid sand Baldwin filtration plant, the 300 million gal per day Fairmount pumping station and several million dollars worth of water mains). The total cost of the project was $15,000,000.

For a short time early in 1925, Mr. Ruggles was associated with R. F. MacDowell, M. ASCE, consulting engineer, Cleveland. From June, 1925, to December, 1927, he was with the United States Cast Iron Pipe and Foundry Company of Burlington, N.J., on sales and engineering work. In February, 1928, he came to New York as civil engineer for the Community Water Service Company.

From October, 1928, until April, 1936, Mr. Ruggles was assistant to the secretary of the American Water Works Association, New York. While serving in this position, he compiled an index to the *Journal* and other publications of the American Water Works Association from 1881 to 1933. During this time he also acted as executive assistant to the chairman of the American Standards Association's Sectional Committee A-21 on Specifications for Cast Iron Pipe and Fittings, of which committee he was one of the most active members. He remained active on the work of the committee until his death.

In November, 1936, Mr. Ruggles returned to the Board of Water Supply, City of New York as assistant engineer designer. From June, 1938, until his death, he was assistant hydraulic engineer of the Water Bureau in the New York Office of the Public Service Commission, State of New York.

Mr. Ruggles was a member of the New England Water Works Association. On September 28, 1943, the Association awarded him the Dexter Brackett Memorial Medal for 1942 for his paper,[2] "Determination by Statistical Methods of the Average Service Life of 6-Inch Cast-Iron Water Mains in Brooklyn, New York." This paper is one of the few on this subject which is one of the bases in the estimating of depreciation of water works properties. Mr. Ruggles was also a member of the Thayer Society of Engineers (Dartmouth College), the Chi Phi fraternity, the Masons, the National Sojourners, and the American Legion.

---

[2] "Determination by Statistical Methods of the Average Service Life of 6-Inch Cast-Iron Water Mains in Brooklyn, New York," by A. V. Ruggles, *Journal* New England Water Works Assn., September, 1942, p. 361.

Those who knew Mr. Ruggles will always remember him for his never failing courtesy, his kindly manner, and his absolute dependability. He never spared himself in his efforts to help others, with the result that associates and subordinates alike knew him to be their friend.

In 1902, he was married to Marion Chellis Nye, and is survived by her.

Mr. Ruggles was elected an Associate Member of the American Society of Civil Engineers on April 30, 1912, and a Member on March 9, 1920.

WILFORD BATES RUSSELL, M. ASCE[1]

Died May 28, 1945

Wilford Bates Russell, the son of Wilbur C. and Roah (Shiffler) Russell, was born on May 30, 1898, at Amboy, Mich. After completing his elementary and high school education at Litchfield, Mich., he entered the College of Engineering at the University of Michigan, at Ann Arbor, and was graduated in 1920 with the degree of Bachelor of Science in Civil Engineering.

After his graduation Mr. Russell entered the employ of the Fargo Engineering Company, at Jackson, Mich., as a draftsman, designer, and surveyor. While affiliated with this firm he was in charge of surveys for the Consumers Power Company on the St. Joseph River and at Niles, Mich. He was also assistant superintendent of construction on the Alcona Dam and Power House built for the same utility.

In June, 1924, he went to Syracuse, N. Y., where he joined David R. Cooper in conducting surveys and making economic analyses of proposed hydraulic engineering projects for the Niagara, Lockport and Ontario Power Company along the Moore and Beaver rivers in the Adirondack Mountains. In January, 1927, Mr. Russell entered private practice as a consulting engineer. In this capacity he continued his field surveys and reporting for the Niagara, Lockport and Ontario Power Company until the job was completed in August, 1928.

Returning to the midwest he accepted a position as engineer with the R. D. Baker Construction Company of Royal Oak, Mich., where he was placed in charge of the estimating and construction of sewers, highways, and dams. Mr. Russell remained with this organization until January, 1933; and then returned to private practice and was engaged by the Peerless Cement Corporation to conduct an appraisal of its plants and properties at Detroit and Port Huron, Mich. In November, 1935, he joined the Peerless organization as chief engineer in charge of all plant engineering and labor relations. In these matters he revealed such outstanding ability that, in April, 1942, he was appointed to the office of vice-president. Quietly and without ostentation he accomplished important tasks. He devoted his fine mind to the betterment of his fellow workers. This was tangibly evidenced by the adoption of the Peerless plan of adjusted compensation, of which he was the author; by his intensive studies of a company pension plan; and by a more effective and satisfactory relationship between the employees and management.

---

[1] Memoir prepared by F. N. Menefee, M. ASCE.

Many outside activities held his absorbed interest. Mr. Russell was an active member of the Society and the Michigan Engineering Society (for several years on its Board of Directors and president during 1943). He was a director and chairman of the Committee on Promotion, on Audits, and on Relationships with the National Society of Professional Engineers, and a member of the Committee on Post Graduate Engineering Studies as well as a trustee of its fund. To the success of each of these organizations he made substantial contributions. He also belonged to the Red Run Golf Club, the Birmingham Golf Club, and the Economic Club of Detroit.

In addition to his professional and business activities, Mr. Russell displayed great interest and talent in other fields. His deep love and appreciation of beauty found expression in the collecting, restoring, and refinishing of fine antique furniture. A splendid craftsman, he took great pride in restoring rare pieces and was considered a local authority in this field. His collection of antique furniture was a source of never-ending enjoyment to him. His other hobbies included stamp collecting and golf.

To those with whom he worked Mr. Russell showed a strength of character and depth of mind not found in ordinary men. His unquestionable ability to perform the tasks to which he set his mind well, his complete honesty in all matters, and his profound respect for honorable conduct—all inspired great trust and confidence among his associates. Capable, efficient, and keenly analytical, he was nevertheless shy and self-effacing. However, so warm and friendly was his personality that it won for him the love and admiration of all who were privileged to know him.

On October 15, 1921, in Ann Arbor, Mich., Mr. Russell was married to Edith Apfel. He is survived by his widow; a daughter, Phyllis; his mother; a sister, Helen Russell; and two brothers, Walter C. and Robert L. Russell.

Mr. Russell was elected a Member of the American Society of Civil Engineers on March 11, 1940.

GEORGE HENRY SAGER, JR., M. ASCE[1]

DIED APRIL 23, 1942

George Henry Sager, Jr., the son of Arthur N. Sager and Elizabeth (Scott) Sager, was born on January 8, 1895 in Yellville, Ark. In 1901 he moved to St. Louis, Mo., where he attended grammar and high schools. He continued his education at Phillips Academy at Andover, Mass. (scientific course), and the Sheffield Scientific School of Yale University at New Haven, Conn. (civil engineering). In 1938 he also studied political science, administration, and city management at the University of Louisville at Louisville, Ky.

---

[1] Memoir prepared by H. E. Whitaker, Vice-Pres. & Chf. Engr., Ford, Bacon & Davis, Inc., New York, N. Y.

Mr. Sager's first employment was with James Stewart and Company, Inc., New York, N. Y., as a junior engineer. In January, 1917, he went into private practice in Kentucky, surveying and mapping for oil companies and others.

During World War I Mr. Sager joined a Red Cross unit formed in Louisville, serving as an ambulance driver in France and later as Sergeant in charge of construction for the U. S. Army Base Hospital No. 40, which included construction of a 60,000-gal activated sludge, sewage-disposal plant near Southampton, England.

From 1919 to 1923 Mr. Sager was field manager of the Allen-McLean Oil Company at Frankfort, Ky. During the following year he was in private practice as general manager of the Sager Construction Company, Monroe, La., supervising the construction of dwellings and two small industrial plants. In 1923 he was employed by the George F. Hardy Company, New York, N. Y., as assistant resident engineer on the construction of the Brown Paper Mill, West Monroe, La. In December, 1924, he joined the forces of Ford, Bacon and Davis, Inc., engineers of New York. From 1924 to 1932 Mr. Sager served in the following capacities on many important commitments:

(*a*) Until December, 1925—field engineer, assistant resident engineer, and superintendent in the construction of a 30,000-kw gas-steam-electric station for the Louisiana Power and Light Company, Sterlington, La.

(*b*) Until April, 1927—assistant engineer to vice-president in charge of surveys, foundation tests, design approach plans, and start of construction on the Lake Pontchartrain Bridge for the New Orleans Pontchartrain Bridge Company, New Orleans, La.

(*c*) Until August, 1928—resident engineer on a 60,000-kw gas-steam-electric station addition to the Louisiana Power and Light Company plant.

(*d*) Until June, 1930—assistant engineer, main office of Ford, Bacon and Davis, Inc., in connection with business reports, valuations, appraisals, estimates, specifications, and design.

(*e*) Until July, 1932—resident engineer in charge of general construction of a 60,000-kw coal-steam-electric station for the West Virginia Hydro-Electric Company, Alloy, W. Va.

(*f*) Until November, 1932—resident engineer on appraisals, estimates, and new business in West Virginia and Kentucky.

In 1932 Mr. Sager went into private practice, and for the following year was affiliated as a consulting engineer with the Blanton Stone Company, Frankfort.

In September, 1933, he entered the government service as engineer-examiner for the Federal Emergency Administration of Public Works, Louisville, and was promoted rapidly to the positions of assistant state engineer, state engineer, acting state director, and state director, successively.

After the liquidation of the state offices of the Public Works Administration in 1937, Mr. Sager became associated with the City of Louisville as engineer, and secretary-treasurer of the City Planning and Zoning Commission; and, as secretary-treasurer, technical adviser, and executive director of the Municipal

Housing Commission, on the construction and operation of two municipally owned slum clearance housing projects, costing approximately $10,000,000.

In June, 1940, he returned to the firm of Ford, Bacon and Davis, Inc., and was engineer in charge of the construction of a large chemical plant for the Carbide and Carbon Chemicals Corporation at Texas City, Tex. During the period from 1940 to 1942 Mr. Sager concurrently was in charge of another very important project—a tin smelter—built by the Defense Plant Corporation at Texas City.. He also acted as consulting engineer for the City of Galveston (Tex.), on improvements to water supply, which included general supervision of construction, and other engineering activities in the Galveston area.

George H. Sager, Jr., was a member of the Phi Gamma Delta fraternity, the National Society of Professional Engineers, the Kentucky Society of Professional Engineers, and the Kentucky and Texas Sections of the American Society of Civil Engineers, as well as being a registered professional engineer in the states of Kentucky and Texas. He was also a member of the Galveston Country Club and the Rotary Club.

Mr. Sager is survived by his widow, the former Nellie Cheatham Rodman, to whom he was married on November 10, 1917, in Frankfort, and a son, Lt. Arthur Rodman Sager. Another son, the late Lt. George Henry Sager, III, a pilot, was killed in action over Luzon, Philippine Islands, in April, 1945.

Mr. Sager was elected an Associate Member of the American Society of Civil Engineers on August 29, 1927, and a Member on January 13, 1936.

ALBERT LYON SCOTT, M. ASCE[1]

Died March 2, 1946

Albert Lyon Scott was born on June 21, 1878, at Cleveland, Ohio, the son of John H. and Florence Madeline (Davis) Scott. His father was a Baptist minister and at one time a college president, which makes significant Mr. Scott's lifetime participation in religious and educational activities. His early years were spent in Ypsilanti, Mich., Minneapolis, Minn., and Chicago, Ill. In the latter city during his high school years he supported himself by selling newspapers and eggs.

He worked his way through Brown University, Providence, R. I., and was graduated in 1900 with the degree of Bachelor of Arts. Although he was preparing for a career in engineering he felt that too many engineers gave insufficient time to cultural subjects.

Immediately after his graduation, Mr. Scott became an assistant resident engineer for the architectural-engineering firm of Lockwood Greene and Company, then a Boston (Mass.) organization, which specialized in the design of textile mills. All Mr. Scott's business life was spent with this company. He became director in 1903, treasurer in 1905, vice-president in 1920, president in 1926. In 1928 the firm name was changed to Lockwood Greene Engineers, Inc.; the executive offices were established in New York, N. Y., and Mr. Scott continued as president until his death.

---

[1] Memoir prepared by David Elwell, Vice-Pres., Lockwood Greene Engrs., Inc., New York, N. Y.

While the design of textile plants has always been a specialty of the firm, during Mr. Scott's career, and considerably due to his stimulation, the company expanded the scope of its work widely through the entire industrial field. He participated in the company's work in an engineering as well as an administrative capacity. From his first employment as assistant engineer at Greenville, S. C., he became resident engineer in charge of construction of a new factory for the American Cigar Company at Richmond, Va.

From 1902 through 1905 Mr. Scott was in charge of the company's southern projects with headquarters at Greenville, having responsible engineering supervision. This included preliminary studies, reports, and cost estimates for cotton mills and water powers, including Yadkin River, Parr Shoals, and Greenville-Carolina Power Company (20,000 hp, 15,000 hp, and 93,500 hp, respectively). He was local supervising engineer in charge of Dan River Power and Manufacturing Company, Danville, Va., and Pacolet Manufacturing Company and No. 5 Mill, Lockhart Mills (mill and water power), both in South Carolina.

In 1905 Mr. Scott was called to headquarters then at Boston, as treasurer of the company; and until 1917, in addition to administrative duties, selected sites and designed and supervised the construction of industrial plants for automobile companies, knitting, woolen, cotton mills, etc.

From 1913 to 1926 he served as his company's representative and general consulting engineer, supervising all engineering projects for the U. S. Rubber Company and its subsidiaries. This work involved the study of plants, new construction, and plant changes and improvements.

An important assignment, in 1931, was a study of operations and value of twenty-four plants of the American Woolen Company, Inc.

In 1933 Mr. Scott was the engineering member of the construction committee for the Cité Universitaire, Paris, France.

His interest in religious and educational affairs is exemplified by the following: He was president of the board of trustees of Riverside Church, New York; secretary of The Corporation, and of the Board of Fellows, Brown University; and a trustee of the University of Chicago, Chicago, Ill., of Spelman College, Atlanta, Ga., and of Lingnan University, Canton, China.

Mr. Scott was a member of the Laymen's Inquiry Commission which wrote "Rethinking Missions." In collaboration with Raymond B. Fosdick[2] he made a study of liquor control systems in the United States, Canada, and Europe in the hope of finding an ideal plan for use in the United States after the repeal of the prohibition amendment.

Mr. Scott was a member of the committee on supplies of the Council of National Defense, 1917; and chief of Supply and Equipment Division, Quartermaster Corps, U. S. Army, from 1917 to 1918. He was also a director for the Textile Research Institute, a trustee for the Textile Museum; and a member of the New York State Society of Professional Engineers, the

---

[2] "Toward Liquor Control," by Albert Lyon Scott and Raymond B. Fosdick, Harper & Bros., New York, N. Y., 1933.

Society of American Military Engineers, the American Historical Association and the Delta Upsilon fraternity. He was a member of the Merchants Club, the University Club of New York, and the University Club of Boston.

On June 12, 1906, at Geneva, Ohio, he married Alice May Chamberlin, of that city, who survives him. He is also survived by a daughter, Alice C. (Mrs. Robert H. Dods); and four sons, David H., Albert L., Jr., Richard C., and Robert L. Scott.

Mr. Scott was elected an Associate Member of the American Society of Civil Engineers on November 7, 1906, and a Member on January 11, 1937.

CHARLES SMITH SHELDON, M. ASCE[1]

Died July 25, 1945

Charles Smith Sheldon was born at Lexington, Mich., on October 1, 1870. His father, Wilbur Carlos Sheldon, was born in Vermont and at the close of his service in the Civil War settled in Lexington, where he married Elizabeth Roach. In 1872 the family moved to Marlette, Mich., where Charles was graduated from high school in 1888. When an appointment to the United States Naval Academy in Annapolis, Md., became void because of his failure to meet the visual requirements for entrance, he spent a winter teaching in a district school. He was then employed for about a year on railroad surveys and construction, another year on land and drainage surveys, and two years as assistant to the city engineer of Port Huron, Mich. In 1893, his ability in that field brought him an offer of the position of topographical draftsman with the Chicago and West Michigan Railway Company and its affiliate, the Detroit, Grand Rapids and Western Railroad Company. At that time these railroads were starting to make complete resurveys of their properties. The maps that he prepared in connection with these surveys are still in daily use and serve as an effective monument to his skill.

Not content with being a first-class surveyor and draftsman, he enrolled in 1899 in the College of Engineering of the University of Michigan at Ann Arbor, Mich., and was graduated in 1902. After a year with the Canadian Bridge Company as draftsman and designer, he served the Cincinnati, Hamilton and Dayton Railway for ten years as assistant engineer and bridge engineer. He became bridge engineer for the Pere Marquette Railroad in 1913 and engineer of bridges and structures in 1929, in which capacity he served until his retirement in December, 1940. Between 1913 and 1925, most of the many timber bridges on the Pere Marquette Railway were replaced by permanent structures; and after 1925 the grades at a large number of highway crossings were separated.

Although many bridges in Michigan and Ohio, as well as several car-ferry terminals on the Pere Marquette Railway, attest his ability as a designer and constructor, Mr. Sheldon looked on himself as primarily a maintenance man and took quite as much interest in prolonging the life of a structure, by adequate strengthening and repair, as in making plans for a new one. His work was characterized by his integrity, and a conservatism tempered by readiness to adopt the new when its merit was well proved.

---

[1] Memoir prepared by Paul Chipman, M. ASCE.

His work was his chief concern, but throughout a busy life he cultivated other interests. In the realm of sport, he engaged in hunting, trout fishing, and golf. Gifted with unusual manual dexterity, he became an expert cabinetmaker and woodcarver, and furnished his home with many beautiful pieces. He was interested in all branches of natural science and had a very good knowledge of local geology. An engaging conversationalist, his terse and piquant observations were the delight of his associates. Life with Charlie Sheldon was never dull!

In his later years, his other hobbies were largley supplanted by travel and color photography. In these activities he had an interested and helpful companion in his wife, the former Stella May White. She was a schoolgirl sweetheart in Marlette, to whom he was married in 1902. Her death soon after his retirement shattered a dream of spending their declining years together in the search for beauty.

Mr. Sheldon is survived by a brother, Lemuel C. Sheldon; and a sister, May Sheldon Wood.

Mr. Sheldon was elected an Associate Member of the American Society of Civil Engineers on June 7, 1905, and a Member on May 5, 1915.

CARLTON MANSON SOULE, M. ASCE[1]

DIED JUNE 28, 1945

Carlton Manson Soule was born in Boston, Mass., on June 10, 1884, the son of John Manson Soule and Ida Waterman (Bates) Soule. He was graduated from Dartmouth College, at Hanover, N. H., in 1906, with the degree of Bachelor of Science, and from the Thayer School of Civil Engineering, in 1907, with the degree of Civil Engineer.

Following three years spent, successively, with the American Bridge Company at Edgemoor, Del., the Hamilton Bridge Works Company, Hamilton, Ont., Canada, and the J. E. Greiner Company, Baltimore, Md., in 1910 Mr. Soule became a bridge designer and, later, assistant chief draftsman of the bridge department of the Baltimore and Ohio Railroad Company in Baltimore, where he remained until March, 1917. During World War I, his activities were devoted to industrial developments directly connected with the production of chemicals essential for the prosecution of the war against the Central Powers. During this period he was associated with Deverell, Spencer and Company, consulting engineers at Baltimore, Richard K. Meade, consulting engineer at Baltimore, and the War Industries Board.

---

[1] Memoir prepared by H. M. Brown, M. ASCE.

From April, 1919, until October, 1925, Mr. Soule was chief engineer of the Spencer Construction Company at Baltimore. This company, under his supervision, constructed many large industrial projects, including a 120-in. plate mill for Bethlehem Steel Company at Sparrows Point, Md., and cement plants for several Portland cement manufacturers. This association developed into the formation, in 1925, of the partnership of Soule and Zepp, consulting engineers, specializing in the design and construction supervision of industrial plants. During this practice, plants for the Pittsburgh Plate Glass Company, Century Cement Company, and others were designed and constructed. As an individual, at this time, Mr. Soule was also associated with J. E. Greiner Company, supervising the design and construction of an $8,500,000 port terminal for the Western Maryland Railway Company at Baltimore. The partnership of Soule and Zepp was dissolved in 1935, when Mr. Soule became director of operations for a district of the Works Progress Administration embracing the city of Baltimore and surrounding counties.

In October, 1938, Mr. Soule became an associate engineer of J. E. Greiner Company, with executive supervision of design. Under his direction many important projects, including $5,000,000 bridge structures over the Susquehanna River at Havre de Grace, Md., and the Potomac River at Dahlgren, Va., were completed. At the time of his death, Mr. Soule was engaged upon the production of construction plans and specifications for the northern portion of a six-lane, divided superhighway between Washington, D. C., and Baltimore.

Mr. Soule's light shone steadfastly and true. Without flash, but with steady brilliance, his friendships were many and warm. His quiet dignity and understanding humor were outstanding attributes of his character, which quietly guided many younger engineers who sought his advice and guidance.

On April 15, 1911, he was married to Mary Ethel Woodrow at Philadelphia, Pa. He is survived by his widow; two sons, John Woodrow Soule and William Carlton Soule; one daughter, Ethel Ida (Mrs. Ralph C. Johnson); and four grandchildren, Carol Ann Johnson, David Soule Johnson, Sara Charlotte Johnson, and Douglas Carlton Soule.

Mr. Soule was elected a Member of the American Society of Civil Engineers on April 10, 1940.

LINFORD SPEARING STILES, M. ASCE[1]

DIED MAY 5, 1943

The sudden death of Linford Spearing Stiles in his seventieth year was a shock to his many friends. He had been construction engineer for the Brooklyn Union Gas Company since 1908, having been employed by that company since 1903.

---

[1] Memoir prepared by Harry F. Crofton, an associate of Mr. Stiles, with The Brooklyn Union Gas Co., Brooklyn, N. Y.

Linford Spearing Stiles, the son of John Edward Stiles and Margaret Cecelia (Walsh) Stiles, was born in Philadelphia, Pa., on October 26, 1872.

After receiving his primary education in "the little red schoolhouse" of those days, he completed four years of grammar school before he was fourteen, the eligible age for high school admission. In the interim between graduation and attaining the age of fourteen he took a senior course in the grammar school provided for such students. He attended the Manual Training High School which prepared students for college entrance in scientific courses. One of his high school subjects was elementary electrical engineering. During these years, Mr. Stiles was a grocery boy after school hours in true Horatio Alger style. On one occasion the proprietor was away sick all summer, and he was in charge, going to market at four in the morning, opening the store at seven, and closing at nine in the evening.

An electrical engineer, the father of one of his school chums, procured a job for Mr. Stiles on the erection of a building with markets on the ground floor and ballrooms and assembly halls upstairs. Although only in his teens, he was in charge of a squad on electric wiring. When the building was completed, he was employed in the boiler room, firing the boilers and assisting the engineer.

He had saved money toward paying his tuition at the University of Pennsylvania in Philadelphia; but his family suffered from financial reverses and he had to forego college. Thwarted in his desire for a higher engineering education, a less indomitable youth might have resigned himself to fate. Instead, Mr. Stiles apprenticed himself for four years to the I. P. Morris Company of Philadelphia, going through all the shops, foundries, etc., and finally reaching the engineering offices. He studied mechanical drawing at night in the Young Men's Christian Association. His teacher was the chief engineer of the Morris works, who, no doubt, spotting the dogged insistence of the boy, took him into the engineering offices. Mr. Stiles attended night classes in Spring Garden Institute, Franklin Institute, and Drexel Institute of Technology in Philadelphia and even paid a private tutor to teach him for a few hours in the evenings.

The William Cramp Shipbuilding Company was working at a fast tempo at that time and absorbed the adjoining Morris works. The merger was accompanied by an expansion of the shipyard facilities. On several miles of waterfront along the Delaware River, new dry docks, shipways, foundries, shops, mold lofts, etc., were erected. Mr. Stiles was assistant to the chief engineer on this construction.

When times became dull, shipyards were avid for any kind of work, and Mr. Stiles often recollected with a chuckle the ambulance-chasing tactics employed to obtain business. The *Maritime News* reported the impending arrival of incoming ships at the Delaware breakwater. He would be one of a group from the Cramp Company that went down the bay to the breakwater, boarded the ship, and accosted the chief engineer about needed repairs. Sketches would be made on the spot, and the men returned posthaste to the office to work on the data. Almost by the time the ship docked in Philadelphia, plans, bills of material, and estimates would be ready.

Mr. Stiles was friendly with one of William Cramp's sons, Benjamin H. Cramp, who often spoke of the desirability of a pneumatic machine that would replace the manual tamping of sand against the molds and the cores for the castings. Mr. Stiles worked on this idea after hours and developed and patented such a machine. Mr. Cramp was pleased with it and financed Mr. Stiles' trip through a number of states to introduce the machine to the trade. The effort brought some success and the Cramp Company manufactured a number of the machines. However, since the machine was a labor-saving device, the opposition of the labor unions was an obstacle to commercial feasibility. Mr. Stiles evidently found the inventive field intriguing for he later developed and patented a number of ideas—a collapsible crate, a non-refillable bottle, and a synchronized phonograph and projecting machine which contained the germ of the present sound, motion pictures. In the manufactured gas field he patented a number of improvements on Williamson generators to increase their capacity.

About this time the toss of a coin might have decided whether Mr. Stiles would remain in the shipbuilding business or transfer to other fields. A friend in the Cramp Company, Joseph W. Powell (later Special Assistant to the Secretary of the Navy), who was studying naval architecture and later became president of the Fore River Shipbuilding Company, left to go with Admiral Francis T. Bowles in the U. S. Navy Department. Because of his friend's interest, the Navy Department made Mr. Stiles an attractive offer, but he stayed with the Cramp Company. Shortly afterward, the father of a school friend was instrumental in Mr. Stiles' employment as a draftsman by the United Gas Improvement Company. The United Gas Improvement Company had leased the Philadelphia Gas Works and was replacing the manufacturing and distributing apparatus with modern equipment. Mr. Stiles worked on the design and construction of the Point Breeze and Twenty-Fifth Ward plants. Later he was transferred to the main office on the design of all types of gas plants.

In 1903 he was employed by the Brooklyn Union Gas Company. Although apparently only a "rookie" and filling what were ostensibly a draftsman's shoes, he was doing real engineering work from the start. His basic training in fundamentals was a fine background in the design and construction phases of the gas business and he soon won recognition. Plant extensions were in prospect, and Mr. Stiles could not resist the temptation to lay out a tentative scheme on his own initiative at home. His plan came to the attention of the president of the company, the late Gen. James Jourdan, who was so impressed by its engineering logic that he stopped the preliminary work which had been done and adopted the plan in full. Shortly after this, the Construction Department was created, and Mr. Stiles was appointed construction engineer. During his thirty-five years with the company, manufacturing capacity expanded from seven billion to twenty odd billion cubic feet each year. Five large plants were entirely rebuilt, and in 1929 the largest project of all, a combination coke oven and water gas plant with a capacity of about fifty million cubic feet a day, was completed. His department also designed and contracted for the erection of numerous office buildings, shops, pumping stations, etc.

His work brought Mr. Stiles in contact with many borough, city, and state department heads and with the War Department engineers of the old Harbor Line Board in connection with waterfront improvements, building permits, etc. His contagious enthusiasm cemented lifelong friendships, and his deep fundamental knowledge impressed his associates.

Mr. Stiles gave much of his time to civic matters. In 1930 he moved from Brooklyn, N. Y., to Great Neck, Long Island, N. Y., but his interest in Brooklyn's welfare never ceased. Perhaps his most noteworthy contribution was as chairman of a fact-finding committee in connection with the proposed railroad tunnel from Greenville, N. J., to Bay Ridge, Brooklyn. The late Frederick L. Cranford, M. ASCE, asked Mr. Stiles to accept this assignment, and he worked on it for two years with the officials and engineers of the Pennsylvania Railroad Company and The Port of New York Authority, submitting a report with accompanying cost estimates.

Mr. Stiles was a member of the American Society of Mechanical Engineers; the Engineers' Club of New York, N. Y.; the Brooklyn Engineers' Club (president for two terms); the National Society of Professional Engineers; and the New York State Society of Professional Engineers (director of this society and president of the Kings County Chapter for two terms). He belonged to the Brooklyn Chamber of Commerce, the Long Island Association, the Pennsylvania Society of New York, and the Crescent Athletic Club (later the Huntington-Crescent Club). He was a registered architect as well as a licensed professional engineer and a member of the Long Island Society of Architects and the New York Council of Architects. He was a trustee and chairman of the administration committee of the House of St. Giles the Cripple, a charitable institution.

In 1914 Mr. Stiles presented a paper before the Brooklyn Engineers' Club, describing a gas holder with a capacity of ten million cubic feet and an attendant pumping station which used gas engines as prime movers.[2] In 1926, before the same organization, he read a paper on a coal handling system erected at one of the gas plants.[3] Each of these papers was awarded the Alfred T. White Prize. Also in 1926 he presented a paper before the Society describing a pipe tunnel under the Gowanus Canal in Brooklyn, built by the trench method without the use of compressed air and shield. This paper was awarded the Thomas Fitch Rowland Prize of the Society in 1927.[4] Subsequently, he accepted an invitation to present the tunnel paper [4] before the Franklin Institute in Philadelphia. He confessed it was with a tingle of pride that he appeared before his native folks on that occasion, for he had left Philadelphia to join the Brooklyn Union Gas Company as a young man who had not yet made his way in life.

In 1900 at Philadelphia, Mr. Stiles was married to Katherine E. Kelly. He is survived by his widow; a son, Linford Edward Stiles; two grandchildren, Linford Edward, Jr., and Elizabeth Anne; and a sister, Adeline M. (Mrs. William Foster).

Mr. Stiles was elected a Member of the American Society of Civil Engineers on May 28, 1923.

GEORGE LEWIS SWENDSEN, M. ASCE[1]

DIED DECEMBER 31, 1944

Louis Peter and Ellen Maria Swendsen, two pioneers of the west, came to the United States in early youth, from Denmark and Wales, respectively, and found their way to Utah via the Emigrant Trail in prairie schooners. Their son, George L. Swendsen, was born at Richland, Utah, on December 21, 1869.

George's early training was on the farms and ranches and in the public schools of that area. He entered Harvard University at Cambridge, Mass., in 1890, and, in 1894, received the degree of Bachelor of Science in Civil Engineering. He returned west to head the Engineering Department of the Utah State Agricultural College, at Logan, where he remained until 1903. During this period, he also engaged in private practice.

The field of his operations, Utah and southern Idaho, was then generally undeveloped or in the pioneer state. Except in the larger towns or centers of population, kerosene lamps and candles provided illumination. Culinary water found its way to the kitchen and bath from open wells, via hand-operated pumps or improvised lifts and the old-fashioned bucket brigade. Sewer systems, septic tanks, and other sanitary conveniences were not yet available.

Agriculture, the then dominating industry, was successful only under irrigation and was limited to areas where water was made easily available by means of simple, and easily constructed canals, aqueducts, and irrigation works. Its further expansion called for the construction of more intricate structures, reservoirs, and dams.

Much of his time, therefore, during that period, was devoted to the design, financing, and construction of irrigation works, culinary water systems, and small hydroelectric power plants. His compensation for this early effort was the satisfaction of rendering service to humanity under trying circumstances rather than from pride in professional accomplishment and monetary return.

Times were "tough" in this "hang-over" period, following a depression then called the "Panic of '93." Money was almost unobtainable and, for the most part, engineering designs had to contemplate the use of available native raw materials, fabricated and placed largely by hand labor. Notwithstanding these improvisions and compromises, necessary under the circumstances, the resulting works are still, with limited expansions and improvements, serving the area in question. Much of the relief from the 1893 panic conditions came from such efforts on the part of the engineering profession as it then existed throughout the west and in many parts of the United States.

---

[1] Memoir prepared by Warren G. Swendsen, Assoc. M. ASCE.

In 1903, Mr. Swendsen left the college, and private practice, and accepted a position as district engineer for the U. S. Reclamation Service. He was placed in charge of work and investigations in Utah and southern Idaho. He inaugurated the first construction on what is known as the Strawberry Valley project, the principal structure involving a 20,000-ft tunnel through the Wasatch Range, which serves to divert water from the upper reaches of the Colorado River basin to the Utah lake area. He left the Reclamation Service in about 1908 to engage in hydroelectric power construction, and other work for the Telluride Power Company—which company was building and operating power plants in Colorado, Utah, and southern Idaho. Leaving this company in 1912, he engaged in private engineering practice, with headquarters at Boise, Idaho, devoting his time largely to the design and construction of irrigation work. In 1915, he entered the service of the Utah Power and Light Company, successor to the Telluride Power Company, with headquarters at Salt Lake City, Utah, where he remained until about 1918, when he went to Fresno, Calif., to serve as manager and chief engineer for the Fresno Irrigation District. He held this position until about 1938, at which time he retired and took up his residence at Long Beach, Calif.

He engaged in consulting engineering work until the beginning of World War II. Notwithstanding his age and physical limitations, and, out of a sense of patriotism, he accepted employment in the shipyard industry, having charge of tool inventories. He was employed in this position at the time of his death.

Mr. Swendsen was married in 1896 to Mary Mathews, deceased, and was married to May Douglas Loughney in 1906. He is survived by his widow; a son, Harold Swendsen; two brothers, Myron Swendsen, M. ASCE, and the writer of this memoir; and two sisters, Meda Swendsen and Mrs. R. E. Herrick.

Mr. Swendsen was elected a Member of the Society of Civil Engineers on June 7, 1905.

VALENTINE VASILIEVISH TCHIKOFF, M. ASCE[1]

DIED OCTOBER 7, 1945

Valentine Tchikoff was born in Vladikavkaz, Russia, on October 30, 1883. He was the son of a prominent Russian General, Vassili Tchikoff, and Anna (Shushpahou) Tchikoff. He was graduated in 1909 from the Institute of Ways and Communications of St. Petersburg (later Leningrad), Russia. This institute is considered the best civil engineering college in Russia and is comparable to our finest American universities. He was graduated among the first of his class and his thesis was left to be used as a text for the classes to follow.

---

[1] Memoir prepared by R. Burchuk, Secretary to Mrs. Tchikoff, Greenbelt, Md.

Upon his graduation he was connected with the construction of the North Donetz Railway. Following this, and for the next five years, he was employed as assistant and chief engineer in the Russian Ministry of Agriculture in Tashkent, Asia. He was sent to Germany by the Russian Government tc make a survey of the Carl Zeis factory studying stereophotographic instruments. He then went to British India for a six-month stay. There he visited Punjab, United Provinces, and Calcutta where he studied water power and reclamation projects, including the economic developments. From May, 1915, to April, 1916, he was chief engineer in Kherson, Russia, and while there he published a report[2] of 208 pages on the feasibility of irrigation of a large area adjacent to the lower part of the Dnieper River. The investigation was made in connection with utilization of the power of a large hydroelectric plant, "Dnieperstroy," then under design and later constructed (destroyed in World War II by the retreating Russian Army). Besides various alternative designs of irrigation systems, the publication includes a complete description and consideration of economic, climatological, hydrogeological, and agricultural factors of this semi-arid region. Among the interesting features of this report, a "Diagram of Probable Droughts" can be mentioned. The importance of this diagram is explained in another of Mr. Tchikoff's articles.[3]

Mr. Tchikoff was always a great admirer of the methods and progress of American engineering and did much to promote friendly relations among the engineers of Russia and America. It was always a dream and secret ambition to come to America for study and research. Because of his interest in furthering the career of fellow engineers and students, both in America and in Russia, he did much to introduce the American methods and technique to Russian students. To further carry out his hope for a more cultural relationship between the two, he required all his assistants to study English so that they would better understand American engineering methods. He also founded and was the first editor of the American Engineering and Industry publication which is now owned and published by the Amtorg Trading Corporation. This publication helped to familiarize the Soviet Union with the latest developments in the field of American engineering and industrial practice. It was devoted to the promotion of closer technical and trade relations between the United States and the Soviet Union.

Mr. Tchikoff came to the United States in 1916, as a member of the Russian Military Purchasing Committee, and was assigned as chief inspector for the committee at the Remington Firearms plant in Bridgeport, Conn., and Hoboken, N. J. After completing this work he took a postgraduate course at the University of California, in Berkeley, studying water power, reclamation, and history of education. At the time he prepared a report for the United States Department of State on water power in Russia. This was written for the American members of the Peace Commission at the request of

---

[2] "Irrigation of Taurida Region, South Russia," by V. V. Tchikoff, Russian, Dept. of Agriculture, Bureau of Soil Conservation, Petrograd, Russia, 1916.

[3] Method of Constructing a Diagram to Show Probable Droughts," by V. V. Tchikoff, *Engineering News-Record,* September 18, 1919, p. 554.

O. C. Merrill, M. ASCE, who was the chairman of the American Committee of the World Power Conference.

The outbreak of the Revolution in Russia, while Mr. Tchikoff was in America with his wife and baby, prevented his return. Following this, Mr. Tchikoff entered private practice for several years as a consulting engineer. Later he did engineering service with the Arcos Trading Corporation of London (New York Branch) and the Amtorg Trading Corporation of New York in the technical departments. As chief of this department he interpreted plans, specifications, and other data prepared in Russian for the use of engineers associated with Col. Hugh L. Cooper, M. ASCE, who was employed by the government of the Union of Soviet Socialist Republics (U. S. S. R.) as a consulting engineer for construction of the Dnieper River power development.

In 1929 he returned to Russia for two years as assistant engineer to the late Arthur P. Davis (Past-President, ASCE), chief consulting engineer for the General Cotton Committee. This assignment consisted of a review of all important reclamation projects in the U. S. S. R., Turkestan, and Transcaucasia. In addition to plans for utilizing power resources in individual drainage basins of rivers, he specialized in the growing of cotton and other crops under irrigation. In conjunction with this work he wrote "Irrigation in Agriculture"[4] for use in the schools in Russia. At this time also we mention the many publications, books, and articles that Mr. Tchikoff wrote in both English and Russian on various engineering subjects. He wrote several discussions in *Proceedings*, ASCE, and *Engineering News-Record* published several of his articles. The *Asia* magazine published one of his important articles on cotton in Turkestan.

Mr. Tchikoff, always the student and pioneer, felt the need of further study and went to France for a year. There he studied water power, reclamation, and economics. He then returned to America and spent some time in writing. One of the reports[5] (written and published for the Soviet Union Middle Asia Water Economy Service) which Mr. Tchikoff wrote after working with Mr. Davis was printed in Russia.

In 1935, he entered public service with the Farms Security Administration as project analyst. His work consisted of making reports on the resettlement projects, water rates, homestead associations, maintenance of structure, and disposition of projects. Later in this same bureau he worked in the capacity of a social economist.

He transferred to the Federal Public Housing Administration and it was there that his health started to fail. He served as senior building and maintenance engineer. However, because of his failing health, he came to Greenbelt, Md., to work, in the same capacity, in a more countrylike and peaceful atmosphere.

A tireless and energetic worker, his character, honesty, and consideration for his fellow men created loyalty in, and left an indelible impression on, all those who had the privilege of working with him.

---

[4] "Irrigation in Agriculture," by V. C. Tchikoff, Donskoy Inst. Novocherkassk, on Don, U. S. S. R., 1932.

[5] "Duty of Water and Duty of Rivers as Determined by Russian and American Specialists," by V. V. Tchikoff, Russian Govt., Taskent, U. S. S. R., March, 1931.

Surviving him are his widow, Mary (Russin) Tchikoff, who was his constant companion and friend wherever his travels and work took him; a daughter, Alla (Mrs. Robert Ford, Jr.); and a granddaughter, Barbara Ford, aged five.

Mr. Tchikoff was elected an Associate Member of the American Society of Civil Engineers on September 9, 1919, and a Member on January 15, 1934.

DANIEL LAWRENCE TURNER, M. ASCE[1]

DIED MARCH 12, 1942

Daniel Lawrence Turner, who retired from an active career in planning and constructing urban and suburban transportation systems in 1933, died on March 12, 1942, at his home, "The Wayne" in Greenway Court, Norfolk, Va. He was born in Portsmouth, Va., on October 25, 1869, the son of Daniel James and Mary Elizabeth (Lawrence) Turner. His early education was received at Norfolk Academy in Norfolk, after which he attended Rensselaer Polytechnic Institute, in Troy, N. Y. He was graduated in 1891 with the degree of Civil Engineer.

After nine years of varied activities, including a year as assistant in mathematics at Rensselaer Polytechnic Institute and seven years as instructor of surveying at Lawrence Scientific School, Harvard University, Cambridge, Mass., in December, 1900, Mr. Turner became an assistant engineer on the staff of the Rapid Transit Railroad Commission of New York, N. Y. In this capacity, he prepared plans for draining New York City's first subway, worked on construction, and finally was in charge of surveys for the Brooklyn extension of the subway.

Then, for thirty-three years, he was continuously associated with the transportation problems of New York City, including the planning and development of the rapid transit system from forty-five miles of elevated track to five hundred miles of subway and elevated track, at a total expenditure of $800,000,000. During this period Mr. Turner advanced through the positions of assistant engineer and general inspector of stations (1903), chief of Bureau of Transit Inspection (1907), division engineer (1912), deputy engineer of subway construction (1913), acting chief engineer (1916), to chief engineer, Public Service Commission (April, 1917). On May 21, 1921, he resigned to become consulting engineer to the Transit Commission and later to the Board of Transportation of New York City. Mr. Turner was also retained in a consulting capacity on transit matters by the cities of Detroit, Mich., and Pittsburgh, Pa., and by the North Jersey Transit Commission. In 1933 he retired from active practice.

An outstanding characteristic of Mr. Turner's personality was his devotion to his chosen profession. He was never too busy to turn down a call to serve on a committee of one of his engineering societies, and the many requests he received from students or others for information related to his work always received sympathetic consideration. Next to his profession came his alma mater, Rensselaer Polytechnic Institute, which in 1933 conferred upon him the honorary degree of Doctor of Engineering. He served several terms as president of the Rensselaer Alumni Association and was elected an alumni trustee of the Institute in 1928.

---

[1] Memoir prepared by Henry Heins, Public Service Comm., New York, N. Y.

Mr. Turner was appointed a United States delegate to the World Engineering Congress meeting in Tokyo in 1929 by President Herbert Hoover. He was a member of the University Club, the Engineers Club of New York, and Theta Xi fraternity; also the Century Association, American Institute of Consulting Engineers, and Sigma Xi fraternity.

On February 3, 1896, Mr. Turner was married to Eva Barcine Denby.

Mr. Turner was elected an Associate Member of the American Society of Civil Engineers on February 2, 1898, and a Member on January 3, 1905.

CHARLES DAVIS VAIL, M. ASCE[1]

Died January 8, 1945

Charles Davis Vail was born on September 11, 1866, on a farm near Lonetree, Ill. He was the son of Richard Randolph and Catherine (Brokaw) Vail. His early education was received in the rural schools of Bureau County, and in the Henry (Ill.) High School. After being graduated from high school, he taught school for a year and then enrolled in the University of Illinois, at Urbana. While still in college, he began his practical engineering career as an engineering assistant on a branch railroad being built from Whitewood, S. Dak., into the Belle Fourche country.

In 1891 "Charlie" received the degree of Bachelor of Science in Civil Engineering from the University of Illinois, and in 1936 the degree of Civil Engineer. He continued his "railroading" by joining a crew of the Union Pacific Railroad Company at Cheyenne, Wyo. Beginning as instrumentman, he soon worked up to the position of assistant to the division engineer, where he remained until the panic of 1893. Then the position was abolished. Nothing daunted by being out of a job in a panic year, he went to Denver, Colo. There he was married to Jessie Paden on December 7, 1893, and they went to the World's Fair in Chicago, Ill.

Returning to the West, he stopped briefly in Denver, and then returned to Cheyenne as a draftsman in the U. S. Surveyor General's office, soon becoming chief draftsman. As might be expected by those who knew him, Mr. Vail's temperament would not permit him to stay long on a strictly office job, so, in 1894, he turned again to railroading and became locating engineer for the

---

[1] Memoir prepared by a Committee of the Colorado Section consisting of Oliver T. Reedy, M. ASCE, Chairman, Arthur V. Williamson, M. ASCE, Dan W. Ormsbee, Assoc. M. ASCE, and Albion H. Vickery, formerly City Engr., Denver, Colo. (deceased).

Trinity, Cameron and Western Railway Company, near Georgetown, Tex., and for a few months was assistant engineer for the Mexican International Railway Company.

Evidently, his association with the Union Pacific proved mutually satisfactory, for, in 1895, he returned to that railroad as assistant engineer. Later, he held the same position with the Union Pacific subsidiary, the Oregon Short Line.

However, during the next eight years, 1897 to 1905, Mr. Vail turned to another engineering field—water—and during that period he was engaged as chief engineer of the Creeklyn Ditch Company, in Jefferson County, Montana; and later as principal assistant engineer, Butte (Mont.) Water Company. He installed a water and lighting system in St. Anthony, Idaho; surveyed and designed water works for East End Irrigation Company, East End, Assinaboia, Canada; designed and installed water works at Basin, Mont., including water supply to concentrator for Montana Ore Purchasing Company; did expert hydraulic work for Missoula (Mont.) Water Company and Helena (Mont.) Water Works; designed water works for Glasgow, Mont., and improvements for water works for Fort Benton, Mont., with numerous reports and estimates on power development.

On account of his experience in railroad engineering, in 1905 the Chicago, Milwaukee, St. Paul and Pacific Railroad Company engaged Mr. Vail to turn aside from his irrigation and water-works practice to become locating engineer over the Continental Divide near Butte. When this work was finished, he became chief engineer of the Ely (Nev.) Townsite Company, and for two years engaged in municipal work, surveying, and platting the town of East Ely, designing and installing water works for both Ely and East Ely, superintending the building of an electric light plant for Ely, as well as making reports on water supplies for mining companies.

In 1908 Mr. Vail organized the consulting firm of Vail, Wolbran and Read, with offices in Denver. This location was the center of his activities until his death, thirty-seven years later. During this period as a consulting engineer, his most important works were: Construction of concrete diversion dam across the Colorado River, near Palisade, Colo.; installation of water works at De Beque, Colo.; construction of the Grand Mesa Irrigation project; chief valuation engineer for the Uintah Railroad Company; construction of the narrow gage railroad from Marble, Colo., into the quarries above the town. (It is from these quarries and over this railroad that the marble was obtained for the Lincoln Memorial in Washington, D. C.)

In 1917 Mr. Vail was appointed railroad and hydraulic engineer for the Public Utilities Commission of Colorado, a position he held until September, 1923, when he was given the position of manager of improvements and parks for the City of Denver. He was responsible for a balanced program of prominent improvements, the most outstanding of which were an extensive system of street and alley paving projects, the construction of the City and County Municipal Building, and the development of Denver's park system, especially that of the Denver Mountain Parks. Scores of these parks, miles beyond the city limits, dot the rugged ranges west of Denver. These are maintained by the city and made easy accessible by splendid roads. Mr. Vail brought this development to such a point that it has attracted nation-wide attention as the "playground of the Colorado Rockies."

With such a background of professional experience, and such evidence of his vision relating to development of public utilities, it is natural that he should be sought after to take charge of Colorado's highways. He was appointed state highway engineer in November, 1930, and from then until his death he had but one goal—developing and improving the highway system of his adopted state. Mr. Vail assumed his new task and great responsibilities with characteristic energy. He analyzed the problems and then outlined a comprehensive, far-reaching program. His chief problem lay in the fact that Colorado then had only 539 miles of hard-surfaced highways and thousands of miles of roads that had to be surfaced to meet modern motor traffic, with a very limited highway income. In view of this fact, he decided to eliminate concrete paved roads, except where definitely indicated by excessive heavy traffic, and specialize in oil-mat surfaced roadways. Thus, Colorado became one of the pioneers in this type of construction, and provided a network of almost 5,000 miles of hard-surfaced highways in a few years, extending throughout the state's vast expanse and through the great mountain empire that makes up almost half of the state's area.

Colorado's road-building program is not finished. It never will be. This is equally true of the other forty-seven states; but the tremendous progress in highway improvement, the system that enables motorists to travel from one corner of the state to the other on hard-surfaced, dustless highways, over every type of terrain, will ever be a monument to the indefatigable energy, the breadth of vision, and the tenacity of purpose of one man—Charles Davis Vail.

One of Mr. Vail's severest newspaper critics describes him as a tough-minded man, and agrees that he had to be since he was in a tough job. He measured up fully to the requirements, and a bit more. At the first meeting of the State Association of County Commissioners after his appointment to the highway job, Mr. Vail stated in an address he had been invited to make,

> "I am often said to be hard-boiled. I'm not hard-boiled, but I don't see any sense in telling you the answer perhaps may be 'yes' when I know positively it cannot be anything other than 'no.'"

He was blunt, undiplomatic, and unruffled by opposition; he never dodged a fight or an issue. Yet with it all, he had a kindly understanding of human relations, and an appreciation of the rights of minorities. To have him for a friend was to be backed by an army.

Mr. Vail was a leader in Colorado Democratic circles, a Thirty-Second Degree Mason, an ardent hunter, and fisherman. He was a member of the Colorado Society of Engineers, the American Road Builders' Association, the Western Association of State Highway Officials, and the American Association of State Highway Officials.

He is survived by three children, Allen P., Kenyon C., Assoc. M. ASCE, and Vera Mary (Mrs. Willis M. Winslow); and one brother, Richard Randolph.

Mr. Vail was elected an Associate Member of the American Society of Civil Engineers on June 6, 1900, and a Member on August 31, 1909. He became a Life Member in January, 1935.

JOHN LANE VAN ORNUM, M. ASCE[1]

DIED NOVEMBER 6, 1943

John Lane Van Ornum, the son of Adoniram Judson and Sarah Josephine (Lane) Van Ornum, was born at Hartford, Vt., on May 14, 1864. His ancestors on his father's side were among the Dutch pioneers of the Hudson River valley, particularly from the area near Albany, N. Y. On his mother's side his ancestors came from England as early as 1635, and were Colonial settlers in Massachusetts.

In his early childhood his parents left Vermont and settled in Racine, Wis. He obtained his engineering training at the University of Wisconsin in Madison, being graduated with the degree of Bachelor of Science in Civil Engineering in June, 1888. The professional degree of Civil Engineer was granted to him three years later in June, 1891.

Mr. Van Ornum began his professional career with the Municipal Engineering Department of Milwaukee, Wis., immediately after graduation. During the next three years he served consecutively as surveyor and inspector of the United States Harbor Works on the coasts of Georgia and Florida; with Army Engineers on plans for improvement of Ocmulgee River, Georgia; assistant engineer of the Milwaukee, Lakeshore and Western Railroad Company (later the "Northwestern"); and United States assistant engineer on river surveys and river improvements in Georgia and Tennessee.

In November, 1891, in compliance with previous arrangements between the United States and Mexico, the International Boundary Commission was organized and immediately made plans for a resurvey and remarking of that part of the boundary between these two countries which is not determined by river courses. Mr. Van Ornum became the chief topographer for this survey and served in that capacity from December, 1891, until May, 1894.

Lt. D. D. Gaillard, one of the commissioners, reported in a letter regarding Mr. Van Ornum's work:

> "His duties embraced reconnaissance, and topographic work, and supplying a large party with food, water and forage in one of the most arid and least traveled regions in our country. His work was always of the highest grade and he showed great capacity for surmounting successfully the numerous difficulties encountered in work of the character described, and marked ability to direct and control employees. He is a man of strong character and great integrity."

---

[1] Memoir prepared by E. O. Sweetser, M. ASCE, and Luther Ely Smith, Secretary of the 3d Volunteer Engrs., U. S. Army (War with Spain), St. Louis, Mo.

In June, 1895, Mr. Van Ornum read a paper on "Topography on the Survey of the Mexico-United States Boundary"[2] at the Annual Convention of the Society. This paper not only tells of the unusual physical conditions surrounding the field work and maintenance of field parties, but also discusses in detail the importance of transit and stadia methods for such work, giving important data regarding the speed and accuracy which were obtained by this system of mapping. He also wrote "Geology in Its Relation to Topography" in 1898,[3] and several discussions.[4]

In June, 1894, Mr. Van Ornum was appointed instructor in the civil engineering department at Washington University, St. Louis, Mo. He served in that capacity until 1897 when he took a leave of absence and, accompanied by his wife and small son, traveled extensively in Europe investigating foreign engineering works and methods.

In July, 1898, Mr. Van Ornum, a man of lofty patriotism, volunteered for service in the War with Spain and was commissioned a Captain in the Third United States Volunteer Engineers, serving under Col. D. D. Gaillard, with whom he had been in close professional and personal association on the Mexican Boundary Survey.

In a memorial tribute in the 1944 *Yearbook* of the Third United States Volunteer Engineers the following appears:

> "Capt. Van Ornum was an excellent officer, solicitous of the real needs of the men under him, insistent upon discipline, yet not unmindful of the human equation in every problem. His men were devoted to him. The exceptional quality of his service as Company Commander and the high estimate placed upon him by Col. Gaillard were clearly indicated when a vacancy occurred among battalion commanders. Capt. Van Ornum was promoted to Major. The men of 'B' Company and of the 2nd Battalion remember him with deep affection.
>
> "Major Van Ornum was entrusted with important special duties both in the United States and Cuba, and he discharged them all with distinction.

A paper[5] by Major Van Ornum published in 1899 describes in some detail the work of this regiment in Cuba from December, 1898, to April, 1899. In addition to the building of docks, establishing of military camps, extensive military road reconnaissance, and the preparation of adequate maps and harbor surveys, principal attention was given to the improvement of sanitary conditions in various Cuban cities. Of particular interest was the case of Cienfuegos where, in a period of fifteen weeks, the weekly death rate of one hundred and thirty eight was reduced to twenty nine. The Army Engineers did this by the consistent attention to sanitary improvement. The Third United States Volunteer Engineers was mustered out of service in May, 1899, and Major Van Ornum returned to civil life.

---

[4] *Ibid.*, Vol LIV, Pt. A, 1905, pp. 369 and 497; Pt. B, 1905, p. 455; and Pt. E. 1905, pp. 207 and 555.

[5] "Work of the Third Regiment U. S. Volunteer Engineers in Cuba," *Engineering News*, Vol. XLI, No. 25, June 22, 1899, pp. 400–401.

In June, 1899, he was appointed professor of civil engineering and head of the department at Washington University, where he began a career of thirty-four years in the field of engineering education.

At the beginning of his appointment as professor of civil engineering he was placed in charge of plans and estimates for grading and developing the new Washington University campus. This new campus was located on a hill in what was then open country just beyond the city limits and required, in its preliminary development, the moving of more than 1,000,000 cu yd of earth, the establishment of roads, and an adequate surface drainage system, as well as an elaborate construction program. The distance of the campus from established sewer systems at that time made it necessary to install an unusually large septic tank. An "all-concrete grandstand," which received its inauguration at the Olympic Games of 1904, was built on the campus and described by Professor Van Ornum.[6] He obviously occupied a position of leadership in the expanding program of the university and demonstrated foresight and engineering skill at a critical period of its development.

In 1903, Professor Van Ornum served as president of the Engineers' Club of St. Louis and took a leading part in preparing the groundwork for an International Engineering Congress which, during the period of the Louisiana Purchase Exposition of 1904, held its meetings in what later became the library reading room of Washington University. This room has on its wall a large bronze plaque, inscribed, "This tablet is erected by the American Society of Civil Engineers to commemorate the International Engineering Congress held under its auspices in these buildings of Washington University, October 3rd to October 8th 1904." The initial plant of the University buildings was, in fact, rented in its entirety by the World's Fair Committee, thereby postponing for one year the removal of the university itself from a "downtown" location. Professor Van Ornum took an active part in the International Engineering Congress participating frequently in the discussions of that body.[7]

His services were frequently sought in major engineering problems of St. Louis. In 1903 he took charge of an investigation of the flow of the Illinois River from Chicago to Grafton, Ill., and its effect upon the Mississippi River from Grafton to the intake of the St. Louis water supply at Chain of Rocks.

In 1907 he served as chairman of a special Lighting Committee appointed by the Civic League to investigate the question of street lighting in St. Louis. After more than a year of study an extensive report was published in May, 1908, which received wide publicity through the St. Louis newspapers and frequent comments by engineering magazines.

In May, 1908, Professor Van Ornum was appointed by the Mayor of the City of St. Louis, to examine and report upon "the progress of preparation for the construction" of the municipal bridge across the Mississippi River. His report resulted in the clarification of responsibilities on the municipal bridge program and promoted progress in the early engineering work of this important project.

[6] "The Proposed Septic Tank and Sewage Purification Studies at Washington University," by J. L. Van Ornum, *Engineering News*, Vol. XLIV, No. 20, November 15, 1900, p. 329.

[7] "Transactions of the International Engineering Congress in 1904," *Transactions*, ASCE, Vols. LIV (see Cumulative Index, 1920, p. 260).

During this same period, Professor Van Ornum served on the building committee for Pilgrim Congregational Church, of which he was a member. His contribution of engineering skill and sound judgment, generously given, promoted wise decisions in the design and construction of this impressive building.

He was a frequent contributor to magazines and journals, demonstrating a wide range of interest in the fields of economic problems, technical developments, and engineering education. The following examples from a long list of publications confirm this statement: "Theory and Practice of Special Assessments,"[8] "Some Engineering Lessons from the San Francisco Disaster"[9] (which followed a personal inspection of the area), and "Elements of Effective Education."[10]

Among his many papers published in the *Transactions* of the Society, three in particular represent research of a "pioneer" character: "The Fatigue of Concrete Products,"[11] "The Fatigue of Concrete,"[12] and "The Effect of Saturation on the Strength of Concrete."[13] These papers attracted wide attention and discussion. References to them may be noted frequently in America and foreign textbooks.

In 1914 his book, "The Regulation of Rivers,"[14] which was widely used as a text for classwork, was published. Extensive and favorable comments appeared in the technical magazines. The *Engineer* of London stated in part, "It is a pleasure to note the sound literary style," and an American reviewer spoke of it as "a noteworthy addition to American engineering literature."

Professor Van Ornum's long career as a teacher was devoted to the development of his students as individuals, trained in clear reasoning, sound judgment, and integrity of purpose. Uncompromising in his attitude toward the superficial, he was prompt to discern and encourage the earnest and sincere student or co-worker. Outstanding records among alumni in later professional life bear witness to the soundness of his instruction and his ideals.

Throughout his life his concern was manifest for the health and welfare of those who served with him. His kindly sympathy and practical help for those in trouble knew no limitations of social position but were given generously without thought of acclaim or reward. He consistently shunned publicity in all matters pertaining to the finer attributes of life and his sterling character and sincere convictions served as a worthy example to his colleagues and students.

In June, 1933, Professor Van Ornum withdrew from active teaching because of poor health and was given a year's leave of absence. In June, 1934, at the age of seventy, he was permitted to retire and was appointed professor emeritus of civil engineering. He lived a very quiet and secluded life for the next ten years, but finally succumbed to a severe heart attack and died at his home on November 6, 1943.

He was a member of many scientific, technical, and educational societies.[15,16]

He was married to Carrie Beattie Scott, of Newburgh, N. Y., on July 25, 1894. He is survived by his widow and a son, Capt. Thurwood Van Ornum (retired).

Professor Van Ornum was elected an Associate Member of the American Society of Civil Engineers on October 3, 1894, and a Member on October 4, 1899.

EVERETT PINE WEATHERLY, M. ASCE[1]

DIED FEBRUARY 22, 1944

Everett Pine Weatherly was born on March 12, 1877, on a farm near Shannondale, a small town in Chariton County, in the central part of Missouri. It was a farming community and his parents, William James and Mary (Elizabeth) Weatherly, raised a family of two sons on what was some of the best farm land in Missouri. William was of French-English descent, and Mary, of Welsh, the families of both having settled in Missouri about 1850.

Everett attended grade and high schools in Salisbury, Mo. He entered Missouri University at Columbia in 1893 and received the degree of Bachelor of Arts in 1897 and the degree of Bachelor of Science in Civil Engineering in 1899. The vacation periods during his college work were spent with railroad field surveying parties.

When Everett left the university he went to the Chicago, Burlington and Quincy Railroad Company as chainman. Viewed in retrospect, the romantic history of railroading had reached its peak, but in 1899 that peak was so close it served only to thrill the imagination, and it is probable that most of Everett's classmates hoped for just such a connection as he made. In this company he gathered experience and knowledge of his abilities as well as the confidence of superiors and associates. Mr. Weatherly progressed from chainman, inspector, and instrumentman, to resident engineer (1900) in charge of maintenance at Brookfield, Mo., and then at Hannibal, Mo., until 1903. He later became assistant engineer at St. Joseph, Mo., in charge of maintenance and construction.

[1] Memoir prepared by A. B. Taylor, Assoc. M. ASCE.

In July, 1909, he was sent to southern Illinois. The construction of the Panama Canal was well under way, and there was much talk of the loss of traffic by railroads to ocean ships. This loss was to be felt particularly by railroads without tidewater terminals on the East Coast or Gulf Coast. The Burlington Line was built into the southern Illinois coal fields, and Mr. Weatherly's new assignment was as engineer of construction for a single-track line from Herrin, Ill., to Metropolis, Ill., which, according to rumor current at the time, was the first step in a line to the Gulf. The new line was forty miles long not counting a gap of semimountainous construction near the upper end. The line was put into service in the latter part of 1910. It is probable that this job gave Mr. Weatherly more satisfaction than any other of his career. He was a young man, and this, his first major work, was a considerable job—$1,000,000 worth of grading, bridging, and stations, and he had handled it in a manner which had pleased T. C. Calvert, chief engineer, and others of his superiors.

Kansas City, Mo., having survived its boom of the nineties, the flood of 1903, and the 1907 depression, was experiencing solid growth. The Kansas City Terminal Railway Company, owned jointly by several of the railroads entering the city, was to be provided with new tracks, the elimination of many grade crossings, and a Union Station, all estimated at $30,000,000. The late J. V. Hanna and Arthur C. Everham, Members, ASCE, chief engineer and assistant chief engineer, respectively, were in charge of the construction. Mr. Weatherly was sent in by the Burlington Line as a division engineer. After a short time on the east division, he was moved to the middle or second division. This division included the Union Station grounds and tracks, and extended east to Kansas Avenue, Kansas City. He had responsibility for the excavation of 630,000 cu yd of earth and rock on the station grounds. The waste from the excavation was hauled east or west over main-line tracks to build outlying yards. This job, being complicated by the use of railroad operating facilities, was done by company forces under the direction of the division engineer. Excavation was by steam shovel and the waste was hauled away first on flat cars and later in side dump cars. To keep the tracks in condition to carry these loads, large repair units were needed at both ends. The widening and deepening of the heavy main line cut to the east was handled in the same manner. This cut, two miles long, already two tracks wide and a maximum of 40 ft deep when the improvement started, was deepened to a maximum of 78 ft and widened to four tracks with many side cuts for industry. The quantities totaled 1,000,000 cu yd, all work being done under traffic. Concurrent with the foregoing was the construction by contract of seventeen street viaducts spanning the cut and retaining walls which ran almost continuously on one or both sides of the cut.

In 1914 most of the terminal work was finished, the Union Station was put in service, and the fine engineering organization which had been assembled for the purpose was disbanded. Mr. Weatherly considered returning to the Burlington Line, but abandoned the idea, and decided that the contracting field was more attractive. Early in 1915 he went out as superintendent on contract work for William M. List of Kansas City. In 1916 he entered into partnership with Mr. List, forming the firm of List and Weatherly, and under that name he continued in business until his death. Mr. List had at the time a successful business as a railroad contractor, and the new partnership was to handle concrete and steel structures on such work. Mr. Weatherly was vice-president and general manager of the new firm and was responsible for the conduct of its work.

Most of the firm's business was in the western part of the Mississippi Valley and was confined to heavy construction, such as bridges, intakes, viaducts, paving, etc. In 1934 the partnership was broken and Mr. Weatherly became president and owner of the business, as well as its active head. The List and Weatherly contracts cover 335 engagements ranging from small jobs to the Long-Allen Bridge over the Red River at Shreveport, La. This bridge was a $750,000 state highway project undertaken in 1930. The completion was delayed on account of shortage of state funds. The successful completion of this contract in 1933 was a matter in which Mr. Weatherly took great pride.

Mr. Weatherly was a member of the Associated General Contractors of America. He was treasurer of the Missouri Branch of the organization in 1929, and its president in 1930. E. C. L. Wagner, M. ASCE, manager of the branch, advises that Mr. Weatherly interested himself in and forwarded the work of the contractors in the matters of "Prequalifications of Bidders" and a depreciation rate schedule for construction equipment. The former was a practice adopted by the Missouri State Highway Department in 1930, whereby a bidder on a contract satisfied the owner—in advance of making a bid—that the contractor was qualified by experience and resources, etc., to undertake the work. The latter was an authoritative rate schedule to be used by bonding companies and in tax matters. This resulted in the adoption in 1931, by the Bureau of Internal Revenue, of a schedule set up by the Associated General Contractors.

Mr. Weatherly got much out of his university work. In addition to his degree, he was elected a member of Tau Beta Pi. His extracurricular interests included membership in Kappa Sigma fraternity. He achieved some prominence in amateur tennis circles while at the university, and continued to enjoy an occasional game until late in life. As his tennis game slowed, he took up bridge. At this game he was excellent, and he was an indulgent partner and opponent. Mr. Weatherly was a soft-spoken man of friendly, nonaggressive demeanor, who made his way through life with a minimum of upsets to an even-tempered disposition. It was extremely seldom that he found sufficient cause for an angry remark or harsh argument. He was a tall, well-built man, who enjoyed the out of doors. A love of the land survived from his early training, and found outlet in supervision of his farm investments, a country summer home, and in the last year of his life—although a semi-invalid—in a victory garden. He was a member of the Christian Church. In politics, he was an Independent Democrat. He was a member of the Masonic Order, Blue Lodge, having taken his degrees at St. Joseph.

On September 23, 1903, Everett Weatherly was married to Rose Drescher of Hannibal, who, with two sons, Edward H. and Everett P., survives him. To two other boys, Edward and Joseph Bounds, orphaned nephews of his wife, he was almost a father. He took them to his home, looked after their estate, and guided them to manhood.

Beginning early in 1909, Mr. Weatherly's home and business headquarters were in Kansas City. Mr. Weatherly was a member of the American Railway Engineering Association.

Mr. Weatherly was elected a Member of the American Society of Civil Engineers on April 30, 1912.

EINAR WEIDEMANN, M. ASCE[1]

Died November 12, 1941

Einar Weidemann was born near Trondheim, Norway, on May 29, 1877, the son of Einar and Johanna (Tonder) Weidemann. He received his preparatory and technical education in Norway, and was graduated from the Technical Institute at Trondheim in 1897 with the degree of Civil Engineer.

Mr. Weidemann served as an engineer for the Norwegian State Railroads from 1897 to 1902. In the spring of 1903, he came to Pittsburgh, Pa.; and in that and the following year served as draftsman for the American Bridge Company, and other structural steel companies. In 1904 he became assistant to Hermann Laub, consulting engineer of Pittsburgh, remaining with Mr. Laub until 1909. During this period his work included design of several river bridges and design and supervision of construction of industrial buildings.

In 1909 he was employed by the Pennsylvania Railroad Western Lines in the office of the chief engineer, Maintenance of Way, at Pittsburgh. Here he devoted practically all his energy to the design of powerhouses and enginehouses, shops, docks, highway bridges, and a multitude of railroad facilities during the period of expansive railroad construction. In 1914, in acknowledgment of his excellent performance of these duties, he was placed in responsible charge, under the chief engineer, of structural designs of the Pennsylvania Freight Terminal in Chicago, Ill., which, in view of its massive and novel development, was a major undertaking.

During the period of development and construction of the Chicago Union Station (1916 to 1926), in which the Pennsylvania Railroad Company participated, Mr. Weidemann was granted leave from his normal duties. On January 1, 1916, he was appointed structural engineer; and, on January 1, 1923, engineer of buildings and structures for the Station Company. He served in these capacities until the completion of the new railroad terminal. Mr. Weidemann was responsible for the preparation of plans and specifications for the various structures, including, besides the essential railroad facilities, several large street viaducts and bridges. Special features of this work included investigation of foundation problems; design of a reinforced concrete bed for supporting the station and approach tracks; and design of the heavy structural steel, concrete, and glass train sheds. The sheds were a new development, with columns centered on the passenger platforms, and roof structure spanning the intermediate tracks and separate trucking platforms.

---

[1] Memoir prepared by Joshua D'Esposito, M. ASCE.

When the Chicago Union Station was in satisfactory operation, Mr. Weidemann returned to the Pennsylvania Railroad Company, being appointed engineer of bridges on April 1, 1927; and on January 1, 1928, he was appointed engineer of bridges and buildings of the Western Region which position he held at the time of his death.

Mr. Weidemann was thorough and accurate in engineering matters, preferring to weigh each problem carefully; but, having made his decision, he was positive in upholding it. No matter how perplexing a situation might become, he was sincere and pleasant, yet he had a becoming dignity that would not permit encroachment upon his authority. It was natural for him to give assistance within his field of knowledge, and to welcome advice from those in associated work. He had that rare ability of not offending those who might temporarily disagree with his opinions; and his quiet reserve and understanding sympathy resulted in the formation of lasting friendships.

The writer, who was associated with Mr. Weidemann for nearly twenty years, cannot remember a single incident when Mr. Weidemann expressed himself unkindly about any person or any organization. All respected him profoundly as an engineer, and valued him as a comrade and fellow man. In fact, Mr. Weidemann was one of nature's gentlemen, always kind and considerate, quiet and unassuming, but possessing a sense of personal dignity without the least vestige of arrogance. He was a lover of nature; and, like a good son of Norway, he enjoyed winter sports, and participated in some of them.

Mr. Weidemann was married on August 10, 1910, to Mary Louise Weidemann, daughter of Mr. and Mrs. Robert H. Weidemann. He is survived by his widow.

He was a member of the Western Society of Engineers and of the Chicago Engineers Club.

Mr. Weidemann was elected a Member of the American Society of Civil Engineers on January 17, 1927.

DETHIC HEWITT WOOD, M. ASCE[1]

Died November 3, 1945

Dethic Hewitt Wood, the son of Col. Gustavus Adolphus Wood and Lydia Caroline (Carpenter) Wood, was born on February 23, 1871, in Chattanooga,

---

[1] Memoir prepared by J. E. Morelock, M. ASCE.

Tenn. Colonel Wood was in command of the 15th Indiana Regiment during the Civil War in and around Chattanooga. He was so impressed with the beautiful scenery of Chattanooga and its environs that, shortly after the close of the war, he resided there permanently.

Dethic Hewitt Wood was named for his great-great-grandfather, Capt. Dethic Hewitt of the 24th Connecticut Regiment, Revolutionary War, killed in action in 1778 at the battle of Wyoming (Wilkes Barre, Pa.).

Mr. Wood was educated in the public schools of Chattanooga and at the University of Chattanooga. He was one of the first graduates from that institution after it qualified as a full college. He took a very active interest in the University during the remainder of his life—serving as chairman of the Building Committee for the construction of the football stadium and always being an active worker and contributor in all campaigns for raising endowment or building funds. He was a member of the Board of Trustees until his death.

He began his work in civil engineering in the employ of the City of Chattanooga, under the late Robert Malcolm Hooke, who was then city engineer. Mr. Wood served as rodman in 1888, as inspector on sewer construction and paving in 1889 and 1890, and as assistant city engineer in 1891 and 1892. During 1892 and 1893 he was engaged in the general practice of engineering for various parties, on railroad location, land subdivision, and mining engineering. During 1894 he was assistant engineer in charge of location and construction of a sewage system for the City of Meridian, Miss. In Meridian he met Miss Alnita Hasselle to whom he was married in 1897.

In 1895 he was engaged as assistant engineer on the survey of Shiloh National Military Park, near Corinth, Miss. On January 1, 1896, he became associated with the late William Hassen Converse, acting first as designing engineer, and later as chief engineer, for the Converse Bridge Company of Chattanooga. When this company was reorganized in 1914, as the Converse Bridge and Steel Company, Mr. Wood became president of the company, a position he held until retirement from active work in 1943. Under his management, this company grew to be one of the leading industries of its kind in the South. During his long connection with the company, he designed and erected many large steel bridges and buildings throughout the South.

About 1925 Mr. Wood became interested in the Southern Chemical Cotton Company of Chattanooga. This company was just beginning the processing of cotton linters for use in the new field of plastics. Mr. Wood served as president of the company from 1925 until 1943—during which time the company became one of Chattanooga's leading and most prosperous industries.

During the nineteen twenties Mr. Wood became interested in banking. He was associated with, and was very active in, the management of various banks for the remainder of his life. At the time of his death he was a director of the American Trust and Banking Company of Chattanooga.

Mr. Wood's vital energy appeared in all his activities both business and social. Although, in later years, executive and financial duties took most of his attention, he was always intensely interested in any engineering problem that might arise. Subordinates might hold the nominal title and responsibility; but Mr. Wood, through his engineering talent and intensive energy, was the chief engineer of any project with which he was connected. In all human relationships his sympathy and understanding of problems were very keen.

In 1943 Mr. Wood retired from active work, becoming chairman of the Board of Directors of the Converse Bridge and Steel Company, and director and vice-president of the Southern Chemical Cotton Company. He also retained his position as director of the American Trust and Banking Company. Mr. Wood served as president of the Chattanooga Manufacturers' Association for two terms—1918 to 1919 and 1919 to 1920. He belonged to the Rotary Club, from 1915 to 1935, Chattanooga Lodge, F. and A.M., John B. Nicklin Chapter, R.A.M., Lockout Commandery Knights Templar, and Alhambra Shrine. He was a life member of Park Lodge, Knights of Pythias, a charter member of the Chattanooga Engineers' Club, and a member of the Mountain City Club. He was an active church member, and had been a member of the Board of Deacons of the Central Presbyterian Church since 1910.

He is survived by his widow; a son, Percy H. Wood; a daughter, Merle (Mrs. B. C. Holtzclaw); and five grandchildren.

Mr. Wood was elected an Associate Member of the American Society of Civil Engineers on February 6, 1907, and a Member on November 1, 1910. He became a Life Member in January, 1942.

AUGUST ZIESING, M. ASCE[1]

DIED FEBRUARY 16, 1942

August Ziesing, the son of Henry and Katherine (Brenneman) Ziesing, was born on February 19, 1858, in Peru, Ill., where he spent the early years of his life. His father was a country physician and surgeon, and one of August's duties was to drive his father about the countryside to the homes of patients. From this early association with horses and their care undoubtedly came his later interest in blooded driving horses, which lasted through most of his life until, as he put it, "The automobile drove me off the road." Since his birthplace was the center of a farming country, he spent his summer vacations on his father's farm as well as on the farms of other relatives in the vicinity. Probably because of this early experience he cultivated a liking for agricultural pursuits.

His early education was obtained by private tutoring and was rather intensive since he entered the University of Illinois in Urbana at the age of sixteen. He was graduated with a Bachelor of Science degree in 1878. The degree of Civil Engineer was conferred on him by the University of Illinois in 1905. He was also an honorary member of Tau Beta Pi, an engineering honor society.

---

[1] Memoir prepared by Albert F. Reichmann, M. ASCE.

After graduation, he was employed for two years (1878 to 1880) as a draftsman with M. Lassig, a bridge builder of Chicago, Ill. From 1880 to 1882, he was employed by the Pennsylvania Railroad Company at Pittsburgh, Pa., as bridge engineer and inspector of iron material and structures. Later he became assistant engineer, in charge of a party relocating a line for double tracking, straightening out curves, and reducing grades on the Pittsburgh, Fort Wayne and Chicago Railway, between Smithsville and Shreeve in Ohio, and in charge of the construction of this line as located. He also supervised parties on preliminary surveys of several connecting lines in Ohio.

In 1882, he became chief draftsman of the Lassig and Alden Bridge Company of Chicago. He was made chief engineer when Mr. Lassig secured control of the company. Later he was appointed general manager and chief engineer of the Lassig Bridge and Iron Works, remaining until August, 1897.

From 1897 to 1901, he was engaged in private practice as a consulting engineer, specializing in the design of iron and steel structures. In this capacity he was employed as consulting engineer of bridges by the Chicago Rock Island and Pacific Railroad, the Chicago and Alton Railroad, the Chicago, St. Paul, Minneapolis and Omaha Railroad, and the Rock Island and Peoria Railroad companies. Also he was employed by five other western railroads, and he designed track elevation at Sixteenth Street in Chicago. Probably the most outstanding structure which he designed was the Missouri River Bridge for the Chicago and Alton Railroad at Glasgow, Mo.

During the time that Mr. Ziesing was engineer for the Lassig Bridge and Iron Works, he directed the designing, construction, and sales of the products of the company. Many of the prominent railroads in the Middle West did not have their own bridge designing departments and depended upon contractors to furnish complete designs with their bids. This all around experience in the three major departments of a structural concern gave him an unique position which undoubtedly influenced his appointment as vice-president and western manager of the American Bridge Company in 1901. He was elected president on September 31, 1905. He held this office until his retirement on April 1, 1927.

About the time he assumed the presidency of the Bridge Company, which had just previously become a subsidiary of the United States Steel Company, a great forward movement in the country's economic development was beginning. It was characterized by extended and improved rail lines, new terminals, heavier locomotives and hence heavier bridges, increased spans (required by the government) over navigable streams, taller buildings, and the rapidly expanding automobile industry.

As modern structures increased in both size and weight, steel of greater strength and larger section became economical. At first a high carbon steel was used and later silicon and other alloys were introduced. The wide flange beam was an even more economical innovation, both as to weight and fabrication cost. These changes necessitated the installation of improved and heavier machinery. During this development period a modernization plan was started, directed, and brought to a successful conclusion by Mr. Ziesing. The Ambridge Plant near Pittsburgh, Pa., the Ambridge Barge Yard, the Elmira (N. Y.) Plant, the Gary (Ind.) Plant, and the Shiffler Tower Plant were all built under his immediate direction and according to his ideas of modernization. Mr. Ziesing also supervised the construction of the Williamsburg Bridge and the Hellgate Bridge (connecting railway), both over the East River in New York.

During his presidency the company fabricated and built the steel structure of many of the largest buildings in the United States. Among them were the Chicago Union Station, the Stevens Hotel, the Palmer House, and the Pure Oil and Bankers buildings in Chicago; and the Metropolitan Towers, the Woolworth Building, and the American Telegraph and Telephone Building in New York, N. Y.

Thus, his most important professional accomplishments were interrelated with a natural expansion in the steel industry and a great growth in the American Bridge Company.

In 1909 Mr. Ziesing bought a large farm in Deerfield, Ill., where he concentrated on the breeding of fine Guernsey cattle. He worked out his own ideas of crossbreeding to produce large stock with heavy production strains but without loss of the quality of the milk. Because of his success in this line he was awarded, by the American Guernsey Cattle Club, a silver pitcher on which were inscribed these words: "May 11, 1938—In recognition of his constructive work in breeding Guernsey cattle over a period of 30 years." His herd at one time was adjudged as fine in quality as any Guernsey herd in the United States.

Although, during his business life, his duties frequently took him away from home, he was, nevertheless, a home lover and maintained a beautiful place in Glencoe, Ill. He surrounded himself with his closest friends. His home life was very simple and his tastes modest. In his later years, besides continuing to superintend the raising of cattle, he spent most of his time reading books, classics in English, French, and German, which he had not had the opportunity to read during his active business life.

Mr. Ziesing was married to Alice C. Hanna of Wooster, Ohio, on February 27, 1884. They had five children: Mabel, Henry Hanna, Margaret (Mrs. Mark D. Rector), Gertrude (Mrs. James S. Kemper), and Katherine (Mrs. Katherine Van Cleave).

He joined The Western Society of Engineers on June 5, 1889, and served as a trustee from 1899 to 1902. He was a member of the American Railway Engineering Association, University Club, Union League Club, Chicago Engineers' Club, and the Skokie Country Club.

Mr. Ziesing was elected a Member of the American Society of Civil Engineers on October 5, 1898.

EARL CURTIS ALEXANDER, Assoc. M. ASCE[1]

DIED FEBRUARY 9, 1942

Earl Curtis Alexander was born in Frankfort, Ind., on March 2, 1883, the son of Wilkenson and Ida (Thompson) Alexander.

His early education was received in the schools of Frankfort. In 1902 he began his civil engineering studies at Purdue University, Lafayette, Ind.; these were continued until 1905, at which time he was employed in the engineering department of the Chicago, Rock Island and Pacific Railway Company.

In 1906 he became a member of the engineering staff of the Philippine Railway Company, and for two years was employed by the railway company and J. G. White and Company, contractors, on location and construction of bridges. Returning to the United States in 1909, he was associated with the bridge department of the Illinois Central Railroad Company as a draftsman; then for a period of five years, from March, 1910, to October, 1915, he was assistant engineer of the Northern Pacific Railway Company in charge of bridge construction, including considerable work on heavy foundations and the installation of drawbridges. In 1915 he returned to the Illinois Central Railroad Company to devote his training and experience to the design of concrete and steel structures. In 1918 he joined the staff of the Massey Concrete Products Corporation as an estimator, and served subsequently from 1921 until 1928, as assistant chief engineer. All his engineering and business experience subsequent to 1918 was devoted to the far-flung activities of the Massey organization. In 1928 he was designated manager of factory operations and, from then until 1940, had complete charge of all plant construction and all production problems. In 1940 he was appointed chief engineer, and, until his death, served in that capacity, continuing at the same time his previous function as manager of operations.

Mr. Alexander was well liked by all his associates; was ever faithful to his duties; and, as one of the pioneers in pre-cast concrete construction, had a large part in developing this field for the railroads, municipalities, and the construction field in general. He had a wide acquaintanceship among the membership of the Society and others engaged in similar work. His untimely death is a distinct loss to his industry and to the profession.

For many years, he was a member of the Chicago Engineers Club, the Western Society of Engineers, and several railway engineering organizations.

On December 27, 1911, Mr. Alexander was married to Hazel Israel. His widow; one son, Maj. William Alexander, U. S. Army; and two daughters, Mary (Mrs. D. F. Hunzilie, Jr.) and Peggy Jean Alexander survive him.

Mr. Alexander was elected an Associate Member of the American Society of Civil Engineers on June 19, 1922.

---

[1] Memoir prepared by G. H. Redding, Pres., Massey Concrete Products Co., Chicago, Ill.

CHARLES NEWTON BAINBRIDGE, Assoc. M. ASCE[1]

Died July 1, 1941

Charles Newton Bainbridge was born in Philadelphia, Pa., on March 29, 1887, the son of George M. and Mary Malinda (Coulson) Bainbridge. In 1907 he received the degree of Bachelor of Science in Civil Engineering from Pennsylvania State College at State College. For a year thereafter he was a draftsman with the American Bridge Company, and then he returned to his alma mater as an instructor in civil engineering. He received the professional degree of Civil Engineering from the college in 1910.

In 1909 Mr. Bainbridge entered the engineering department of the Chicago, Milwaukee, St. Paul and Pacific Railroad Company, under Charles F. Loweth (Past-President, ASCE), and remained in its service until 1933, with the exception of a six months' interval with the Baltimore and Ohio Railway Company in 1911. While with the Chicago, Milwaukee, St. Paul and Pacific Railroad Company, he worked in the positions of draftsman, squad foreman, office engineer, and engineer of design. As office engineer he had charge of detail, design, and special studies for grade separation projects in Minneapolis, Minn., Milwaukee, Wis., Chicago, Ill., and Evanston, Ill. As engineer of design he was responsible for the design of bridges and structures on the following track separation projects of the railroad company: Mayfair track elevation in Chicago from Irving Park Boulevard to Forest Glen; North Side track depression in Milwaukee, Wis., with reinforced concrete overhead highway crossings; and track elevation north of Church Street in Evanston, Ill.

After leaving the railroad company, Mr. Bainbridge was engaged by the Public Works Administration on various projects.

In 1910 Mr. Bainbridge was married to Lillian Schwab of Chicago. He is survived by his widow; two children, Mary Katherine (Mrs. G. W. Stephens) and Charles Newton Bainbridge; two grandchildren, Glenn and David Stephens; and a brother, Edmond Bainbridge.

The home of Mr. Bainbridge was at Lombard, Ill. He took an active interest in the affairs of his community, being a Village Trustee for ten years, president of the Zoning Board, and president of the First Trust Bank of Lombard. At all times he was ready to give the village the benefit of his engineering ability and experience. He was a loyal friend and was held high in the esteem of all those who came in contact with him. He was a Royal Arch Mason.

Mr. Bainbridge became an Associate Member of the American Society of Civil Engineers on October 9, 1917.

---

[1] Memoir prepared by Theodore Lovel Donner Hadwen, M. ASCE.

WALTER CHRISTMAS BODYCOMB, Assoc. M. ASCE[1]

Died December 1, 1944

Walter Christmas Bodycomb, the son of Rosser and Mary (Christmas) Bodycomb, was born at Olyphant, Pa., on June 5, 1875. Both parents were of Welsh descent. The family moved to Wilkes-Barre, Pa., in 1882, where Walter obtained his education in the grade schools and high school. From the Wilkes-Barre High School he went to Wyoming seminary, at Kingston, Pa.

He was employed first by I. E. Hartwell and later by the Crescent Coal Mining Company, both of Wilkes-Barre, as rodman, chainman, and transitman. In 1898 and 1899, he worked on railroad locations for the El Paso Northern Railroad and with the New Mexican Fuel Company, prospecting and surveying for coal lands in New Mexico.

For two years he was employed by Westinghouse Church Kerr Company, as inspector of bridge construction on the Lackawanna and Wyoming Railroad. In 1903 and 1904, he was with G. W. Milnes as chief of party on railroad, land, and mine surveying, with headquarters at Clarksburg, W. Va.

In 1904, he returned to Westinghouse Church Kerr Company, continuing with that firm and its successors until his death. For about six years he was field engineer on location and construction for the Lackawanna and Wyoming Valley Railroad at Scranton, Pa.; on location of B. F. and H. Railway at Frederick, Md.; on hydroelectric reports, appraisals, and surveys; and on the construction of the Chicago, Burlington and Quincy Railroad Company at Havelock, Nebr.

Beginning in 1910, for thirty-four years, Mr. Bodycomb was employed as superintendent of construction on heavy industrial and railroad work—his ability in handling the many problems of management being demonstrated repeatedly on important jobs. He supervised the building of the Westinghouse Electric and Manufacturing Company plant, consisting of heavy reinforced concrete factory buildings and power plant, at Newark, N. J. In 1912 the J. I. Case Threshing Machine Company built the South Works Plant at Racine, Wis., under his direction, including foundry, machine, and erection shops, with sewers, water supply, and power distribution. He then rebuilt the shops of the Chesapeake and Ohio Railroad Company, at Peru, Ind. (after they had been destroyed by fire and flood). A notable feat of engineering-construction work was accomplished under his direction in correcting the uneven foundation settlement of the Empress Hotel in Victoria, B. C., Canada. To obtain relief of an overloaded area some 25,000 tons of earth were removed and replaced with concrete decking, thus preventing further settlement of the south wing.

In 1914, Mr. Bodycomb supervised improvements for the Canadian Pacific Railroad Company at Winnipeg, Man., Canada, including track elevation, main street subway, and remodeling the station and Royal Alexandria Hotel.

---

[1] Memoir prepared by Wallace E. Belcher, M. ASCE.

During World War I (in 1915), he was field engineer on a rush plant for the Aetna Explosives Company, at Drummondville, Que., Canada, where a complete powder manufacturing plant with seventy-five buildings covering six hundred and forty acres, was completed in twenty weeks. Also, in 1915, he supervised construction of the East St. Louis Cotton Oil Company plant, and, in 1916, the Lehigh Valley Railroad engine terminal at Niagara Falls, N. Y., with the usual powerhouse, roundhouse, coaling station, turntable, and shops.

The construction and equipment installation of the Artillery Ammunition Assembly Plant, at Rock Island Arsenal, Rock Island, Ill., in 1917, was remarkable not only for the magnitude of the work, and the speed with which it was accomplished, but also for certain methods developed to meet conditions, such as:

(*a*) The pouring of mass concrete in subzero weather by a system of steam piping to protect the concrete from the time it entered the feeding chutes;

(*b*) Rock excavations under winter conditions where vast quantities of water were encountered; and

(*c*) The construction of the first modern igloos for storage of explosives—accomplished without removing any of the natural forest by offsetting lines to avoid clearing.

After this war work came the building of the Baltimore and Ohio Railroad Company shops at Cumberland, Md.; the construction of a fifteen-stall roundhouse for the Pittsburgh and West Virginia Railway Company at Rook, Pa., the remodeling of the locomotive shops of the Pennsylvania Railroad at Fort Wayne, Ind.; and the construction of the new shops for the Westinghouse Electric and Manufacturing Company extension at Essington, Pa.

The Westinghouse Church Kerr Company became part of the organization of Dwight P. Robinson and Company in 1920. Mr. Bodycomb's first assignment was superintendent on a four-story, reinforced concrete, manufacturing plant for the Westinghouse Lamp Company at Indianapolis, Ind., followed by the construction of a five-story, reinforced concrete, hotel building for the Middletown Hotel Company, at Middletown, Ohio.

At the American Rolling Mill Company plant in Ashland, Ky., Mr. Bodycomb supervised blast furnace improvements and general mill construction including the installation, under secret processes, of the first continuous strip steel mill in 1922. Later for the same company, at Middletown and at Butler, Pa., he constructed blooming mills, open hearth furnaces, a rolling mill, other buildings, and equipment.

In 1924, he built the locomotive repair shops for the Southern Railway at Birmingham, Ala. At Bessemer, Ala., the construction of car shop, machine shops, lumber storage, dry kilns, power plant, and office—a project costing five million dollars—was handled in record speed for the Pullman Car Manufacturing Company. The United Engineers and Constructors, Inc., of which Dwight P. Robinson and Company became an integral part, was formed in 1928.

In 1930, for the St. Joseph Lead Company plant at Josephtown, Pa., Mr. Bodycomb built an electric furnace zinc oxide smelter. Then followed the construction of improvements for the Public Service Gas and Electric Company at the Kearny and Burlington power plants. Additional buildings for the United States Pipe and Foundry Company were completed at Chattanooga, Tenn., in 1935 and 1936. A complete plant for making asbestos pipe was constructed for the Keasbey and Mattison Company at Ambler, Pa.

From 1940 to 1942, Mr. Bodycomb supervised the erection of the United States Navy Power Plant at Parris Island, N. C. His last work as construction superintendent was the steam power plant for the Republic Steel Corporation at Cleveland, Ohio, finished on May 1, 1944. He then retired to St. Petersburg, Fla., where he lived until his death.

Mr. Bodycomb was a lifelong member of the Westminster Presbyterian Church of Wilkes-Barre, and a devoted member of the Masons and of the Shrine. He took an active interest in the Westinghouse-Church-Kerr Alumni Association.

In 1902, Mr. Bodycomb was married to Caroline Booth at Forty Fort, Pa. She died in 1915. In 1917 he was married to Helen B. Smith at St. Louis, Mo. He is survived by his widow; his daughter, Irma Joyce Bodycomb; and three sons, Frederick, Walter C., Jr., and Capt. Rosser I. Bodycomb.

Mr. Bodycomb was elected an Associate Member of the American Society of Civil Engineers on September 2, 1914.

CHARLES BARTO BROWN, Assoc. M. ASCE[1]

Died November 2, 1944

Charles Barto Brown, the son of Charles Edgar and Henrietta (Hitchcock) Brown, was born on September 22, 1873, in New Haven, Conn. He received his early education in the schools of that city, and was graduated from Sheffield Scientific School in 1894 with the degree of Bachelor of Philosophy. He received the degree of Civil Engineer from Yale in 1896.

After graduation he was employed on general city engineering work in and around New Haven; later going to Binghamton, N. Y., where he became a member of the Chenango Engineering Company, and was engaged in preliminary surveys, estimates of cost, and estimates of traffic for thirty-two miles of steam road. From July, 1898, to May, 1903, he left engineering and became connected with Connecticut State Department of Insurance, and, during the last year, was in charge of actuarial work. In the succeeding twenty months he suffered an illness, after which, in March, 1905, he became connected with the New Haven Gas Light Company as inspector on heavy foundations and building construction on contracts involving several millions of dollars. In August, 1906, he went to the University of Maine, at Orono, as instructor in civil engineering. He soon won promotion, and in 1908 became professor of railroad engineering. In 1916 his title was changed to professor of civil engineering.

---

[1] Memoir prepared by Harold S. Boardman, M. ASCE.

Although Professor Brown was an excellent teacher and successful in his work at the University, he never lost his desire for a business life. He resigned in 1919 and returned to New Haven, where he became associated with Frederick M. Ward Company, real estate and mortgages. He remained until 1928. The following year he was state appraiser for the United States Bond and Mortgage Corporation of Connecticut. In 1929 and 1930 he was state appraiser for the Connecticut Mortgage and Title Guaranty Company of New Haven. In 1930 he went into the mortgage department of the Connecticut Savings Bank of New Haven, and he was connected with this organization when he passed away.

As a teacher, Professor Brown was dignified, courteous, and sympathetic; he was keenly aware of the thoughts of those about him, and oftentimes took the troubles of the students as his own. In his business life his chief desire was to be of assistance to his clients without thought of reward. To those who knew him well he was a true friend, and his word was "as good as his bond."

He was interested in music, played the piano with more than average ability, and also was trained in vocal music.

He was a charter member of the Yale chapter of Sigma Xi, and a member of Tau Beta Pi, Phi Kappa Phi, and the Connecticut Society of Civil Engineers.

On October 21, 1896 he was married to Maude Manwaring; he is survived by his widow, and a daughter, Madeleine Brown.

Mr. Brown was elected an Associate Member of the American Society of Civil Engineers on February 4, 1914. He became a Life Member in January, 1944.

LEONARD DEMPSTER BROWNELL, Assoc. M. ASCE[1]

Died June 12, 1945

Leonard Dempster Brownell was born in Lassellsville, N. Y., on September 23, 1877, the son of Ezekiel Milton Brownell and Julia (Dempster) Brownell. He attended schools in Lassellsville and Gloversville, N. Y., and, in 1903, was graduated from Purdue University, Lafayette, Ind., with a degree of Bachelor of Science in Civil Engineering. He was awarded a Master's degree in Civil Engineering in 1910.

Mr. Brownell began his engineering career in 1899, as rodman with the Cincinnati, Hamilton, and Dayton Railroad Company at Cincinnati, Ohio. During vacations of his college years, he worked also as rodman for the

---

[1] Memoir prepared by William Robinson, Dist. Engr., State Dept. of Public Works, Syracuse, N. Y.

Delaware, Lackawanna and Western Railroad Company at Binghamton, N. Y. Following graduation from Purdue, he was, from June, 1903, to July, 1904, local manager of the Badger Coal Company at Beloit, Wis. In August, 1904, he entered the engineering service of New York State and remained in the state service until his death. His first assignment was at Syracuse, N. Y., as leveler in the department of the state engineer and surveyor. From March, 1906, until January, 1912, he held the title of assistant engineer and from that date until May, 1915, he was resident engineer in the same department. During these years his work was in connection with highway surveys, construction, preliminary studies for the Barge Canal structures, and hydraulic investigations connected with the Barge Canal improvement.

In May, 1915, he was transferred to the newly organized New York State Highway Department, and was in charge of construction and maintenance on various highways of the state system. His headquarters were at Syracuse. In February, 1920, he was appointed district engineer with headquarters at Utica, N. Y. After 1924 his duties were enlarged to include supervision of both highways and canals in the six counties comprising district No. 2. During this period he had an important part in the development of the present New York State Highway System.

In 1906 Mr. Brownell was married to Mabel Duane. He is survived by a son, Leonard Dempster Brownell; and two daughters, Jane (Mrs. Kenton Flint) and Emily (Mrs. Russel Dunmore). Mr. Brownell was a Thirty-Second Degree Mason and a member of Ziyara Temple. He was a member of the City Club of Utica and of the Sigma Alpha Epsilon fraternity. He was also an active member of the North Atlantic States Association of Highway Officials, and of the New York State Association of Highway Engineers.

Mr. Brownell was elected an Associate Member of the American Society of Civil Engineers on November 6, 1907.

WALLACE LYON CALDWELL, Assoc. M. ASCE[1]

DIED APRIL 2, 1945

Wallace Lyon Caldwell was born at Indianapolis, Ind., on July 23, 1888, the son of pioneer Indiana parents, William Caldwell and Elizabeth (Braden) Caldwell.

After completion of his education he taught for two years in the Manual Training High School of Indianapolis and was for three years engineering chemist for the City of Indianapolis. He left this position in 1912 to come to Birmingham, Ala., as paving chemist for the Pittsburgh Testing Laboratory. In 1913 he was advanced to manager of the Birmingham office. During this assignment he was the laboratory's paving consultant for the entire

---

[1] Memoir prepared by a Committee of the Alabama Section consisting of J. H. Mayer, M. ASCE, Chairman, R. D. Jordan, M. ASCE, and J. H. Conzelman, Assoc. M. ASCE.

United States. In 1921 he went to Louisville, Ky., as president of the Kentucky Rock Asphalt Company where he remained until 1927. Through his knowledge of the paving industry he greatly improved the technique of control and production of this native rock asphalt; this work had far-reaching effects. From 1927 to 1928, he was vice-president of the Peoples Light and Power Company. His duties with this company took him to all parts of the United States. He returned to Birmingham, in 1928, as president of the Alabama Asphaltic Limestone Company and served in this capacity until his death. He was widely known in Birmingham and the United States. At the time of his death he was also president of the Southern Vacuum Concrete, Inc., the Aerocrete Western Corporation of Chicago, Ill., vice-chairman of the Southern Research Institute, director of the National Association of Manufacturers, and past-president of the Associated Industries of Alabama.

In 1940 he was awarded the Modern Pioneer Award of the National Association of Manufacturers in recognition of distinguished achievement in the field of science and invention which advanced the American standard of living. His work in perfecting machinery which improved the quality and production of light aggregates did much for the industry.

Aside from his membership in the Society he was a member of the American Chemical Society, American Society for Testing Materials, American Society of Municipal Engineers, American Concrete Institute, Association of Asphalt Paving Technologists, and Engineers Club of Birmingham. Mr. Caldwell organized and was the first president of the Boys Club of Birmingham. He was always active in civic affairs and always ready to give of his time and talents to any project for the benefit of Birmingham or the State of Alabama. He was a deacon of the Independent Presbyterian Church and a member of the Rotary Club of Birmingham and the Mountain Brook Country Club.

On November 30, 1911, Mr. Caldwell was married to Leona Templeton of Indianapolis. He is survived by his widow; two daughters, Elizabeth Jane (Mrs. Glenn Means Tindall) and Lenore Lyon Caldwell; two grandchildren, Richard Caldwell and William Lyon Tindall; and two brothers, Dumont and Braden Caldwell.

Mr. Caldwell was a man of exceptionally fine character and moral worth. His attainments as a chemist, engineer, and scientist were widely known and recognized. His advice was freely sought and given in a great variety of scientific and industrial endeavors. This, coupled with his fine executive ability, and his long and varied professional experience and wide culture, made him a consultant of the first order in his chosen life work. The engineering profession has lost one of its most earnest and outstanding members in his death.

Mr. Caldwell was elected an Associate Member of the American Society of Civil Engineers on June 1, 1920.

BENJAMIN LEFEVRE COULSON, Assoc. M. ASCE[1]

DIED FEBRUARY 24, 1946

Benjamin LeFevre Coulson, the son of William and Martha (LeFevre) Coulson, was born on December 21, 1870, near Mason, Ohio. His parents died during his childhood, and his education was guided by an uncle, Benjamin LeFevre. He first attended the public schools near Mason and later Phillips Exeter Academy at Exeter, N. H. He was graduated from Rensselaer Polytechnic Institute at Troy, N. Y., in 1893.

Mr. Coulson was city engineer of Sidney, Ohio, from 1894 to 1897. In this capacity he designed and supervised the sanitary system for the city; and, serving as chief engineer of the Sidney Sewer Commission, from 1921 to 1923, he supervised the enlargement and modernization of the system. Mr. Coulson was an instructor in the Columbia Summer School of Surveying, at New York, N. Y., in 1897.

He moved to Hodgenville, Ky., in 1898, where he built and managed the Hodgenville Manufacturing Plant and the Hodgenville Electric Plant until 1901. In 1901 he supervised special track layouts for the Paige Iron Works, Harvey, Ill. From April, 1902 to March, 1906, Mr. Coulson was assistant engineer for the Louisville and Nashville Railroad Company. His important assignments, while serving in this capacity, were: Engineer in charge of improvements at Columbia, Tenn.—constructing new passenger and freight depots and a coaling plant, eliminating grade crossings, and enlarging and rearranging yards; and engineer in charge of construction of the new terminal at Knoxville, Tenn. From March, 1906, to May, 1907, he was employed as assistant engineer by the Erie Railroad Company in charge of the Mansfield and Ontario (Ohio) improvements, consisting of double tracking and rearrangement of yards and switching facilities at Mansfield. From May to December, 1907, Mr. Coulson was associated with the late John F. Stevens,[2] Past-President and Hon. M. ASCE, as division engineer on the valuation of the New York, New Haven, and Hartford Railroad. In 1907 and 1908, he served in the same capacity for the Erie Railroad.

Mr. Coulson was appointed professor of civil engineering at the University of the South at Sewanee, Tenn., teaching there from 1919 to 1924. During this time he designed and supervised the construction of a new Science Hall, to complete the quadrangle of the campus. He returned to valuation of railroad properties from 1914 to 1916, and was in charge of a division of such work for the Louisville and Nashville Railroad Company.

He was associated with the Jennings Lawrence Engineering Company of Columbus, Ohio, from 1916 to 1920—supervising the layout and construction of streets and sanitary systems for subdivisions and in charge of the construction of the sanitary system for the cantonment at Chillicothe, Ohio, in 1917. From 1923 to 1930, he was engaged in private practice at Cincinnati, Ohio. Mr. Coulson retired from active service in 1930, and in 1932 moved to Lakeland, Fla., where he had business and grove interests, remaining until his death. He was a member of All Saints Parish of the Episcopal Church at Lakeland, and F. and A. M. Lodge of Mason, Ohio.

---

[1] Memoir prepared by W. H. Coulson, County Extension Agent, Co-operative Extension Work, State of Ohio, Woodsfield, Ohio.

[2] For memoir, see *Transactions*, ASCE, Vol. 109, 1944, p. 1440.

Benjamin LeFevre Coulson was married to Mary E. Leadley in June, 1893. To this union two sons were born, William Henri and James. He is survived by both sons and a sister, Nettie (Mrs. F. J. Canty).

He retained an active interest in, and prided himself on keeping posted on, engineering techniques. He was possessed of a poised, well-balanced, and active mental capacity and a cheerful disposition to the end.

Mr. Coulson was elected an Associate Member of the American Society of Civil Engineers on May 6, 1908. He became a Life Member in January, 1941.

BERNARD REUVELT CROWLEY, Assoc. M. ASCE[1]

Died November 28, 1944

Bernard Reuvelt Crowley, the son of Jess Crowley and Maude (Davis) Crowley, was born on September 10, 1905, at Paris, Tex. From 1922 to 1926 he was a student in the Agricultural and Mechanical College of Texas, at College Station, Tex., studying textile engineering.

He began his civil engineering career in 1928, when he was employed by the Texas Highway Department at Paris, as chainman and rodman on highway location and construction projects. His entire professional career was in connection with this department where he was promoted through the various grades to resident engineer. In these various capacities he handled all types of surveys, plans, and construction incident to the development of a modern highway system.

Mr. Crowley's outstanding characteristics were honesty, industry, and loyalty. He was a good student and had the courage of his convictions, which enabled him to defend his decisions stoutly.

On December 24, 1933, he was married to Willa Merle Johnson, daughter of Mr. and Mrs. Era Johnson of Avinger, Tex. He is survived by his widow and one daughter, Marilyn Johnson Crowley.

Mr. Crowley was elected an Associate Member of the American Society of Civil Engineers on July 8, 1941.

---

[1] Memoir prepared by James E. Pirie, M. ASCE.

ERNEST BUEL DAY, Assoc. M. ASCE[1]

Died February 28, 1945

Ernest Buel Day was born in the Town of Jericho, in the State of Vermont, on April 14, 1884. His father, Hiram Byron Day, was also born in Jericho, and his mother, Persis (Goodwin) Day, in Milton, Vt. His ancestors settled in Vermont. A monument in Underhill, Vt., commemorates members of the Brown branch of his family who were twice kidnapped by the Indians, but escaped each time. Mr. Day, himself, served five years with the Seventh Regiment of the New York National Guard.

Orphaned at the age of nine, he went to live with an uncle in Fort Worth, Tex. He later attended the Manual Training School of St. Louis, Mo., where he was the valedictorian of his graduating class. In 1906 on his graduation from the evening course in general science of Cooper Union for the Advancement of Science and Art, in New York, N. Y., he received the degree of Bachelor of Science; in 1919, the postgraduate degree of Civil Engineer was conferred on him.

From July, 1901, to August, 1906, he was a draftsman with the Manhattan Elevated Railroad Company of the City of New York; and, from August, 1906, to February, 1909, he served in a similar capacity with the Board of Education of the City of New York.

On February 26, 1909, he became a draftsman in the engineering department of the Hudson and Manhattan Railroad Company, New York City; a designer in September, 1909; an assistant engineer in December, 1911; and engineer of design in March, 1921, holding that position with this company until his demise on February 28, 1945. He was a licensed professional engineer in the State of New York.

While in charge of the design department of the Hudson and Manhattan Railroad Company, he was given many important assignments. He designed a number of this company's stations and buildings above and below ground surface as well as additions and changes to tunnel structures, improvements to rolling stock, and other numerous problems relating to railroad practice.

On the day of his death he went to his office apparently in good health, but passed away suddenly in the afternoon. He is survived by his widow, the former Eleanor Hubbard Miller, to whom he was married on April 2, 1915; and a daughter, Marjorie.

A man of tireless energy, and of pleasant instant response, he was greatly respected and esteemed by the management and the employees of the Hudson and Manhattan Railroad Company, which it will be noted he served for a period of thirty-six years.

Mr. Day was elected an Associate Member of the American Society of Civil Engineers on April 2, 1913.

---

[1] Memoir prepared by James Forgie, M. ASCE.

HARRY KERCHEVER DEVLIN, Assoc. M. ASCE[1]

Died May 8, 1945

Harry Kerchever Devlin was born in Toronto, Ont., Canada, on July 23, 1891, the son of James Kerchever and Minnie (Carney) Devlin.

Mr. Devlin received his training as civil engineer at McGill University, Montreal, Que., Canada. On January 11, 1915, he enlisted in the Sixth Canadian Engineers in World War I. Upon arriving in England he was transferred to the British Field Engineers, with whom he served throughout the war with rank of First Lieutenant. While in France, as field engineer, his work covered such matters as army bases, water supply, railheads, casualty clearing stations, hospitals, roadwork, and narrow gage railroads. On returning to the United States he became field engineer with the U. S. Structural Company of Detroit, Mich., and was in charge of the layout for the construction of the Hudson motor car plant.

In recent years, and until his last illness, he was chief estimator with Gibbs and Hill, Inc., of New York, N. Y., for foundations, abutments, overhead bridges, catenary structure, and substations in the electrification of the Pennsylvania Railroad from New York to Washington, D. C. He was also estimator in connection with construction of power stations, transmission lines, and various industrial projects. These included, for example, a power station at San Antonio, Tex., the Lake Charles (La.) power plant, the Dilles Bottom plant, and the power station of the Jones-Oslow Power Corporation; a transmission line of the Consolidated Edison Company in Brooklyn, N. Y.; and industrial plants of the Detroit Sulphite Pulp and Paper Company, the American Viscose Company, and the Utica Knitting Company.

Of his earlier connections may be mentioned the U. S. Structural Company (1919-1923), where he was field engineer in charge of the layout of the Dayton Power and Light Company's station, and of the Hellgate power station; he was estimator and job runner on the construction of the extensive Coral Gables development in Miami, Fla. He was also engaged on the construction of schools and hospitals in New York State in the employ of Deriso Brothers, Inc. For Starrett Brothers and Eken, he worked on the Williamsburg housing project. As estimator for A. L. Hartridge of New York, he was associated, among other things, with seven projects at the New York World's Fair. Among his first activities in 1940–1941 was the preparation of estimates for competitive bidding on Curtiss-Wright Corporation plants; this was followed by estimates for the Trinidad Naval Base prepared on behalf of the James Stewart Associates of New York.

For avocations Mr. Devlin turned to hunting, fishing, and boating. He built his own sailboats and motorboats. In his high school days and at McGill University he played on the hockey team, and in one season won a special prize.

---

[1] Memoir prepared by Alfred J. Lotka, Asst. Statistician, Metropolitan Life Insurance Co., New York, N. Y.

He was a member of Keystone Lodge, of the Masonic Order in Sault Ste. Marie, Ont., Canada; a member of the Society of American Military Engineers; and a member of the Technical Valuation Society. A mere list of Mr. Devlin's activities, such as here recited, although testifying to his varied experience and his excellence in his profession, gives only a very incomplete picture of the man in his total human relations. His was the modesty that so often accompanies high competence; and the personal worth that made him a friend firm and true. The writer deeply appreciates the privilege of having been chosen to pay these last respects to him.

Mr. Devlin is survived by his widow, Florence Perkins Devlin.

Mr. Devlin was elected an Associate Member of the American Society of Civil Engineers on May 11, 1936.

EMERSON DOLLIVER, Assoc. M. ASCE[1]

Died December 2, 1944

Emerson Dolliver was born in Milwaukee, Wis., on April 19, 1897, the son of John Walter and Marth (Fernekes) Dolliver. His grandfather, Capt. John Sargent Dolliver, sailed around Cape Horn in 1850, was a pilot on the Yangtze River in China until 1864, and for forty-six years thereafter was a bar pilot at San Francisco, Calif. One of his most noted exploits was the rescue of the English ship, *Jessomene,* during the great hurricane of February, 1891. Mr. Dolliver's father likewise followed the sea, but forsook it to study in Germany, afterward returning to the United States and settling in Milwaukee. Six months after Emerson was born, he moved to San Francisco where he practiced architecture until his death in June, 1927.

Emerson Dolliver obtained his early schooling in Marin County, California, being graduated from the Tamalpais High School in 1916. Entering the service of his country on October 16, 1917, he was first assigned to the 28th Engineers. He left the United States on January 3, 1918, assigned to the Transportation Headquarters Troop, 2d Army Corps, and saw active service with the American Expeditionary Forces in the Somme Offensive, the Ypres-Lys Defensive Sector, and other operations in Belgium. He also took part in the attack on the Hindenburg Line (Bellicourt, Nauroy, and Bony) from September 29 to October 2, and in the attack on Brancourt, St. Souplet, Selle River, and Mazingham (with Corps troops) from October 7 to 21. As a Private First Class, he landed in the United States on February 19, 1919, and received his honorable discharge at the Presidio in San Francisco on March 18, 1919.

He entered the College of Engineering of the University of California at Berkeley, Calif., and was graduated in 1923 with the degree of Bachelor of

---

[1] Memoir prepared by Stewart Mitchell, M. ASCE, and William H. Holmes and Theodore Neuman, Assoc. Members, ASCE.

Science in Civil Engineering. He was a member of the Alpha Chi Rho fraternity. After graduation he was employed by the county engineer of Marin County on highway location and bridge design. As a member of the contracting firm of Dolliver and Cuffe, in San Rafael, Calif., he was engaged in building roads and small structures for the county and for the town of Larkspur, Calif. In 1927, he was employed by the Wallace and Tiernan Company, of Newark, N. J., as sanitary engineer, and later became their district manager with headquarters at Seattle, Wash. At the close of 1932, he went on active duty as a Second Lieutenant in the U. S. Army Reserve Corps serving with the Civilian Conservation Corps, and later was employed as an engineer by the Federal Land Bank. From August, 1936, to March, 1938, he was employed by Charles H. Lee, M. ASCE, as assistant hydraulic engineer on the construction of works on Treasure Island, San Francisco, for the Pan-Pacific Exposition.

On April 1, 1938, Mr. Dolliver was appointed an assistant hydraulic engineer in the Division of Water Resources of the California Department of Public Works. Four years later, he advanced to the grade of associate hydraulic engineer and served as office engineer for the Department of Dams until his death.

Emerson Dolliver had many interests outside of his daily work. He was an active member of the Sacramento Section of the Society, serving on the Committee on Juniors in 1939, on the Program Committee in 1940, and as Secretary in 1941. He was a delegate to the Local Section Conference in San Diego, Calif., that same year. Intensely interested in the subject of mapping, he spoke before the Local Section in February, 1939, on the subject of "A Plane Coordinate System for California." At the time of his death he was chairman of the Aerial Mapping Project Committee of the State Reconstruction and Reemployment Commission.

His interest in the welfare of boys was outstanding as shown by his activities in scouting. He had been a boy scout himself and had served as an assistant scoutmaster. After becoming a resident of Sacramento, Calif., he assumed a leading part in this group, first as a troop committeeman and then as the promoter and organizer of Cub Packs. In January, 1943, he was made a board member on the Golden Empire Council of the Boy Scouts of America and held this position until his death. In addition to scouting, Mr. Dolliver found time to take part in many other civic activities such as civilian defense work following Pearl Harbor. Those with whom he worked will miss the friendly nature and sense of humor that lightened many tasks.

On September 19, 1925, he was married to Kathrine Green of Berkeley. Mrs. Dolliver and their three sons, Robert Emerson, Richard Sargent, and Peter Clarke, survive him.

Mr. Dolliver was elected a Junior of the American Society of Civil Engineers on January 14, 1924, and an Associate Member on March 11, 1929.

THOMAS JONES HENDRIX, Assoc. M. ASCE[1]

Died December 31, 1944

Thomas Jones Hendrix, the son of Clyde and Estelle Hendrix, was born in Decatur, Ala., on February 8, 1909. After completing his high school course in the local public schools, he entered Alabama Polytechnic Institute at Auburn, from which he was graduated in 1930 with the degree of Bachelor of Science. He was a member of the Pi Kappa Alpha fraternity and his college career was distinguished both by his scholastic attainments and the wide range of his extracurricular activities.

In June, 1930, he was engaged by the Alabama State Highway Department as an inspector and draftsman on all stages of highway and bridge construction. In 1933, he was promoted to the position of assistant office engineer, in charge of laying out, planning, and supervising highway engineering and construction. In May, 1939, his outstanding ability was recognized by his elevation to the position of executive head of division shop and warehouse, in charge of repair, maintenance, and proper dispatching of all equipment and materials allocated to the State Highway Department. Mr. Hendrix occupied this position until he entered the military service of the United States in 1943.

During the early part of 1942, the shipbuilding division of the Decatur Iron and Steel Company in Decatur, which had been awarded contracts for the construction of landing craft for the United States Navy, offered Mr. Hendrix the position of chief engineer, in charge of all hull construction and mechanical installations on such vessels. Mr. Hendrix declined this offer with the statement that he felt compelled to give his services to the Armed Forces.

In January, 1943, Mr. Hendrix accepted an appointment as Second Lieutenant, Corps of Engineers, Army of the United States, and proceeded to Camp Claiborne, Louisana, for his initial training. Following the successful completion of this course, he was transferred to Camp Grant, Illinois, for additional training. In July, 1943, he was promoted to the rank of First Lieutenant and received a letter of commendation for the superior manner in which he performed his duties at this installation.

Lieutenant Hendrix proceeded to an overseas destination in March, 1944, with the 1301st Engineers (General Service Regiment), as engineer officer. In July, 1944, he was promoted to the rank of Captain and thereafter served as planning and training officer (S-3) of his regiment, which was assigned to the Third Army, during battles through France, Belgium, and Germany. In recognition of the heroic manner in which he performed his duties in the course of these engagements against the enemy, he was awarded the Bronze Star Medal.

In January, 1945, his family was notified that Captain Hendrix had been killed in action on December 31, 1944. He had served the United States faithfully as an officer in the Corps of Engineers and died, as he would have wished, serving his country in time of war.

---

[1] Memoir prepared by R. T. Harris, Pres., Southeastern Metals Co., Decatur, Ala., assisted by John A. Caddell, Attorney at Law, Decatur, Ala., and Seybourne H. Lynne, U. S. District Judge, Birmingham, Ala.

Captain Hendrix was a leader in every phase of community life. His outstanding characteristic was his unselfish love of his fellow man. His death in the line of duty both shocked and inspired all who knew him.

In 1935, Mr. Hendrix was married to Helen Wallace, who survives him.

Captain Hendrix was elected an Associate Member of the American Society of Civil Engineers on November 13, 1944.

HARRY LEGRAND HILTON, Assoc. M. ASCE[1]

DIED MAY 20, 1945

Harry LeGrand Hilton was born in Omro, Wis., on July 13, 1876, the son of William Harley and Mattie Hilton.

He was educated in the Omro Public Schools, and after graduation he entered the State Normal School at Oshkosh, Wis. Two years later, he entered Lawrence Scientific School, Harvard University, at Cambridge, Mass., where he majored in civil engineering, completing his education at that institution in 1902.

Mr. Hilton was first employed by J. H. Wallace and Company at the Portsmouth, N. H., plant, first as a stenographer, then testing cement, running transit and level, inspecting steel erection, etc. In 1903 he was transferred to the New York, N. Y., office of that firm as a draftsman.

Late in 1903, Mr. Hilton was appointed assistant city engineer of Bangor, Me. He served in this capacity for four years, during which time he completed design, plans, and specifications; and he had direction of construction of sewer extension lines, water lines, heavy building foundations and retaining walls, and the design and erection of steel trestle sidewalks.

From 1907 to 1910, Mr. Hilton was employed as a civil engineer for the Quartermaster's Corps of the U. S. Army. During this time, under Maj. J. M. Carson, Jr., Mr. Hilton was superintendent of construction on the $10,000,000 enlargement project of the U. S. Military Academy at West Point, N. Y.

In June, 1910, Mr. Hilton transferred to the United States Navy department where, until March, 1917, he served as civilian assistant and expert aide to the Public Works Officer of the Navy Yard at Portsmouth. It was during these years, when he served as chief draftsman, head of survey parties, chief inspector on the Bureau of Yards and Docks contracts, and administrative assistant that Mr. Hilton gained the background of wide experience in naval administration and procedure which served him so well during his long career as an officer in the U. S. Navy.

On April 11, 1917, Mr. Hilton was commissioned a Lieutenant in the Civil Engineer Corps of the U. S. Navy. He was, until 1920, assistant to the Public Works Officer of the Navy Yard, Portsmouth, and in this capacity he assisted in the construction and administration of extensive facilities which included the naval hospital and the railway and highway bridge at Portsmouth.

---

[1] Memoir prepared by Alden K. Fogg, Assoc. M. ASCE.

In 1920, Lieutenant Hilton was transferred to the Navy Yard at Boston, Mass., where he served as assistant to the Public Works Officer at that station until December, 1922. He was then transferred to the Bureau of Yards and Docks in Washington, D. C., to assist in the preparation of the Bureau manual.

This important work was completed in May, 1923, at which time Lieutenant Hilton was assigned to duty as assistant to the Public Works Officer of the Eleventh Naval District at San Diego, Calif. From this duty, Lieutenant Hilton was ordered to the Naval Air Station at Pensacola, Fla., in 1926. In the capacity of Assistant Public Works Officer at that station, he supervised the construction of the Bayou Grande Bridge at Pensacola. It was in June, 1930, that he was transferred as Assistant Public Works Officer of the Navy Yard, Pearl Harbor, Territory of Hawaii, where he served until June, 1932.

Lieutenant Hilton was transferred in July, 1932, to the post of Public Works Officer of the Submarine Base, New London, Conn., where he was stationed until September, 1935. During this tour of duty, he supervised the design and construction of the sewage disposal plant at that station.

In 1935 Lieutenant Hilton was transferred to the Third Naval District in New York, where he served as Assistant Public Works Officer until June, 1939, at which time he received his promotion to the rank of Lieutenant Commander. He was then given duty as Public Works Officer of the Naval Air Station, Terminal Island, Calif. He was instrumental in negotiating part of the initial leases of land which marked the expansion of the Terminal Island Air Base to its present proportions. Lieutenant-Commander Hilton remained at this post until he was retired from active duty on August 1, 1940, having reached the statutory age limit.

Upon being recalled to active duty on October 25, 1940, Lieutenant-Commander Hilton was assigned to duty in the War Plans Section of the Eleventh Naval District, San Diego. In this assignment Lieutenant-Commander Hilton, with his broad and comprehensive knowledge of the naval shore establishment, was of great assistance in advanced planning for facilities and camps throughout Southern California.

After completing his assignment in the War Plans Section, he was made Executive Assistant Public Works Officer of the Eleventh Naval District. He was promoted to the rank of full Commander on April 20, 1942.

In 1940 he had returned from a well-earned retirement to take up the service of his country. He died in the performance of his duty on May 20, 1945, at the U. S. Naval Hospital in San Diego. He had spent a lifetime in the service of his nation and had done his work well.

He had aided in the design and construction of vast facilities for the training and equipping of our fighting men. He had materially aided the expansion of the Naval Shore Establishment from its peacetime standards to a mighty war machine.

Commander Hilton was a member of the Society of American Military Engineers. Always interested in the welfare of handicapped children, he was active in supporting the Shrine Crippled Childrens Home at San Francisco, Calif. He was keenly interested in Society affairs and was a frequent speaker at Society meetings.

On October 19, 1903, Commander Hilton was married to Helen C. Locke of Portsmouth, who survives him.

Commander Hilton was elected an Associate Member of the American Society of Civil Engineers on June 1, 1909.

ALBERT HOWARD HORTON, Assoc. M. ASCE[1]

DIED MARCH 4, 1945

Albert Howard Horton, the son of Elmer and Christiana (Thompson) Horton, was born near Fairview, Butler County, Pa., on July 24, 1875. He was a descendant of Roger Williams, and his ancestors were closely connected with the early development and settlement of New England and New York. Shortly after his birth his parents moved to Silver Creek, N. Y., where they were pioneers in the development of the later renowned vineyards of western New York. After receiving his preparatory education in the high school at Silver Creek, he attended the College of Civil Engineering, Cornell University, Ithaca, N. Y., from which he was graduated with the degree of Civil Engineer in June, 1898.

His first engineering employment was with the U. S. Board of Engineers on Deep Waterways. During the period of about one year with the Board of Engineers, he was engaged on field surveys in central and northern New York. These surveys were in connection with improvements to the old Erie Canal, over which his grandfather, Albert Horton (for whom he was named) had migrated westward.

From 1899 to 1903 he was with the U. S. Lake Survey. During this period he was identified with the early stream-flow measurements on the St. Clair, Niagara, and St. Lawrence rivers. During his four years with the U. S. Lake Survey, he developed at least two characteristics which remained with him through life—namely, a passion for accuracy in stream-flow measurements and a capacity for giving written and oral orders which he expected to be followed implicitly.

In May, 1903, he was appointed an assistant engineer in the U. S. Geological Survey and was engaged on surveys and estimates for the Shoshone and Utah Lake projects of the U. S. Reclamation Service, then a part of the Geological Survey but later a bureau of the Department of the Interior. Except for the two years or less spent on those early western irrigation projects in Wyoming and Utah, all Mr. Horton's work was in the central and eastern portions of the United States.

---

[1] Memoir prepared by William G. Hoyt, M. ASCE.

In 1905 he was engaged in making discharge measurements in the Central Atlantic States. During the same year he was in charge of a field party which surveyed the Roanoke River from the mouth to its headwaters at the request of, and in cooperation with, the state geologist of Virginia.

In January, 1906, he became district hydrographer in charge of the Upper Mississippi River District, consisting of the states of Minnesota, Wisconsin, Michigan, and Illinois, with headquarters in Chicago, Ill., where he worked in cooperation with the states and the Chicago Sanitary District. One of his important contributions during this period was an intensive investigation of errors resulting from the use of dams as gaging stations. He determined that, as a result of leakage, obstruction to gates, and other causes, the records based on computations of flow through openings in dams were likely to be grossly in error. In 1907, when it became necessary to close the Chicago office because of lack of funds, Mr. Horton was transferred to the Washington, D. C., office and later to Newport, Ky., where he was district engineer in charge of surface-water investigations in the Ohio River basin.

In connection with flood measurements of the Ohio River, he developed a reel and crane for handling the heavy weights needed to hold the current meter in its proper position during the observations of velocity. Although reels and cranes are used extensively, Mr. Horton was the first to use them in Geological Survey work and took an active part in developing them as efficient tools in stream gaging. His earlier experiments on the U. S. Lake Survey in measuring deep rivers "stood him in good stead." After August, 1913, he supervised the Ohio River work from headquarters in Washington, D. C. While district engineer of the Ohio River District, he made an important contribution to hydrologic literature through the analysis of fragmentary records of stage and discharge of the Ohio River and its tributaries, which led to the compilation of long-time records of these important waterways.

At the beginning of World War I, no one had reliable information as to the installed power resources of the United States, and there was no over-all record of electric power output or of fuel consumption. To meet the war needs the Division of Power Resources was organized in the Geological Survey on July 1, 1918. In August, 1918, Mr. Horton was detailed to this division, and on July 1, 1919, he became its chief. One of the first tasks that was undertaken was the compilation of a mailing list of all concerns engaged in business as electric utilities. Thereupon was started a collection of data pertaining to the installed capacities, fuel consumption, and output of all electric power plants in the United States. The records collected by the Division of Power Resources were of inestimable value in connection with the prosecution of World War I. Following the Armistice the Survey continued the collection and compilation of statistics and the dissemination of information concerning power output and fuel consumption. Mr. Horton continued this work until July, 1936, when the activities relating thereto were transferred to the Federal Power Commission.

The studies and analyses by Mr. Horton focused attention for the first time on the wide variations in the consumption of fuel per kilowatt hour and to the wide differences in fuel consumption between efficient and inefficient equipment and methods. Mr. Horton must be given some of the credit for the remarkable increase in the efficiency of power plants obtained during the decade from 1920 to 1930. On July 1, 1921, he became district engineer in charge of surface water investigations in the Middle Atlantic District, with headquarters at Washington, D. C., until June, 1940, when they were moved to College Park, Md. During this period his position as chief of the Division of Power Resources was continued.

Bert, as he was affectionately called by his friends, was a keen student and an enthusiastic worker. His wit and dry humor and his outstanding personality were recognized at all gatherings of Survey engineers. This was especially so at the conferences of district engineers, which he attended for many years. Many of the improvements in the technique of stream gaging, especially in construction methods and procedures were brought about through his advice and suggestions. One of his most recent suggestions, for which he received a substantial cash award from the Board of Suggestions Awards, Department of the Interior, related to a method of marking the number of days remaining on supply rolls of paper for water stage recorders.

Of his nearly forty-seven years in federal employment, forty-two years were with the Geological Survey. Mr. Horton trained a considerable number of the present district engineers of the Survey, and many of the engineers in charge of responsible work. W. E. Wrather, director, Geological Survey, wrote of him as follows:

> "Mr. Horton for many years has been one of the highly respected engineers of the Geological Survey on whom the Directors, Dr. Smith, Dr. Mendenhall, and I have relied for information, especially in relation to power matters, not only in this country but throughout the world."

Harold L. Ickes, Secretary of the Department of the Interior, wrote that:

> "* * * in his service with the Geological Survey for over 40 years, he was always faithful and conscientious in the performance of his many and varied duties. His technical skill and judgment will be greatly missed."

Although Mr. Horton had not been in the best of health for several years, he had been critically ill for only a short time prior to his death at Garfield Hospital, Washington, D. C., on March 4, 1945. Few had realized the seriousness of his illness.

Mr. Horton was married to Althea Wilbor Briggs on October 25, 1905. Their marriage was an extremely happy one. Surviving Mr. Horton are his widow; a daughter, Adah (Mrs. Thomas Wriggins); a son, John Horton, associate engineer, U. S. Geological Survey (John is following in his father's footsteps); a brother, Judge Clinton Horton, referee judge of the State Supreme Court, Buffalo, N. Y.; and four grandchildren, Natalie Ann Wriggins, Adah Virginia Wriggins, Thomas Wriggins, III, and John Michael Horton.

He was a member of the Cosmos Club, Washington, D. C., and the Washington Society of Engineers.

Mr. Horton was elected a Junior of the American Society of Civil Engineers on June 3, 1902, and an Associate Member on March 6, 1907.

CHARLES PORTERFIELD KAHLER, Assoc. M. ASCE[1]

Died February 25, 1946

Charles Porterfield Kahler, the son of Charles P. and Harriet Agnes (Moran) Kahler, was born on November 25, 1880, in Baltimore, Md. He attended the Baltimore City College and the Maryland Institute and was graduated from the University of Notre Dame, Notre Dame, Ind., with the degree of Bachelor of Science in Civil Engineering, in 1904.

He then entered the employ of the Cleveland, Cincinnati, Chicago and St. Louis Railway Company, as assistant engineer, and in 1906 became assistant engineer for the Oregon Short Line Railroad Company at Salt Lake City, Utah. He was appointed electrical engineer in 1912.

In 1931 Mr. Kahler was appointed electrical engineer—system—with headquarters at Omaha, Nebr., having jurisdiction over all Union Pacific Railroad lines. In April, 1945, he became general electrical engineer.

During his railroad service Mr. Kahler participated in the planning of many important projects involving not only electrical works, but also steam power plants, locomotive boiler washing plants, and oil development projects.

Mr. Kahler was married to Mary Heinekamp in January, 1908. He is survived by his widow and daughter, Mary Agnes.

He was a member of the American Association of Railroads (Electrical Section), the American Institute of Electrical Engineers, and the Nebraska Engineering Society.

Mr. Kahler was elected an Associate Member of the American Society of Civil Engineers on March 13, 1917.

MARTIN WILLIAM LAUTZ, Assoc. M. ASCE[1]

Died April 23, 1945

Martin William Lautz, the son of Martin F. and Elizabeth (Bank) Lautz, was born at Buffalo, N. Y., on July 13, 1886.

He studied civil engineering at Princeton University in Princeton, N. J., from 1904 to 1907, and at the Massachusetts Institute of Technology in Cambridge, Mass., from 1907 to 1908, where he was a member of Sigma Chi fraternity.

During summers he worked on surveying parties for the Pennsylvania Railroad; Lackawanna Steel Company; and C. C. Conkling and Company, consulting engineers.

---

[1] Memoir prepared by B. H. Prater, Chf. Engr., Union Pacific R.R. Co., Omaha, Nebr.

[1] Memoir prepared by R. J. McIntosh, Mgr. of Sales, Bethlehem Steel Co., Bethlehem, Pa.

After college he spent six years, from 1908 to 1914, as assistant engineer with the Ferederick K. Wing Company of Buffalo, on field work as chief of party on surveys for sewer systems, townsites, electric railways, etc. He was resident engineer on the East Aurora, N. Y., sewer and disposal plant construction.

From 1915 to 1922, he was assistant engineer for the Lackawanna Steel Company working on the development and use of steel sheet piling when the product was just starting to be used generally.

In 1922 he became designing engineer for the Bureau of Water, Filtration Division, City of Buffalo, on concrete design and later was in charge of inspection of the $5,000,000 filtration plant. After completion of this job, he became associated with the John W. Cowper Company, general contractors, as engineer on the construction of the structural Grey Mill for the Bethlehem Steel Company at Lackawanna, N. Y., and as superintendent of construction on a Harrison Radiator Company job at Lockport, N. Y.

In 1930 he became sales engineer for the Bethlehem Steel Company at Bethlehem, Pa., on steel sheet piling and structural steel bearing piles. In this work he collaborated with engineers and contractors on the use of steel piling on many important engineering projects throughout the United States.

He was a member of the Piling Sub-Committee of the American Iron and Steel Institute Committee on Building Codes and of the Committee on Bearing Value of Pile Foundations of the Waterways Division of the American Society of Civil Engineers. At the 1945 annual meeting of the Society in New York, N. Y., Mr. Lautz presented a discussion[2] of Karl Terzaghi's paper on "Cellular Cofferdams."

For many years Mr. Lautz was a member of the Guido Chorus of Buffalo and sang at many of the concerts given by this famous men's chorus including the competitions of the Associated Glee Clubs of America in New York. He was also a member of the Bach Choir of Bethlehem. He was licensed as a professional engineer and surveyor by the State of New York in 1925.

In 1913, Mr. Lautz married Helen Hyde Tobin of Syracuse, N. Y. Mrs. Lautz and two daughters, Helen (Mrs. Albert Weinrich) and Elizabeth, survive.

Mr. Lautz was a huge man physically with a forceful personality and keen intellect. In his work he combined a thorough knowledge of engineering with a sound practical sense. His greatest interest was his family to whom he was devoted. His cheerful and kindly disposition made friends of all who knew him.

Mr. Lautz was elected an Associate Member of the American Society of Civil Engineers on December 15, 1924.

---

[2] *Transactions*, ASCE, Vol. 110, 1945, p. 1083.

RANSOME TEDROWE LEWIS, Assoc. M. ASCE[1]

DIED MAY 17, 1945

Ransome Tedrowe Lewis was born at Indianapolis, Ind., on January 22, 1868, the son of George W. and Sarah J. (Tedrowe) Lewis.

He was graduated from Purdue University at Lafayette, Ind., in 1888 with the degree of Bachelor of Civil Engineering, after working his way through college. In 1892, after four years of practical experience, he received the professional degree of Civil Engineer from Purdue.

Like most civil engineers of those days his first engagement was with a railroad. He was in the Maintenance of Way Department of the Corps of Engineers of the Pittsburgh, Cincinnati, Chicago and St. Louis Railroad Company from August, 1888, to March, 1890, at Pittsburgh, Pa. This led to specialization in the field of railway and other structures and later into fabrication of structural steelwork for all types of construction.

After March, 1890, he spent six years with G. W. G. Ferris and Company, engineers and inspectors, of Pittsburgh, as assistant and principal inspector, inspecting structural steelwork at various shops and mills in Pittsburgh and throughout the Middle West. Some of the more important works for which he inspected the steel during this period were: Ohio Connecting Railway Bridge at Pittsburgh; Metropolitan Elevated Railroad at Chicago, Ill.; Halsted Street Lift Bridge at Chicago; Section 3, Park Avenue Improvement at New York, N. Y.; portions of the Boston (Mass.) subway; and the Ferris Wheel and the Administration Building at the Chicago World's Fair.

From March, 1896, to December, 1899, Mr. Lewis was with the Osborn Engineering Company of Cleveland, Ohio, in charge of steel inspection for the Northwestern Elevated Railroad of Chicago, the Elmira Bridge Company, Ltd., Elmira, N. Y., and the Union Bridge Company, Athens, Pa. He then worked at the home office in Cleveland as draftsman, assisting on the design of several Buffalo grade crossing structures, buildings, and railroad structures. In April, 1899, he went back to Elmira in charge of inspection of steel for the Buffalo grade crossing work and also finished the inspection for the Northwestern Elevated of Chicago. From December, 1899, to November, 1900, he was in charge of mill and shop inspection of steel for bridges as chief inspector for the New York Central and Hudson River Railroad Company. He then returned to the Osborn Engineering Company, representing this concern in the Philadelphia District until September, 1901, when he became manager of the Athens Plant of the American Bridge Company, which was then engaged on the steelwork for a New York City subway. In February, 1902, he was transferred to the Elmira plant of the company as manager, a position which he held until his retirement in 1933, almost a third of a century.

---

[1] Memoir prepared by G. J. Watson, M. ASCE, with the assistance of F. A. Barnes, M. ASCE.

Even after nearly forty-five years of active practice, his retirement did not mean cessation of activities to Mr. Lewis. In November, 1935, he was made president of the Elmira Precision Tool Corporation, and later was retained in a consulting capacity when the company was absorbed by Remington-Rand, Inc. He retained this position until his death on May 17, 1945.

In 1894, he was married to Etta L. Hillard, who survives him, together with their two children, Joseph H. Lewis, vice-president and general manager of the Blue Ridge Glass Corporation, Kingsport, Tenn., and First Lieutenant Kathleen Lewis, a dietitian in the United States Army.

During his forty-three years of residence at Elmira, Mr. Lewis performed many acts of kindness and helpfulness known only to the recipients. He was particularly interested in the welfare of those working under his direction and they were always at liberty to consult him at either office or home. His keen interest in the community gained him a wide circle of friends and acquaintances in all walks of life.

One of his primary interests was scouting. He served as a Boy Scout Commissioner for many years, and was president of the Elmira Area Council of Boy Scouts for ten years. The esteem in which he was held by his associates in this work was attested by his election as a Silver Beaver Scouter, the highest honor in the gift of any local council.

Other community activities included membership on the Elmira Board of Education, services as chairman of the Board of Trustees of the Steele Memorial Library, and member of the Board of Elders of the First Presbyterian Church from 1915 until his death. He was also a Mason, a Rotarian, and a member of the Flat Tires and the Torch clubs. He was a charter member of the Ithaca Section of the Society and served a term as its President. He was always keenly interested in its activities and faithfully attended its meetings whenever possible.

Mr. Lewis was elected an Associate Member of the American Society of Civil Engineers on June 6, 1906. He became a Life Member in January, 1939.

CLARE SLOAN McARDLE, Assoc. M. ASCE[1]

DIED JANUARY 2, 1942

Clare Sloan McArdle, the son of Lucian and Mittie (Sloan) McArdle, was born on February 9, 1892, at Ferry, Mich., where he obtained his early education. In 1910 he entered Michigan State College of Agriculture and Applied Science at East Lansing, Mich., and was graduated with the degree of Bachelor of Science in Civil Engineering in 1914.

From 1914 to 1917 he served the Department of Highways of the State of Illinois, in various capacities from transitman to assistant division engineer in charge of construction and surveys.

---

[1] Memoir prepared by Harry E. Frech, Assoc. M. ASCE.

When World War I was declared, Mr. McArdle went on active duty as a First Lieutenant, Corps of Engineers, at Fort Sheridan, Ill. Later he was transferred to Fort Leavenworth, Kans. He was promoted to Captain and then to Major. As Captain, Corps of Engineers, he was assigned to the American Expeditionary Force, North Russia Expedition, in July, 1918. While serving on the Archangel front in north Russia, he distinguished himself as a capable and resourceful officer as indicated by the Distinguished Service Order for Conspicuous Gallantry and Ability awarded to him by the British Government. The men who served under his command had high praise for his valor and leadership.

On his return from Europe in August, 1919, he was employed by the Illinois State Highway Department, and was placed in charge of four large construction plants operated by the state. As general superintendent of day labor construction, Mr. McArdle built more than 100 miles of concrete roads. During the next five years he was engaged in private engineering and contracting practice.

In 1927 he became western technical service manager for the Atlas Portland Cement Company and later was division sales manager at Birmingham, Ala. Until 1941 he was employed by the Missouri Portland Cement Company of St. Louis, Mo., as general sales manager and as vice-president.

Mr. McArdle's ability as a civil engineer in both military and civilian assignments was held in high esteem by his colleagues. He believed in close application to his work, but found time to take part in outdoor sports. Golf was one of his favorite pastimes and a place in his foursome was much sought after. His ability to make friends and hold them was a great part of his success in his business and professional career.

On April 15, 1924, in Kingsport, Tenn., Mr. McArdle was married to Lucile Dorsey. He is survived by his widow and daughter, Dorothy Ann.

Mr. McArdle was elected an Associate Member of the American Society of Civil Engineers on October 21, 1924.

DONALD GRANT McKIM, Assoc. M. ASCE[1]

Died July 29, 1945

Donald Grant McKim, the son of John R. and Jennie (Grant) McKim, was born on January 9, 1887, at Pickrell, Nebr. He was graduated from Manual Training High School at Kansas City, Mo., in 1906.

From 1909 to 1918, Mr. McKim was connected with several railroad companies in the midwest and southwest on location, construction, and maintenance. He served in the U. S. Army from July, 1918 to March, 1919; and, upon his release, became construction superintendent for the Western Oil Corporation at Burkburnett, Tex., handling the construction of casing-head gasoline plants until 1921. From 1921 to 1927 he was supervisor of bridges and buildings for the Kansas, Oklahoma and Gulf Railroad Company with headquarters at Muskogee, Okla.

---

[1] Memoir prepared by W. J. Van London, Engr.-Mgr., Houston Urban Expressways, Houston, Tex.

From 1928 until his death Mr. McKim was resident engineer for the Texas Highway Department in charge of construction of many of the most important bridges constructed in the state during that period.

Mr. McKim was a man of unquestionable integrity and high professional ethics. He was a member of the Episcopal Church, the Masonic Lodge, and the Houston Engineers Club.

In 1920, at Fort Worth, Tex., Mr. McKim was married to Katharine D. Brown of Culpeper Court House, Virginia. He is survived by his widow; his mother; and a sister, Elizabeth McKim.

Mr. McKim was elected an Associate Member of the American Society of Civil Engineers on November 11, 1929.

JOHN DONALD MITSCH, Assoc. M. ASCE[1]

Died January 18, 1946

John Donald Mitsch was born in Boston, Mass., on March 2, 1898. He was the son of John A. Mitsch and Mary (Joyce) Mitsch, both of Pittsburgh, Pa. His early education was obtained in Boston, Mass. He enrolled for one year in the Engineering School of Tufts College in Medford, Mass., and then transferred to the Massachusetts Institute of Technology (M.I.T.) in Cambridge, Mass. Mr. Mitsch was graduated, in 1920, with the degree of Bachelor of Science in Civil Engineering.

After graduation Mr. Mitsch remained at M.I.T. as assistant instructor in civil engineering for two years. He then spent one year with the Barney-Ahlers Construction Corporation of New York, N. Y., as estimator and field engineer on construction in reinforced concrete. In September, 1923, he returned to M.I.T. and remained on the faculty until his death. At M.I.T. he held, successively, the positions of instructor in civil engineering from September, 1923, to June, 1934, assistant professor in civil engineering from July, 1934, to June, 1940, and associate professor of civil engineering from July, 1940, until his death.

Professor Mitsch's major field was structural engineering with emphasis on theory of structures and design of reinforced concrete structures. He also devoted much time to the teaching of surveying with teaching assignments at the M.I.T. Summer Mining Camp at Dover, N. J. (from 1924 to 1934), and at the M.I.T. Summer Surveying Camp at East Machias, Me. (since 1927). In addition to his regular daytime work, he conducted evening classes in surveying problems for the Massachusetts State Department of Education, from 1930 to 1935, and, from 1935, in reinforced concrete design for the

---

[1] Memoir prepared by Eugene Mirabelli, M. ASCE.

Lowell Institute at Cambridge. During his career he was engaged at various times as estimator on building construction, as structural designer of buildings and bridges, as consultant for insurance companies, and as expert witness in court cases on surveying and structural design.

His popularity with both faculty and student body led to his appointment on various faculty committees and also to various special administrative duties. In 1935 he was made administrative officer in charge of the Surveying Camp at East Machias. During the war he was liaison officer and adviser to military and naval students at M.I.T. With the approach of the end of the war, he was appointed chairman of the M.I.T. Surplus Property Committee. The duties of this committee were disposal of property on terminated government contracts with M.I.T. and procurement of government surplus property to accommodate M.I.T.'s postwar expansion program.

He took an unusual interest in M.I.T. alumni affairs and served on the Alumni Council and the Executive Committee of the Alumni Association, and for several years was chairman of the Alumni Day Committee.

He was a very active member of the Boston Society of Civil Engineers and served as chairman of many committees. He was also a member of the American Concrete Institute and the Society for the Promotion of Engineering Education. For a number of years Professor Mitsch was faculty adviser to the Student Chapter of the American Society of Civil Engineers. He belonged to Phi Kappa fraternity, held an honorary position in Chi Epsilon, and was a member of the Knights of Columbus.

On January 18, 1946, while returning from a business trip for M.I.T., during which he attended the Society's Meeting in New York, he met his death in an airplane crash in Cheshire, Conn.

Professor Mitsch had a remarkably good understanding of human nature and was always interested in the welfare of both young and old. This characteristic permitted him to make friends easily and to maintain them. He was admired by his students not only as a teacher but as one who took a friendly, personal interest in their affairs. His associates will miss his quiet, good-fellowship, and his dependable counsel and readiness to be of service.

In June, 1938, Professor Mitsch was married to Frances McFaul of Machias, Me. He is survived by his widow; a daughter, Mary Regina; a son, John Donald, Jr.; his mother; three brothers, Walter A., Paul F., and Arthur E.; and a sister, Cyrilla R. (Mrs. Joseph G. Green).

Professor Mitsch was elected an Associate Member of the American Society of Civil Engineers on August 12, 1935.

WILLARD AVERELL POLLARD, JR., Assoc. M. ASCE[1]

DIED FEBRUARY 20, 1942

Commander Willard Averell Pollard, Jr., an officer of the Civil Engineer Corps of the United States Navy, was born in Washington, D. C., on August

---

[1] Memoir prepared by R. E. Bakenhus, M. ASCE.

15, 1895. He was the son of Willard A. Pollard who was a native of Washington, D. C., and of Olivia (Guest) Pollard, a native of Baltimore, Md. He lived in a period when the art of design and construction of concrete in various structures was undergoing its greatest development, and he contributed materially to this development. His outstanding work in this line was recognized when the U. S. Maritime Commission named one of its concrete ships in his honor, namely, *The Willard A. Pollard,* on July 30, 1944.

Willard A. Pollard, Jr., chose civil engineering as his profession; he was graduated from Lafayette College, Easton, Pa., in June, 1916, with the degree of Civil Engineer. From that date until January, 1918, he was a concrete designer with Westinghouse, Church, Kerr and Company—Dwight P. Robinson Company. In the meantime, the United States Navy held competitive examinations for appointments, from civil life, of officers in the Civil Engineer Corps. This corps conducts a great variety of work in connection with public works of the Navy, and the examinations are correspondingly broad and difficult. Mr. Pollard stood second in a group of distinguished engineers who were appointed from the large number of competitors. He was commissioned Lieutenant (Junior Grade), Civil Engineer Corps (CEC), U. S. Navy, as of January 12, 1918. He was promoted to Lieutenant as of July 1, 1920; to Lieutenant Commander as of October 2, 1925; and reached the rank of Commander on June 30, 1935.

Upon first reporting he was assigned to temporary duty under instruction at the United States Naval Academy in Annapolis, Md. Upon completion of the course in February, 1918, he was assigned to the Bureau of Yards and Docks and served first as assistant project manager and then as project manager for public works at ordnance stations and the U. S. Helium Production Plant. This assignment included responsible charge of designs, plans, specifications, and estimates for public works, including the technical features of construction.[2] From October, 1921, until 1924, he was Public Works Officer at the Navy Mine Depot and Fuel Oil Station, Yorktown, Va. As plant maintenance superintendent he had duty at the Navy Yard, Philadelphia, Pa., until 1926.

In 1926 he was assigned to the Virgin Islands where, although he was Public Works Officer of the Naval Station, his duties were principally with the civil governor. This was due to the fact that the Public Works Officer was brought into more immediate contact with people of all classes than any other officer under the civil government. In addition, he had jurisdiction over the Civil Engineer Officer at St. Croix, Virgin Islands.

Next he stood duty from 1929 to 1934 at the Naval Operating Base at Norfolk, Va. At this time two concrete barges designed, constructed, and tested under his direction were used with some success as crane barges.

During 1934 and 1935 he attended the Army Industrial College at Washington, D. C., under instruction. This course was intended to establish close liaison and understanding on the part of the Army with civilian industry, and, by assignment of naval officers to these courses, to establish even closer liaison between the Army and Navy, as well as with industry.

---

[2] "U. S. Helium Plant," by Willard A. Pollard, Jr., *Public Works of the Navy,* 1920.

Another tour of duty in the Bureau of Yards and Docks occurred from 1935 to 1938. Here as Assistant War Plans Officer and then War Plans Officer, he was instrumental in the conception and development of all types of advance base equipment including barges.

As Public Works Officer of the 15th Naval District, Commander Pollard went to Panama in 1939. Here in conjunction with the Bureau he did outstanding work in the preparation of studies for dry docks which later formed the basis for getting appropriations for construction of dry docks at Pearl Harbor, Hawaii, Puget Sound, Washington, and Mare Island, California.

In January, 1940, his physical condition was such as to require hospitalization in the Gorgas Hospital at Panama. In March he was returned to the United States to the Naval Hospital at Washington, D. C.; and in September, 1940, he was placed on the retired list and relieved of all active duty.

During his career in the Navy he served on numerous boards some of which were the following: Member of Board for Examination of Sites in Southern States to select sites for Marine Corps air stations (1918); member of board to select sites for free-balloon stations; senior member of board to report upon suitability of site at Lakehurst, N. J., for a dirigible construction station (1919); member of Naval Examining Board for Civil Engineers, examining four groups of candidates (1921); member of board to recommend tropical and winter clothing for enlisted personnel (1936); recorder of selection board for officers of CEC, U. S. Navy; and member of board to make studies of naval needs and interests in connection with strategic raw materials.

Commander Pollard belonged to the Phi Beta Kappa and the Tau Beta Pi fraternities. He was a member of the Army and Navy Club of Washington, D. C., and of the Army and Navy Country Club of Arlington County, Virginia. He was a man of an obliging and friendly disposition, always ready to serve a friend. He was essentially modest as to his own attainments, yet positive and vigorous in the execution of his duties and in meeting his responsibilities. His work was always well done—efficiently, promptly, and without ostentation. He gave his country outstanding service during World War I and World War II, and in the preparatory period between.

He is survived by his wife, Julia (Bottum) Pollard, a native of South Dakota, and by three children, Lt. (jg) Willard A. Pollard, III, U. S. Navy, Anne S. Pollard, and Philip H. Pollard.

Commander Pollard was elected an Associate Member of the American Society of Civil Engineers on November 21, 1921.

EDWARD WILLIAM ROBINSON, Assoc. M. ASCE[1]

DIED MAY 5, 1942

Edward William Robinson was born in Hamburg, Germany, on May 13, 1874, the son of the American Consul General at Hamburg and of Rose Weisman. Mr. Robinson attended school in New York, N. Y., Stevens Preparatory School in Hoboken, N. J., and was graduated from Stevens Institute of Technology in Hoboken (class of 1895) with the degree of Mechanical Engineer.

---

[1] Memoir prepared by Frederic R. Harris, M. ASCE.

From 1900 to 1905, he was a member of the firm of Smith and Robinson, constructors of river and harbor works in the New York area, and then he joined the Snare and Triest organization, contractors for harbor works. From 1910 to 1917, he was vice-president of the Ruggles and Robinson Company, building constructors in New York. In 1917 he attended the Officers' Training School at Plattsburg, N. Y., being graduated with the rank of Captain, thereafter becoming a Major in the Corps of Engineers. In 1920 he was released from the Army to become vice-president and general manager of the Triest Contracting Company of New York, on subway work, at Queens Plaza, New York; on bridge foundations of the Goethals Bridge; and on work for port improvements at Philadelphia, Pa., and in the Delaware River. In 1935 he became associated with the consulting engineering organization of Frederic R. Harris, Inc., New York, and later became president of Construction Management, Inc., New Jersey, an affiliated company, in which he was active on national defense for the Navy Department and the Maritime Commission. He was also a director of the Federal Water and Gas Corporation and the New York Water Company, both of New York. He was a well-known construction engineer and director of utility companies.

Mr. Robinson was for some time an alumnus-trustee of Stevens Institute of Technology. He belonged to the Engineers Club of New York. He was a member of the Mayflower Society, the New York Chapter of the Sons of the American Revolution, and the Smithtown Country Club.

Edward W. Robinson was first married to Georgia Brock, after whose death, many years ago, he was married to May Olivia Andrews of New Orleans, La. She died about a year before his death. Mr. Robinson is survived by his brother, Herman Robinson. Mr. Robinson's son, Edward Robinson, was a private in the Army and died in France during World War I.

Mr. Robinson was elected an Associate Member of the American Society of Civil Engineers on October 7, 1908.

LESTER CHAUNCEY SMITH, Assoc. M. ASCE[1]

DIED NOVEMBER 17, 1944

Lester Chauncey Smith was born in Montgomery, Ala., on February 9, 1889, the son of Lester C. Smith and Annie (Jackson) Smith. He died on November 17, 1944, at Mobile, Ala. Mr. Smith was educated in the primary schools of Montgomery, and was graduated from the Alabama Polytechnic Institute at Auburn, with the degree of Bachelor of Science in Civil Engineering in the class of 1909.

---

[1] Memoir prepared by J. P. Ewin, Doullut and Ewin, Inc., New Orleans, La.

Subsequent to his graduation he spent approximately one year in railroad surveying and construction, approximately one year with the Alabama Power Company on hydroelectric development on the Coosa and Tallapoosa rivers in Alabama, and approximately six years as a junior engineer with the United States Engineer Department on various surveys and construction projects for river improvement.

During World War I, he was a First Lieutenant and subsequently a Captain in the Second Division, Second Engineers of the regular army. His company participated in eight major battles during the war, the principal ones being the First and Second Battles of the Marne, Soissons, Chateau Thierry, and Belleau Woods. He received the Croix de Guerre for gallantry in action.

After the war Mr. Smith returned to the practice of engineering. From 1920 until 1925, he worked as a construction engineer for the firm of Doullut and Williams, Inc. During that time he was principally engaged in the construction of piers and other river terminals, the principal one of which was a wharf for the Standard Oil Company at Baton Rouge, La. Subsequent to that engagement, and up until a short time prior to his death, Mr. Smith was a member of the firm of Doullut and Ewin, Inc. During approximately twenty years with this firm, he had charge of design and construction of many projects, including piers, bulkheads, shipbuilding ways, bridges, and other similar structures. He was in charge of the field work on the construction of the Sugar Bowl Stadium in the City of New Orleans, La.

He was a member of the Louisiana Engineering Society, New Orleans.

In 1919 Mr. Smith was married to Mary Baldwin Williams of Montgomery. In addition to his many friends, he is survived by his widow and four children, Lester Chauncey Smith, Jr., Mary Baldwin Williams Smith, Etheldra Graham Smith, and Martin Baldwin Smith. His oldest son, Lester C. Smith, Jr., served in the United States Army, as a gunner and engineer, on a B-17 in flights over Germany.

Mr. Smith was elected an Associate Member of the American Society of Civil Engineers on July 9, 1923.

RALPH CARL SMITH, Assoc. M. ASCE[1]

Died September 2, 1945

Ralph Carl Smith was born February 14, 1894, at Grant, Iowa, the son of Frank E. Smith and Annie (Gray) Smith. In his childhood he moved with his parents to the State of Washington and located in Stevens County.

Mr. Smith obtained his primary education and part of his high school education in the public schools of Kettle Falls. This is a small community about ten miles northwest of Colville, the county seat of Stevens County. He completed his high school course at Vancouver, Wash., working to pay his way, and being graduated in 1914. In 1922 he entered Washington State College at Pullman, Wash., and completed his sophomore year; during 1925 and 1926 he finished his junior year; and in 1941 he received the degree of Bachelor of Science in Civil Engineering with high honors. His persistent determination to have an education was outstanding and most commendable.

---

[1] Memoir prepared by H. J. Doolittle, M. ASCE.

He started his engineering career in 1915 as a helper to a land surveyor. In 1917 he went with the Washington State Highway Department, working at intervals to 1940 through the various positions of computer, inspector, instrumentman, resident engineer, and location engineer. From March to August, 1940, he was the principal inspector on a Naval Air Base at Kodiak, Alaska. He held a similar position with the United States Army Engineers at the Galena (Wash.) air depot, ten miles west of Spokane, Wash., from February to August, 1942, when illness forced him to resign.

Throughout his life Mr. Smith showed unusual ambition; he was always exceedingly honest; and, he always put his work first, regardless of personal inconvenience, or personal gain. Integrity of character was his most outstanding characteristic in both his professional and personal life. He was an asset to any community, for this reason as well as for his virile, colorful personality. He exemplified the true engineer in his vitality, strength, and love of the great outdoors. His sincerity and warm personality won him friends among all classes of people. He was a veteran of World War I and a member of the Masonic Lodge.

In 1928 Mr. Smith was married to Esther L. Johnson of Rice, Wash., and in 1940 they adopted a little boy, Alan Smith. He is survived by his wife and son.

Mr. Smith was elected an Associate Member of the American Society of Civil Engineers on October 9, 1941.

JAMES HARGRAVES TEBBETS, Assoc. M. ASCE[1]

DIED JUNE 12, 1945

James Hargraves Tebbets, the son of James Edward Tebbets and Harriet B. (Hargraves) Tebbets, was born on June 20, 1882, in Somersworth, N. H., where his father was in the banking business. His grandfather was born in England but lived in the United States and was in the woolen mill business in Maine. Mr. Tebbets went to the local schools in Somersworth until 1901 when he entered Massachusetts Institute of Technology at Boston, with the class of 1905.

After a little more than a year in the offices of Lockwood, Greene and Company, and Stone and Webster in Boston, he was employed by the firm of Charles T. Main, Inc. He was in the Boston office for two years and then transferred to the office at Great Falls, Mont. Here he worked on the Rainbow Falls hydroelectric development for the Montana Power Company.

---

[1] Memoir prepared by Howard M. Turner, M. ASCE.

During the next four years he had further experience in power plant design, both steam and hydroelectric, with Byllesby in Chicago, Ill., and with Stone and Webster on the Falls Village, Conn., hydro plant. In 1915 he again went out to Great Falls for Charles T. Main, Inc., on the Montana Power Company's Volta and Thompson Falls hydroelectric developments where he was engineer on mechanical equipment (except water wheels). He returned later to work in the Boston office until 1918.

For the next three years he was in charge of mechanical engineering, Central Plant Engineering Department, of the Bethlehem Shipbuilding Company at Bethlehem, Pa. This work was on the mechanical equipment of shipyards, docks, and floating dry docks. After two years at the American Woolen Company in Lawrence, Mass., he spent five years with Vaughan Engineers in Boston on hydroelectric projects in the United States, Canada, and the West Indies. This work was on valuations, rate cases, and industrial work, and on the design and construction of the Jackman hydro development at Hillsboro, N. H. He spent two more years with Charles T. Main, Inc., in charge of design and field inspection on the 2-mgd filtration plant and the boiler plant for the Slaterville Finishing Company, returning to the Vaughan Engineers office for another year as principal assistant. From 1935 to 1940 he did various engineering work around Boston, generally not of long duration, until 1941, when he assumed charge of the layout of the water distribution system at Camp Edwards.

From 1941 until his death he was with the writer as general engineering assistant on various consulting work in connection with utility valuation, hydroelectric studies, and design. During this time he spent a month in Charleston, S. C., and another in Puerto Rico on consulting work for Jackson and Moreland of Boston.

He had a serious operation in the summer of 1944 but after that worked for as much of the time as his health would permit.

Mr. Tebbets was married to Mary Mathieson in 1907 in Dorchester, Mass. He is survived by his daughter, Mrs. Helen M. Tolman.

Except for the periods when he was away from Boston he made his home in Wollaston, Mass., with his family. Golf and bowling on the green were his forms of recreation, and his chief hobby was making ship models.

It is apparent that Mr. Tebbets was a man of wide experience in general engineering work, particularly in the field of power plants, hydraulic work, and engineering costs and valuations. Everything he did was characterized by an honest thoroughness that left no loose ends. This quality, coupled with his experience, made him an extremely capable and reliable engineer. His work was an expression of a loyal and conscientious character which made it impossible for him to compromise on what he thought was right, any more than it would allow him to do sloppy or careless work. He was always interested in his work and apparently derived much satisfaction from it.

He was elected an Associate Member of the American Society of Civil Engineers on April 14, 1919.

FREDERICK WAZNEY TOWNROW, Assoc. M. ASCE[1]

DIED JANUARY 5, 1946

Frederick Wazney Townrow, the son of Frederick W. and Sarah (Thompson) Townrow, was born in Philadelphia, Pa., on August 9, 1873.

At the age of nineteen, while working as a rodman with Samuel H. McElroy of Brooklyn, N. Y., Mr. Townrow took the initial step of his formalized engineering career by beginning a correspondence course in bridge engineering. The eight years between 1894 and 1902 Mr. Townrow spent working as a tracer and a draftsman for the Union Bridge Company of Athens, Pa., and also as a division engineer, performing routine field work in the Pennsylvania and New York Division of the Lehigh Valley Railroad. He also performed the duties of a detailer for the Elmira Bridge Company of Elmira, N. Y., and then served as a draftsman and checker for the McClintic-Marshall Construction Company of Pittsburgh, Pa.

In 1902 Mr. Townrow began his 22-year relationship with the Fort Pitt Bridge Works of Canonsburg, Pa., as a squad leader, designer, and assistant engineer, acting as plant engineer and designer. Until 1908 he directed the detailing and checking of railroad bridges, office buildings, and numerous other projects. He was responsible for accurate design, engineering judgment, and correspondence. In 1909 he very capably designed the open-hearth plant for the Jones and Laughlin Steel Company of Aliquippa, Pa. The following years found him actively engaged in designing and building the following projects: The Cleveland and Indianapolis track elevation for the Pennsylvania Lines West; buildings for the Massillon Rolling Mills Company in Massillon, Ohio, and the Mark Manufacturing Company of Indiana Harbor, Ind. He redesigned the Syria Temple, in Pittsburgh, as well as the falsework for the erection of the roof. He also redesigned the New Statler Hotel in Buffalo, N. Y.; and the steel design, falsework, and method of erection for part of the Pennsylvania Railroad's Ohio Connecting Bridge at Pittsburgh. During this time, while under agreement with the Fort Pitt Bridge Works, he also assisted S. Diescher and Sons, Engineers, Pittsburgh, on the redesign and investigation of existing structures, including an inclined railroad, for the Wheeling Steel and Iron Company. He also spent several months designing, inspecting, and repairing county bridges with the engineer of Mercer County, Pennsylvania.

In 1924 Mr. Townrow became associated with the Koppers Company as a designer of steelwork for the various by-product plant structures, particularly the material handling equipment. This association continued intermittently until 1945, when Mr. Townrow retired from the company. During this time he also served as the assistant staff engineer of the County Emergency Relief Board of Washington County, Pennsylvania.

---

[1] Memoir prepared by James R. Hess, M. ASCE.

Prior to his death, Mr. Townrow was engaged in the designing of coal washing equipment for the McNally-Pittsburgh Manufacturing Corporation of Pittsburgh.

He was married to Helen Josephine Jones on May 30, 1898, in Brooklyn.

Mr. Townrow's inherent honesty, unstinted generosity, diligence, and conscientiousness in work, together with his keen wit and warm humor were but a few of the very fine characteristics that brought Mr. Townrow the respect and friendship of all those who were associated with him both professionally and socially.

He is survived by his widow; a daughter, Helen (Mrs. Louis D. Donaldson); a sister, Ione (Mrs. M. W. Macready); and four grandchildren.

Mr. Townrow was elected an Associate Member of the American Society of Civil Engineers on December 15, 1924.

ALBERT OTIS TRUE, Assoc. M. ASCE[1]

DIED MARCH 9, 1945

Albert Otis True, the son of Col. Edward A. and Jane (Milnes) True, was born on December 26, 1879, in Lowell, Mass. He was a descendant of Capt. Henry True who settled in Salem, Mass., in 1654. His father was colonel of the 8th Maine Volunteers, during the Civil War, and his grandfather, Edward True, was a captain in the Revolutionary War and the War of 1812.

Mr. True was graduated from the public schools in Newton, Mass., and from the Massachusetts Institute of Technology (Cambridge) in 1905 with the degree of Bachelor of Science in Sanitary Engineering. For two years after graduation he was assistant to the chief engineer, draftsman and designer for the Pittsburgh Filter Manufacturing Company, Pittsburgh, Pa. During the summer of 1906 he inspected a number of sanitary works in England. In May, 1907, he joined the staff of the late Rudolf Hering and George W. Fuller, Members, ASCE, hydraulic and sanitary engineers, New York, N. Y., as assistant engineer and worked there until May, 1910. He was employed on the design of mechanical filtration plants for Bangor, Me., and Burlington, Vt., and was in charge of design and plans for a pumping station and mechanical filter plant at Botany Worsted Mills, Passaic, N. J., costing $98,000. In March, 1908, he made a series of tests on hydraulic performance of large aeration nozzles. He was in charge of the plans and details of various works in connection with reports of the firm as chief engineer of the Passaic Valley Sewerage Commission. In 1908 Mr. True and E. G. Manahan, M. ASCE, designed water sterilization works for Jersey City, N. J., (50 mgd) and worked on surveys and designs of various sewage-disposal plants. The summer of 1909 he was acting resident engineer on three miles of pipe sewers and a small disposal plant at Kings Park, N. Y.

---

[1] Memoir prepared by George H. Maurice, M. ASCE.

Following this, in June, 1909, he was consulting engineer on revision and extension of sewerage and sewage-disposal works for the Massachusetts State Hospital for Epileptics at Monson, Mass.

From 1910 to 1913, he was an assistant sanitary engineer for the New York State Department of Health, and, from 1913 to 1916, he was sanitary engineer for the New York State Department of Architecture. In 1916, he became the junior member of the firm True and McClelland, of Boston, Mass.

It was natural for Mr. True to follow the family military tradition and, on September 26, 1917, he was commissioned Captain of the Corps of Engineers of the United States Army. He held this commission until November 8, 1920. His tour of duty included: Command of the Water Supply School at Camp A. A. Humphreys, Va. (April, 1918); second in command of the 78th Engineers (October, 1918); an assignment in the Historical Data Section, Office of the Chief of Engineers (November, 1918, to October, 1919); and, from November, 1919, to November, 1920, Utilities Officer at Newport News, Hospital No. 43, Hampton, and Fort Monroe, all in Virginia. He was also in charge of army water supplies on the lower Virginia peninsula. During the summer of 1921, he was resident engineer on construction of a reservoir for the City of Wauseon, Ohio. From October, 1921, to April, 1922, Mr. True was assistant engineer for the Pennsylvania State Department of Health, and in April, 1922, he became sanitary engineer for the Proximity Manufacturing Company, Greensboro, N. C., and continued in that capacity until his death. During his engineering career he had many papers published in technical journals.

On June 18, 1913, at Rensselaer, N. Y., Mr. True was married to Charlotte Elizabeth Bishop who survives him.

At a meeting of the North Carolina Section, on December 11, 1944, at Winston-Salem, Mr. True was presented with a Life Membership certificate at which time he spoke with feeling of his deep appreciation and how much his membership in the Society had meant to him during the many years he had been a member.

Mr. True was a member of the American Water Works Association, and served as chairman of the North Carolina Section; the National Geographic Society; the Henry K. Burtner Post of the American Legion at Greensboro; and the Forty and Eight Club.

He was a member of Holy Trinity Episcopal Church of Greensboro for many years. On March 11, 1945, the Reverend Robert E. Roe, Rector Emeritus of that church held the funeral services of the late Albert Otis True. The internment was at Albany, N. Y.

Mr. True's recreations had been, during earlier life, tennis and volleyball, and in later years, walking and motoring. He was of an unusually quiet and retiring disposition. Company officials have words of highest commendation for Mr. True, his department being so well and capably handled that it never gave them a moment's concern; it functioned perfectly.

Mr. True was elected a Junior of the American Society of Civil Engineers on February 5, 1907, and an Associate Member on May 31, 1910.

WILLIAM HOWELL WOOD, Assoc. M. ASCE[1]

Died May 7, 1945

William Howell Wood was born in Waco, Tex., on November 16, 1896, the son of William Howell Wood and Annie (Battle) Wood. From his earliest years, when he secured his first job at the age of ten, he became self-educating and self-supporting. Upon his graduation from Waco High School he started learning engineering the hard, but thorough, way—by practical experience.

Practically all Mr. Wood's professional work was performed in Texas, covering a very large part of its area. His engineering work began in the railroad field in 1917, with the Panhandle and Santa Fe Railroad Company, and then with the North Texas and Santa Fe Railroad Company. Later he accepted positions with the Morgan Engineering Company, the Texas Power and Light Company, the Reclamation Service, U. S. Department of the Interior, and the City Engineer's Office of Waco.

In 1919 Mr. Wood entered the highway engineering field with the firm of Bryant and Huffman, at Denton, Tex., supervising field parties and preparing estimates for construction. During 1922 and 1923, he was superintendent for the F. P. McElwrath Construction Company of Corsicana, Tex., in charge of highway construction projects in Fannin, Kaufman, Freestone, and Navarro counties. For the next fifteen months he conducted preliminary locations of highways in Freestone County for J. E. Johnson, county highway engineer.

In the fall of 1925, when he was twenty-nine years of age, he realized the need for technical training to advance himself in his chosen profession, and he entered the College of Engineering of the University of Texas at Austin, Tex. From June, 1927, to December, 1928, while a student at the University, he was also assistant city engineer of Austin. In 1929 he received the degree of Bachelor of Science in Civil Engineering from the University of Texas.

Nearly half Mr. Wood's career was spent with the Texas State Highway Department. In August, 1924, he was appointed maintenance engineer in the Waco division, and served in that capacity until November, 1925. Shortly after receiving his engineering degree from the University, he returned to the Texas State Highway Department as engineer of materials and tests. He was administrative head of that division, including the department's laboratories, and continued in that capacity until August, 1936, when he was made asphalt research engineer. In September, 1937, he returned to his former position as engineer of materials and tests.

One of the outstanding accomplishments of Mr. Wood's professional life was planning, organizing, and supervising the building up of the Texas State Highway Department's Materials and Tests Laboratories until they ranked among the best in the United States.

In February, 1940, he resigned from his position as engineer of materials and tests to enter business for himself at Austin, Tex., selling materials for the construction of highways and airports. Here his long years of practical experience, which had engendered self-confidence, gave him the ability to act quickly in the war emergency, and his reputation for reliability among engineering friends and associates secured for him large and remunerative contracts in connection with the airfields of the United States.

---

[1] Memoir prepared by Henry C. Porter, M. ASCE.

Mr. Wood's illness was of short duration. A man of simple and temperate habits, he was expected to have a long and useful future. A typical Texan, product of one of her smaller cities, schooled from early boyhood by hard work and duty's stern demands, he was, nevertheless, totally lacking in the egotism or grimness which sometimes characterize self-made men; instead, an overwhelming optimism and zest for life characterized all his undertakings and constituted the mainspring of his personality. Quiet and unassuming in manner, he possessed a sense of humor and tolerance which made him very successful in handling men. He loved his work and devoted practically all his time to engineering matters. At the same time he enjoyed the companionship of his many friends and he was always a genial and entertaining host.

On May 7, 1931, Mr. Wood was married to Elise Burnett of Austin. He is survived by his widow and two sons, William Howell Wood, III, and Charles Burnett Wood.

Mr. Wood was a licensed professional engineer of the State of Texas, a member of the Texas Society of Professional Engineers, the Austin Rotary Club, and the Baptist Church.

Mr. Wood was elected an Associate Member of the American Society of Civil Engineers on June 13, 1938.

ROBERT TYRIE BENTON, Jun. ASCE[1]

Died March 24, 1945

Robert Tyrie Benton, the son of the late Dean John Robert Benton, of the College of Engineering, University of Florida, at Gainesville, and Maybelle (Williams) Benton, was born on June 24, 1915, in Williston, Fla.

His preparatory education was received in the Gainesville High School. He was graduated, magna cum laude, from the University of Florida with the degree of Bachelor of Science in Civil Engineering in June, 1935.

During the winter of 1935–1936, he assisted in surveying the route for the proposed Florida Cross State Canal. After the discontinuance of the canal project in 1936, he was employed in the office of the United States Government Engineers at Vicksburg, Miss., on the work of Mississippi River flood control.

In the fall of 1937, he resigned this position in order to take part in a sailboat race between St. Petersburg, Fla., and Havana, Cuba, in which he and two friends sailed a thirty-three-foot boat. Later, with a crew of four, they spent several months cruising around the Bahama Islands.

---

[1] Memoir prepared by Mrs. John Robert Benton, Gainesville, Fla.

From August, 1938, until January, 1939, he worked as surveyor with a land company in New Smyrna, Fla. In February, 1939, he went to Venezuela to work as a gravity meter operator for the Socony-Vacuum Oil Company. He continued in this work until he returned home, in 1942, to enter the United States Army.

He began his basic training at Fort Leonard Wood, Missouri, in October, 1942. From there he was sent to Grand Rapids, Mich., for a nine months' course in meteorology. The *Forecaster,* weather school publication, chose him "Cadet of the Day" to represent the activities of a typical day's routine there. He finished second in a class of several hundred, and received his commission as Second Lieutenant in September, 1943. He was about to be sent out on foreign duty as weather forecaster in the Air Forces, when, because of a shortage of navigators, he was selected with fourteen other members of his class to become a navigator. He completed the four and a half months of navigation training at Monroe, La., with the highest record in the history of that navigation school. He was retained there as an instructor for about six months.

He was sent to England in August, 1944, as a navigator on a C–47 Skytrain transport plane. From his base in southern England he took part in missions over Europe until his squadron was transferred to France for the greatest air offensive of the war. A letter from his commanding officer, dated April 20, 1945, states that he had received his promotion to the rank of First Lieutenant, effective April 1.

Lieutenant Benton's C–47 departed from France on a glider tow mission on March 24. The plane ran into flak two miles southeast of Wesel, Germany, after having completed its mission, and caught fire. All crew members parachuted over enemy territory. Lieutenant Benton was shot down and killed. The other crew members were taken prisoners and later liberated. He was awarded, posthumously, the Purple Heart, the Air Medal, and two Oak-Leaf Clusters.

Lieutenant Benton was scholarly and lovable, always ready to serve or befriend those with whom he came in contact. Just before leaving England, Lieutenant Benton visited a relative whom he had never met before. In her letter to his mother after his death, she wrote:

> "I have a vivid picture of Robert standing tall on the hearthrug. He seemed so lighthearted I hardly thought of the danger he was running. I was struck with the accord between him and his air corps friend. They just looked like boys who did serious work together."

Interested in his profession to the end, Lieutenant Benton wrote a friend that he had developed some improved methods of navigation.

His commanding officer wrote:

> "Robert was respected and admired for his quiet and efficient performance of work, and liked by all for his pleasant amiability."

Lieutenant Benton is survived by his mother and three brothers. The brothers are Sgt. Charles R. Benton, Lt. (jg) Hugh Herbert Benton, and John J. Benton, M.D.

Lieutenant Benton was elected a Junior of the American Society of Civil Engineers on November 10, 1941.

BERLIN FRANK CODAY, JR., Jun. ASCE[1]

Died April 9, 1945

Berlin Frank Coday, Jr., was born in Commerce, Okla., on February 14, 1921, the son of Berlin F. Coday and Ruby C. (Latimer) Coday. He attended public schools in Tulsa, Okla.; San Antonio, Tex.; and Springfield and Kansas City, Mo. He was graduated from Southwest High School in Kansas City.

He attended Kansas City Junior College for two years, and then entered the University of Utah at Salt Lake City, Utah, where he received his engineering degree in June, 1944. He was affiliated with Beta Theta Pi fraternity.

During his summer months in Salt Lake City, Frank worked in the engineering department of the Intermountain Contractors on the building of Camp Kearns, Utah. He also worked on various engineering projects for the Illinois Powder Manufacturing Company, making surveys and estimates on large quarry blasts for the Ideal Cement Company's quarry at Devil Slide, Utah.

After being inducted into the Army in July, 1944, Frank was sent overseas the following December and assigned to Company A, 383d Infantry, 96th Division of the Tenth Army. He was killed in action on Okinawa Island on April 9, 1945, while acting as a personal messenger for his company commander. He had previously been awarded the Infantryman's Combat Badge for excellence in infantry combat.

Frank enjoyed outdoor life to the fullest extent. His hobbies were music, golf, and hunting. He was a clean sportsman, a true American of high character, integrity, and ideals. He was loved by all who knew him. He is survived by his parents; a sister, Betty Jean Coday; and an aunt, Mrs. Maude Davis.

Mr. Coday was elected a Junior of the American Society of Civil Engineers on March 12, 1945.

JUAN CRISOSTOMO DORIA PAZ, Jun. ASCE[1]

Died December 28, 1944

Juan Crisostomo Doria Paz was born in Linares, Nuevo León, Mexico, on June 24, 1911. He was a son of Juan C. Doria and Leonarda Paz de Doria.

---

[1] Memoir prepared by Frank E. Bodine, San Francisco Mgr., Westinghouse Elec. Corp., San Francisco, Calif.

[1] Memoir prepared by Lisandro Peña, Jr., Architect, Monterrey, N.L. Mexico.

His grandfather, a doctor from Villagrán in the same state, came to reside in Linares when quite young and there Juan C. Doria, Sr., was married and started practice as a civil engineer. Later they changed their residence to Monterrey, Nuevo León, Mexico, where the family lived while Juan, Sr., worked continuously on the development of railroads which were then in their infancy. The line from Monterrey to Tampico, Mexico, was pioneered, planned, and executed by Juan C. Doria, Sr.

After graduating at the old Colegio Civil in Monterrey, Mr. Doria followed his father's footsteps and studied at the Agricultural and Mechanical College of Texas at College Station, Tex., from which he was graduated on June 2, 1934.

Immediately after graduation he started to work for Compañia Fubdidora de Fierro y Acero in Monterrey designing steel structures and eighteen months later he went into partnership with Luis F. Flores, architect and college friend. He was then registered as civil engineer in the Office of Public Works of the State of Nuevo León. This partnership lasted for three years. During this time he initiated his work in residential construction, to which he dedicated most of his time after the partnership was dissolved in 1939.

In the following six years his office handled more than two and one half million pesos which went into such construction jobs as: A swimming pool for the Círculo Mercantil, structures of Florida theater, a nail factory, Banco Popular, Molinos El Fenix, Facultad de Ciencias Quimicas, and many residences.

On the 28th of December, 1944, he made his usual visit to the Cristo Rey Temple job where the concrete roof was being poured. He climbed the wooden forms and started to check the pouring. The vertical posts collapsed, and he and seventeen workmen on the job fell to their deaths from a height of sixty feet. They were buried in thirty tons of concrete and steel.

He left, besides the Cristo Rey Temple, such unfinished jobs as the million peso bridge to Del Valle suburban development, the Santos Office Building, another bridge across the Santa Catarina River, Industrias Thermoplásticas Factory, and numerous other factories and residences.

Mr. Doria is survived by his wife Idolisa Salazar; his two daughters, Idolsia Margarita and Maria Eugenia; his father, Juan C. Doria; his brother, Attorney Francisco Doria Paz; his sister, Elena; and numerous other relatives.

Juan C. Doria Paz will never be replaced either professionally or in the hearts of his friends, including his colleagues and many members of other professions. The vacant spot he left as chairman of the Engineering Faculty of the University of Nuevo León will be difficult to fill. His energy and "drive" in local society and public work will be greatly missed. His Christianity, charm, and gentleness will long live in the memories of all his friends.

Mr. Doria Paz was elected a Junior of the American Society of Civil Engineers on February 11, 1935.

EDWARD FRY, JR., Jun. ASCE[1]

DIED NOVEMBER 23, 1944

Edward Fry, Jr., the son of Edward Fry, and Ethel (Neale) Fry, was born in Brownsville, Tex., on November 10, 1918. He attended high school and junior college in that city, and was graduated from the junior college in 1938.

In 1939, he entered the Agricultural and Mechanical (A. and M.) College of Texas, at College Station. In 1942, he was made First Lieutenant in the cadet corps at A. and M., and was second in command of Company "A" Engineers. Lieutenant Fry distinguished himself as a student, and received the degree of Bachelor of Science in Civil Engineering in January, 1943. During his four years at Texas A. and M., Lieutenant Fry was a member of the Student Chapter of the American Society of Civil Engineers, the Society of American Military Engineers, and a member of the rifle team.

Immediately after he received his Bachelor of Science degree, he was inducted into the army. He went to Fort Belvoir, Va., where he was commissioned a Second Lieutenant on May 12, 1943. His first assignment was at Camp Swift, Texas. He was sent overseas in November, 1943, with the 82d Combat Engineers, being stationed first in North Africa and later in England. In March, 1944, he received his promotion to First Lieutenant.

Lieutenant Fry was with the First Army under Gen. Courtney H. Hodges, Jr., and left England on D-Day, moving through France, Holland, Belgium, and into Germany. On November 23, 1944, he was killed in action, in Germany, and was buried in a United States Military Cemetery in Holland. He was awarded, posthumously, a Presidential Citation and the Purple Heart, for military merit and for wounds received in action which caused his death. These awards were presented to his mother, Mrs. Jack Hirschmann, who survives him.

Lieutenant Fry was elected a Junior of the American Society of Civil Engineers on June 14, 1943.

RICHARD ALDEN KEASEY, Jun. ASCE[1]

DIED FEBRUARY 4, 1945

Richard Alden Keasey, the son of Dorr E. and Florence Anne Keasey, was born on July 21, 1911, in Portland, Ore. He was educated in Portland, being graduated from Lincoln High School in June, 1929. In September, 1929, he entered the University of Oregon at Eugene, majoring in business administration. In June, 1931, he was awarded membership in Alpha Kappa Psi (Kappa Chapter).

---

[1] Memoir prepared by C. E. Sandstedt, Assoc. M. ASCE.

[1] Memoir prepared by Mrs. Florence A. Keasey, Portland, Ore.

He entered the service of the Oregon State Highway Commission in 1931, serving as head chainman until 1935, when he was employed by the Bonneville Dam Administration at Bonneville, Ore. In September, 1938, he entered Oregon State College at Corvallis, majoring in civil engineering. He served in the Engineering Corps of the Reserve Officers Training Corps, receiving the commission of Second Lieutenant. He belonged to the Phi Delta Theta fraternity (Oregon Beta), being manager of his house in 1940. He was graduated from Oregon State College, with the degree of Bachelor of Science.

Lieutenant Keasey was a member of the following societies; Tau Beta Pi (Alpha of Oregon); Sigma Tau (Zeta Chapter, Oregon State College); Pi Mu Epsilon (Oregon Beta Chapter); and the national military society, Scabbard and Blade.

In April, 1941, he was called to active duty in the United States Army and ordered to report in Manila, Philippine Islands. On April 17, 1941, he went to Fort Mason in San Francisco, Calif. He left San Francisco on April 22, 1941, on the Army transport *Washington,* and arrived in Manila on May 8, 1941. In Manila he was assigned to the Philippine Department Headquarters, Corps of Engineers, Fort Santiago. Fort Santiago being headquarters for all the Army posts and air corps fields in the Islands. The day following his arrival, he took over supervision of construction of a new runway for Nichols Field, about five miles from Manila. His office was at headquarters where his duties included procurement work, all requisitions to the engineer depots, estimates, and requisitions to the depots of supply. Later he was sent around on payrolls, inspections, supervisions, and other duties.

In November, 1941, he was sent to Cabanatuan, Nueve Eciji Province, Luzon. He was in charge of construction of airplane runways, roads, railroad sidings, warehouses, barracks, etc. He was the only officer there, and the only other white man in the immediate country was a merchant in Cabanatuan.

Sometime in November, 1941, he flew by Army plane and Navy amphibian plane to the south, on engineering duties, covering such places as Baler, Tayabes, Bolinao, Pangasinan, Lubang Island, Mindora, and as far south as Mindinao. In the Philippines he served as adjutant to his Commanding Officer, Major Findley, until the latter part of October, 1941, when Major Findley died. Lieutenant Keasey was commissioned a First Lieutenant effective January, 1941.

After December 7, 1941, two letters were received—one from somewhere in the Philippine Islands, on March 16, 1942, and the other from somewhere in Bataan. On Easter morning, April 2, 1942, he sent a telegram from the Island of Cebu. His last letter was dated April, 1942, from somewhere in Bataan. After the "Death March," he was taken to Cabanatuan Camp No. 1, remaining there until the latter part of October, 1944, when the Japanese moved able-bodied prisoners of war to Bilibid Prison Camp. On December 15, 1944, he was put aboard a prison ship that was torpedoed a short way out from Manila Bay. However, he was rescued and taken to Honshu Island, dying of acute colitis on February 4, 1945, in Fukuoka Prisoner of War Camp No. 22, in Japan.

Richard Keasey early showed the characteristics of a student. In the elementary grades he ranked first in his school. He also won a bank account for an essay on "Savings," written at the age of twelve. In high school he was graduated with honor. During this period, he won six medals and the silver champion loving cup, in one night's performance, for junior athletics at the Multnomah Athletic Club. He was an honor student at University of Oregon and Oregon State College.

His personality could best be summed up by an expression of his professor, Charles A. Mockmore, M. ASCE, head of the civil engineering department who called him a "Christian gentleman" and stated that he had never had a student for whom he had so much regard. The different activities of his life showed that Lieutenant Keasey was always striving to attain perfection in whatever he undertook. Lieutenant Keasey was not married. He was an only child.

Lieutenant Keasey was elected a Junior of the American Society of Civil Engineers on October 9, 1941.

ROBERT AUGUSTUS LEWIS, Jun. ASCE[1]

Died September 20, 1944

Robert Augustus Lewis, the son of Lt.-Col. Augustus T. and Blanche (Deloison) Lewis, was born at Quantico, Va., on October 26, 1920. He was graduated from the San Diego (Calif.) Army and Navy Academy, in 1938; and he immediately enrolled in the Virginia Military Institute (V. M. I.) at Lexington, being graduated at the top of his class in 1942. He was on the roll of honor every month during his four years at college, and his diploma shows him to be a distinguished graduate of V. M. I. During his vacation from college, in 1941, he was employed as a civil engineer by the Angle Construction Company at Parris Island, S. C.

Mr. Lewis received his commission as Second Lieutenant of Infantry in the Army of the United States upon his graduation from V. M. I., and reported for duty immediately at Fort Benning, Ga. He served as commanding officer of Company B, 15th Armored Infantry Battalion, Fifth Armored Division, from the time of its organization until his death.

In January, 1944, he arrived in England; and on August 6, 1944, he distinguished himself by personally wiping out a pocket of Germans in France for which he was awarded the Bronze Star medal. He was also awarded the Infantryman's Combat Badge, and the Purple Heart.

On September 19, 1944, his division received orders to withdraw from Germany, and Company B was assigned to cover the Americans' withdrawal. His company remained at its post and was sacrificed. Lieutenant Lewis was in the vicinity of Wallendorf, Germany, when he was killed by a direct hit from artillery. His body was buried in the United States Military Cemetery at Foy, Belgium.

---

[1] Memoir prepared by Lt.-Col. Augustus T. Lewis, U. S. Marine Corps, San Diego, Calif.

Lieutenant Lewis was elected a Junior of the American Society of Civil Engineers on November 9, 1942.

STEPHEN TENER LOWRY, Jun. ASCE[1]

Died September 9, 1944

Stephen Tener Lowry, the son of Swift Lowry and Katharine (Tener) Lowry, was born in Cleveland, Ohio, on October 16, 1919. He was graduated from Shaw High School in East Cleveland. He was a member of the National Honor Society, and became an Eagle Scout. In September, 1937, he entered Lehigh University in Bethlehem, Pa., from which he was graduated, with honors, in June, 1941, with the degree of Bachelor of Science in Civil Engineering. At Lehigh his principal extracurricular activity was intramural and intercollegiate debating, and he was elected a member of Delta Omicron Theta, honorary debating society.

A member of the Reserve Officers Training Corps, Stephen was commissioned a Second Lieutenant upon his graduation and was called to active duty on July 6, 1941. After eight months at Fort Custer, Mich., he went to Iceland as a member of the Eleventh Infantry Regiment of the Fifth Division. While there he was promoted to First Lieutenant. In July, 1943, the Division moved to England, then to Ireland, and in July, 1944, became part of the Third Army under the late Gen. George S. Patton, Jr., in the drive across France. Early in September, Lieutenant Lowry was made a Company Commander and recommended for a Captaincy. He was killed while leading one of the units crossing the Moselle River south of Metz, France. The Purple Heart and the Silver Star medals were awarded to him posthumously. A fellow officer wrote, "His first thoughts were always for his men and he was protecting them when he was killed."

He is survived by his father, a veteran of World War I; his mother; two brothers, William and Robert, both veterans of World War II; and a sister, Katharine (Mrs. M. C. Dietrich, Jr.).

Mr. Lowry was elected a Junior of the American Society of Civil Engineers on November 10, 1941.

---

[1] Memoir prepared by Swift and Katharine Lowry, Cleveland, Ohio.

HAROLD LESTER ODOM, Jun. ASCE[1]

Died January 7, 1946

Harold Lester Odom, the son of George A. and Alma (Deaton) Odom, was born at Many, La., on July 2, 1917. He attended the public schools of Jackson Parish, Louisiana, and was graduated from Jonesboro (La.) High School in 1934. In September, 1934, he entered Louisiana State University at Baton Rouge. In 1936 he went to work for the Soil Conservation Service in Ruston, La. He subsequently entered Louisiana Polytechnic Institute at Ruston, as an engineering student, and continued to work on part-time basis for the same agency for two years. At the same time, he engaged in the publication of a newspaper with his brother, Roy, in the capacity of reporter, typist, and salesman. In 1938 he was employed in Baton Rouge by the U. S. Bureau of Agricultural Economics on map drafting and statistics, and a few months later he was transferred to the Little Rock, Ark., office. In 1939 he accepted a position with H. V. Howe, head of the Lousiana State University School of Geology, as a draftsman, resuming his college career in the School of Engineering and working part time in the geology drafting room. Mr. Odom was awarded the degree of Bachelor of Science in Civil Engineering in 1941. In July, 1941, he enlisted in the United States Marine Corps and was sent to Quantico, Va., for training as an officer.

In January, 1942, he was commissioned a Second Lieutenant in the United States Marine Corps Reserve and was selected for further training in the Field Artillery. He was then attached to the Second Defense Battalion and joined the Second Marine Brigade on the American mandate island of Samoa. At that time this was the furthest outpost of our defense system and he was actively engaged in preparing the defenses on the island. In September, 1942, he was promoted to the rank of First Lieutenant and transferred to the Eighth Marine Regiment, in command of a heavy and light machine gun platoon.

In November, the Eighth Marines were assigned to the First Marine Division on Guadalcanal where they were engaged in the first offensive action against the enemy. Lieutenant Odom's platoon was actively engaged in combat for more than three months and was several times cited for repulsing enemy "Banzai" attacks.

Eventually the Eighth Marines were sent to New Zealand with the Second Division. Lieutenant Odom was promoted to Captain and given command of Company "K," Third Battalion. After an extensive training period, the Second Division went into action in the Gilbert Islands on the atoll of Tarawa and Captain Odom's Company was one of the first to land. He was personally responsible for the reorganizing of two rifle companies and for leading the attack against some of the enemy's strongest emplacements. He was wounded slightly but refused to leave his troops—his actions at all times were an inspiration to his men. For his actions, bravery, and leadership during this attack, he was awarded the Silver Star Medal personally presented by Admiral Chester W. Nimitz in Hawaii.

---

[1] Memoir prepared by Maj. Scott Corbett, Jr., Nelson Equipment Co., Portland, Ore.

The Second Division was reorganized and retrained on Hilo, Hawaii, where Captain Odom was primarily responsible for development of some new infantry tactics—tank cooperation and the use of demolitions against pillboxes. In May, 1944, he again took his company into action against the enemy on the Island of Saipan and, at one time, was acting Battalion Commander. In a long extensive campaign he was responsible for leading his men time and again against the enemy and again his actions and leadership carried his battalion through. He was severely wounded during this campaign; but, after spending several weeks in the hospital, rejoined his troops in time for the Tinian offensive action.

After thirty months overseas and four major campaigns, he was returned to the United States and promoted to the rank of Major. He was assigned command of an Officers' Training Battalion at Camp Pendleton, Calif., and served in that capacity until the end of the war and his release from the Marine Corps.

While in the service, Major Odom had become interested in construction machinery and chose his civilian career along those lines. He became associated with a concern in Portland, Ore., with branch offices in the states of Washington and Idaho. With his engineering and military background, a very brilliant future was predicted for him. While en route along the Columbia River Highway to his new office in Boise, Idaho, the car in which he was riding was struck by a rolling rock and thrown off a steep cliff. He was killed instantly—this man who had offered up his life time and again for his country in overseas combat—in pursuit of his civilian profession on the highways of the United States.

His death was an extreme shock and mystery to those who loved him. His future life promised nothing but success and service to a constructive country—yet, in his short span of years, he did fulfill the duties and promises of a lifetime. All who associated with him will bear the sorrow of his death, but they will remember with pleasure the privilege of being associated with him, his sincerity and honesty, his clarity of purpose, his personal character and courage, and his love of life.

Major Odom is survived by his widow, Nedra Foster; his three-month-old son, Tom; five brothers, Leo M., M. ASCE, Roy H., Thomas D., George E., and John S. Odom; and two sisters, Elsie (Mrs. Frank B. Brown) and Nell (Mrs. Sydney Chalmers).

Major Odom was elected a Junior of the American Society of Civil Engineers on November 10, 1941.

"Mathematical Examination of the Highway Transition Spiral." John Oran Eichler and Howard W. Eves. 959. Discussion: Joseph Barnett, Ralph W. Stewart, Donald Thompson, T. F. Hickerson, Allen H. Brownfield, René S. Pulido y Morales, C. C. Wiley, Max C. Koehler, and William T. Pryor. 976.

DAMS

"Design Developments—Structures of the Tennessee Valley Authority." A Symposium. (With Discussion.) 1159.

"Deterioration of Concrete Dams Due to Alkali-Aggregate Reaction." R. F. Blanks and H. S. Meissner. (With Discussion.) 743.

DAMS, MOVABLE

"A Plan for a Movable Dam." Isaac DeYoung. 253. Discussion: C. L. Hall, C. E. Meyerdick, Ralph R. Leffler, Jay L. Southworth, L. C. Sabin, A. W. Sargent, and Isaac DeYoung. 262.

DEPRECIATION

See VALUATION

DRAINAGE

"Flow from Drainage Basins Determined by Short-Term Records." Lloyd L. Harrold. 597. Discussion: Samuel Roberts, and Lloyd L. Harrold. 609.

EARTH DAMS

"The Effect of Blankets on Seepage Through Pervious Foundations." Preston T. Bennett. (With Discussion.) 215.

EARTH PRESSURES

"Stresses in the Linings of Shield-Driven Tunnels." Anders Bull. (With Discussion.) 443.

ECONOMICS

"Economics of Photogrammetry." Leon T. Eliel. (With Discussion.) 567.

ENGINEERS AND ENGINEERING

"Stewardship of Professionalism Given High Priority." Address at the Annual Convention, Spokane, Washington, July 17, 1946. W. W. Horner. 1401.

EVAPORATION

"Evaporation from a Free Water Surface." G. H. Hickox. 1. Discussion: Carl Rohwer, C. W. Thornthwaite, Harry F. Blaney, Arthur A. Young, A. A. Kalinske, Adolph F. Meyer, Maurice L. Albertson, and G. H. Hickox. 34.

FAILURES

"Deterioration of Concrete Dams Due to Alkali-Aggregate Reaction." R. F. Blanks and H. S. Meissner. (With Discussion.) 743.

FLOOD CONTROL

"Correlating Flood Control and Water Supply, Los Angeles Coastal Plain." Finley B. Laverty. (With Discussion.) 1127.

FLOODS

"Correlating Flood Control and Water Supply, Los Angeles Coastal Plain." Finley B. Laverty. 1127. Discussion: A. L. Sonderegger, Warren N. Thayer, George B. Gleason, and Finley B. Laverty. 1145.

FLUMES

"Flow in a Channel of Definite Roughness." Ralph W. Powell. (With Discussion.) 531.

"Transportation of Suspended Sediment by Water." Vito A. Vanoni. 67. Discussion: Ralph W. Powell, E. R. Van Driest, Weston Gavett, Berard J. Witzig, A. A. Kalinske, Paul F. Nemenyi, and Vito A. Vanoni. 103.

FOUNDATIONS

"The Effect of Blankets on Seepage Through Pervious Foundations." Preston T. Bennett. 215. Discussion: Reginald A. Barron, V. A. Endersby, Harry R. Cedergren, W. J. Turnbull, Kenneth S. Lane, and Preston T. Bennett. 229.

FRAMEWORKS

See **STRUCTURES, THEORY OF**

FRICTION

"The Mechanism of Energy Loss in Fluid Friction." Boris A. Bakhmeteff and William Allan. (With Discussion.) 1043.

GROUND WATER

"Correlating Flood Control and Water Supply, Los Angeles Coastal Plain." Finley B. Laverty. (With Discussion.) 1127.

"Utilization of Ground-Water Storage in Stream System Development." Harold Conkling. 275. Discussion: Raymond A. Hill, Clarence S. Jarvis, John R. Charles, C. W. Sopp, J. A. Bradley, Irving B. Crosby, G. B. Drummond, Raphael G. Kazmann, Donald M. Baker, Hyde Forbes, and Harold Conkling. 306.

HEAT

"Effects of Radiant Heat on Reinforced-Concrete Rigid Frames." Milan A. Johnston. (With Discussion.) 1103.

HIGHWAYS AND ROADS

"Design of Roadbeds." Ira B. Mullis. 699. Discussion: Charles W. Britzius, J. T. L. McNew, Gustavo Pérez Guerra, Jacob Feld, Jasper L. Stuckey, Delbert L. Lacey, René S. Pulido y Morales, K. B. Woods, and Ira B. Mullis. 719.

"Mathematical Examination of the Highway Transition Spiral." John Oran Eichler and Howard W. Eves. (With Discussion.) 959.

HYDRAULICS

"Conversion of Kinetic to Potential Energy in Flow Expansions." A. A. Kalinske. 355. Discussion: F. T. Mavis, J. C. Stevens, Boris A. Bakhmeteff, E. R. Van Driest, A. R. Thomas, and A. A. Kalinske. 375.

"Design Developments—Structures of the Tennessee Valley Authority." A Symposium. (With Discussion.) 1159.

"The Mechanism of Energy Loss in Fluid Friction." Boris A. Bakhmeteff and William Allan. (With Discussion.) 1043.

"Transportation of Suspended Sediment by Water." Vito A. Vanoni. (With Discussion.) 67.

MAPS

"Economics of Photogrammetry." Leon T. Eliel. 567. Discussion: Raymond A. Hill, Raymond L. Moore, Ralph S. Pearse, George D. Whitmore, Benjamin A. Wasil, Charles H. Davey, Robert H. Randall, W. J. Ryan, Oliver S. Reading, and Leon T. Eliel. 577.

MATERIALS OF CONSTRUCTION

"Design of Roadbeds." Ira B. Mullis. (With Discussion.) 699.

MATHEMATICS

"Mathematical Examination of the Highway Transition Spiral." John Oran Eichler and Howard W. Eves. (With Discussion.) 959.

MEMOIRS OF DECEASED MEMBERS

See name of member in Author Index; also Contents, page x.

METEOROLOGY

"Evaporation from a Free Water Surface." G. H. Hickox. (With Discussion.) 1.

MINERALS

Reaction characteristics of minerals (Table 2). 768.

MOMENTS

"Interrelation of Certain Structural Concepts." Camillo Weiss. 391. Discussion: Ralph W. Stewart, R. C. Brumfield, Max W. Strauss, Leon Beskin, Alexander Dodge, William C. Spiker, T. F. Hickerson, Dean F. Peterson, Jr., A. A. Eremin, and Camillo Weiss. 405.

MOVABLE DAMS

See **DAMS, MOVABLE**

NOMOGRAPHS

Nomograph for sludge dosing. 652.

PHOTOGRAPHY, AERIAL

"Economics of Photogrammetry." Leon T. Eliel. (With Discussion.) 567.

PIPE LINES

"Elimination of Cross Connections in Los Angeles, Calif." Harry Hayes. 613. Discussion: Roy O. Van Meter, Robert P. Lowe, and Harry Hayes. 628.

POWER PLANTS

"Design Developments—Structures of the Tennessee Valley Authority." A Symposium. 1159. Discussion: A. T. Larned, Willam P. Creager, I. L. Tyler, Philip Sporn, Joseph R. Bowman, Paul Gisiger, Oren Reed, R. L. Smart, Abraham Streiff, and Ross M. Riegel, George P. Palo and Constant R. Marks, III, and Adolf A. Meyer. 1199.

PRESSURES

See **EARTH PRESSURES**

RAINFALL

Rainfall in the upper Colorado River basin states. 1271.

REINFORCED CONCRETE

"Effects of Radiant Heat on Reinforced-Concrete Rigid Frames. Milan A. Johnston. 1103. Discussion: I. Oesterblom, N. M. Newmark, L. C. Hollister, A. A. Eremin, and Milan A. Johnston. 1115.

REPORTS OF COMMITTEES

"Principles of Depreciation": Final Report of the Special Committee Authorized by the Board of Direction to Analyze and Discuss the 1943 Report of the National Association of Railroad and Utilities Commissioners' Committee on Depreciation. 1343.

RESERVOIRS

"Correlating Flood Control and Water Supply, Los Angeles Coastal Plain." Finley B. Laverty. (With Discussion.) 1127.

"Future of Lake Mead and Elephant Butte Reservoir." J. C. Stevens. (With Discussion.) 1231.

See also **DAMS**

RUNOFF

"Flow from Drainage Basins Determined by Short-Term Records." Lloyd L. Harrold. (With Discussion.) 597.

Water and silt runoff, Colorado River and Rio Grande basins. 1282–1286.

SAFETY

Design speeds on curved highways (Table 4). 1008.

SEDIMENTATION

"Future of Lake Mead and Elephant Butte Reservoir." J. C. Stevens. 1231. Discussion: D. C. Bondurant, John H. Bliss, Luna B. Leopold, Carl B. Brown, G. E. P. Smith, Albert E. Coldwell, Walter B. Langbein, C. S. Howard, Charles Kirby Fox, H. V. Peterson, L. C. Crawford and P. C.

Benedict, Charles P. Berkey, Stafford C. Happ, Berard J. Witzig, Hugh Stevens Bell, E. W. Lane, F. E. Bonner, Joe W. Johnson, Harold H. Munger, William Mayo Venable, Edward Gerald Smith, Clarence S. Jarvis, L. Standish Hall, and J. C. Stevens. 1255.

"Sedimentation and the Design of Settling Tanks." Thomas R. Camp. 895. Discussion: Norval E. Anderson, R. A. Mulholland, P. Charles Stein, Lynn Perry, E. Sherman Chase, Rolf Eliassen, and Thomas R. Camp. 937.

"Transportation of Suspended Sediment by Water." Vito A. Vanoni. (With Discussion.) 67.

SEEPAGE

Percentage porosities at three levels. 352.

"The Effect of Blankets on Seepage Through Pervious Foundations." Preston T. Bennett. (With Discussion.) 215.

"Utilization of Ground-Water Storage in Stream System Development." Harold Conkling. (With Discussion.) 275.

SETTLING BASINS

"Sedimentation and the Design of Settling Tanks." Thomas R. Camp. (With Discussion.) 895.

SEWAGE DISPOSAL

"Computing Coagulant Requirements in Sludge Conditioning." A. L. Genter. (With Discussion.) 635.

"Sedimentation and the Design of Settling Tanks." Thomas R. Camp. (With Discussion.) 895.

SEWAGE TREATMENT

See SEWAGE DISPOSAL

SIPHONS

"Determination of Pressures Within a Siphon Spillway." I. M. Nelidov. 679. Discussion: A. Shukry, and I. M. Nelidov. 689.

SLABS

"Structural Skew Plates." F. L. Ehasz. 1011. Discussion: John W. Allen, William A. Conwell, Julius Sigman, and F. L. Ehasz. 1037.

SLUDGE DIGESTION

"Computing Coagulant Requirements in Sludge Conditioning." A. L. Genter. 635. Discussion: Paul D. McNamee, D. L. McLean, K. Fraschina, Walter H. Brown, Jr., and A. L. Genter. 659.

SOILS

"Design of Roadbeds." Ira B. Mullis. (With Discussion.) 699.

"The Effect of Blankets on Seepage Through Pervious Foundations." Preston T. Bennett. (With Discussion.) 215.

SPILLWAYS

"Determination of Pressures Within a Siphon Spillway." I. M. Nelidov. (With Discussion.) 679.

SPIRALS

Memoir of. 1506.

MACKENZIE, D. A.
Moving loads. 843.

MacKENZIE, LEON RODERICK
Memoir of. 1502.

McKIM, DONALD GRANT
Memoir of. 1596.

McLEAN, D. L.
Coagulant requirements. 661.

McMILLAN, JOHN GILMORE
Memoir of. 1507.

McNAMEE, PAUL D.
Coagulant requirements. 659.

McNEW, J. T. L.
Design of roadbeds. 720.

MARKS, CONSTANT R., III
"Design Developments—Structures of the Tennessee Valley Authority (Symposium): Design of Hydroelectric Stations." 1175.

MAVIS, F. T.
Flow expansions. 375.

MEISSNER, H. S.
"Deterioration of Concrete Dams Due to Alkali-Aggregate Reaction." 743.

MERRITT, FREDERICK S.
Moving loads. 867.

MEYER, ADOLF A.
"Design Developments—Structures of the Tennessee Valley Authority (Symposium): Civil Engineering Features of Steam Plant at Watts Bar." 1190.

MEYER, ADOLPH F.
Evaporation. 53.

MEYERDICK, C. E.
Movable dam. 263.

MITSCH, JOHN DONALD
Memoir of. 1597.

MOISSEIFF, LEON SOLOMON
Memoir of. 1509.

MOORE, RAYMOND L.
Photogrammetry. 579.

MOTLEY, PHILLIPS BATHURST
Memoir of. 1512.

MULHOLLAND, R. A.
Settling tanks. 938.

MULLIS, IRA B.
"Design of Roadbeds." 699.

MUNGER, HAROLD H.
Future of reservoirs. 1319.

MURRAY, EVERETT BODMAN
Memoir of. 1513.

NEEDHAM, EGBERT STEPHEN
Memoir of. 1514.

NEELD, CHARLES MARSHALL
Memoir of. 1517.

NELIDOV, I. M.
"Determination of Pressures Within a Siphon Spillway." 679.

NEMENYI, PAUL F.
Suspended sediment. 116.

NEWMARK, N. M.
Radiant heat. 1119.

OESTERBLOM, I.
Radiant heat. 1115.
Reduced equations. 157.

OGDEN, JAMES CLARENCE
Memoir of. 1518.

OLSEN, ARTHUR KERSHAW
Memoir of. 1519.

OSGOOD, WILLIAM R.
"Column Formulas." 165.

PALMER, SHEPARD BROWN
Memoir of. 1521.

PALO, GEORGE P.
"Design Developments—Structures of the Tennessee Valley Authority (Symposium): Design of Hydroelectric Stations." 1175.

PATERSON, HARRY THOMAS
Memoir of. 1522.

PEARSE, RALPH S.
Photogrammetry. 583.

PÉREZ GUERRA, GUSTAVO
Design of roadbeds. 721.

PERRY, LYNN
Settling tanks. 944.

PETERSEN, CLIFFORD
Moving loads. 886.

PETERSON, DEAN F., JR.
Structural concepts. 435.

PETERSON, H. V.
Future of reservoirs. 1287.

PHILLIPS, JASPER MARION
Memoir of. 1524.

POLIVKA, JAROSLAV
Reduced equations. 161.

POLLARD, WILLARD AVERELL, JR.
Memoir of. 1598.

POSEY, C. J.
Channel roughness. 563.

POWELL, RALPH W.
"Flow in a Channel of Definite Roughness." 531.
Suspended sediment. 103.

PROCTOR, RALPH R.
Alkali-aggregate reaction. 760.
PRYOR, WILLIAM T.
Transition spiral. 1002.
PULIDO y MORALES, RENÉ S.
Design of roadbeds. 728.
Transition spiral. 991.
PURCELL, STEUART
Memoir of. 1525.
RAMOS CASELLAS, RAMON
Memoir of. 1526.
RANDALL, ROBERT H.
Photogrammetry. 590.
READING, OLIVER S.
Photogrammetry. 593.
REED, OREN
TVA structures. 1215.
RIBBLE, JOHN MARSHALL
Memoir of. 1527.
RICH, GEORGE R.
Energy loss. 1081.
RIEGEL, ROSS M.
"Design Developments—Structures of the Tennessee Valley Authority (Symposium): Structural Features of Hydraulic Structures." 1160.
RIGGS, HENRY E.
Final Report of the Special Committee Authorized by the Board of Direction to Analyze and Discuss the 1943 Report of the National Association of Railroad and Utilities Commissioners' Committee on Depreciation on Principles of Depreciation. 1343.
RIGHTS, T. B.
Moving loads. 870.
ROBERTS, SAMUEL
Short-term records. 609.
ROBINSON, EDWARD WILLIAM
Memoir of. 1600.
ROBINSON, HOLTON DUNCAN
Memoir of. 1530.
ROHWER, CARL
Evaporation. 34.
ROLSMA, G.
Moving loads. 851.

ROSS, ELMER WAYLAND
  Memoir of. 1536.
ROUSE, HUNTER
  Energy loss. 1087.
RUGGLES, ARTHUR VALENTINE
  Memoir of. 1538.
RUSSELL, WILFORD BATES
  Memoir of. 1540.
RYAN, W. J.
  Photogrammetry. 591.
SABIN, L. C.
  Movable dam. 265.
SAGER, GEORGE HENRY, JR.
  Memoir of. 1541.
SARGENT, A. W.
  Movable dam. 269.
SCHAFFNER, CHARLES E.
  Moving loads. 844.
SCHURE, STANLEY S.
  Moving loads. 855.
SCOTT, ALBERT LYON
  Memoir of. 1543.
SEABURY, GEORGE TILLEY
  Memoir of. 1411.
SHELDON, CHARLES SMITH
  Memoir of. 1545.
SHUKRY, A.
  Siphon spillway. 689.
SIGMAN, JULIUS
  Skew plates. 1041.
SMART, R. L.
  TVA structures. 1215.
SMITH, EDWARD GERALD
  Future of reservoirs. 1321.
SMITH, G. E. P.
  Future of reservoirs. 1270.
SMITH, LESTER CHAUNCEY
  Memoir of. 1601.
SMITH, RALPH CARL
  Memoir of. 1602.

SONDEREGGER, A. L.
  Water supply. 1145.
SOPP, C. W.
  Ground-water storage. 326.
SORKIN, JOSEF
  Reduced equations. 155.
SOULE, CARLTON MANSON
  Memoir of. 1546.
SOUTHWORTH, JAY L.
  Movable dam. 264.
SPAULDING, RALPH E.
  Column formulas. 183.
SPENCER, R. W.
  Alkali-aggregate reaction. 776.
SPIKER, WILLIAM C.
  Structural concepts. 431.
SPORN, PHILIP
  TVA structures. 1205.
STANTON, THOMAS E.
  Alkali-aggregate reaction. 768.
STEIN, P. CHARLES
  Settling tanks. 939.
STEVENS, J. C.
  Energy loss. 1084.
  Flow expansions. 380.
  "Future of Lake Mead and Elephant Butte Reservoir." 1231.
STEWART, RALPH W.
  Moving loads. 834.
  Structural concepts. 405.
  Transition spiral. 979.
STILES, LINFORD SPEARING
  Memoir of. 1547.
STRAUSS, MAX W.
  Moving loads. 841.
  Structural concepts. 413.
STREIFF, ABRAHAM
  TVA structures. 1216.
STUCKEY, JASPER L.
  Design of roadbeds. 724.

SWENDSEN, GEORGE LEWIS
Memoir of. 1551.

TCHIKOFF, VALENTINE VASILIEVISH
Memoir of. 1552.

TEBBETTS, JAMES HARGRAVES
Memoir of. 1603.

THAYER, WARREN N.
Water supply. 1148.

THOMAS, A. R.
Flow expansions. 388.

THOMPSON, DONALD
Transition spiral. 981.

THORNTHWAITE, C. W.
Evaporation. 37.

TOWNROW, FREDERICK WAZNEY
Memoir of. 1605.

TRUE, ALBERT OTIS
Memoir of. 1606.

TURNBULL, W. J.
Pervious foundations. 237.

TURNER, DANIEL LAWRENCE
Memoir of. 1555.

TYLER, I. L.
TVA structures. 1204.

VAIL, CHARLES DAVIS
Memoir of. 1556.

VAN den BROEK, J. A.
Tunnel stresses. 475.

VAN DRIEST, E. R.
Flow expansions. 386.
Suspended sediment. 106.

VAN METER, ROY O.
Cross connections. 628.

VAN ORNUM, JOHN LANE
Memoir of. 1559.

VANONI, VITO A.
"Transportation of Suspended Sediment by Water." 67.

VEATCH, N. T.

Final Report of the Special Committee Authorized by the Board of Direction to Analyze and Discuss the 1943 Report of the National Association of Railroad and Utilities Commissioners' Committee on Depreciation on Principles of Depreciation. 1343.

VENABLE, WILLIAM MAYO

Future of reservoirs. 1320.

WASIL, BENJAMIN A.

Photogrammetry. 587.

WEATHERLY, EVERETT PINE

Memoir of. 1563.

WEIDEMANN, EINAR

Memoir of. 1566.

WEISS, CAMILLO

"Interrelation of Certain Structural Concepts." 391.

WHITMORE, GEORGE D.

Photogrammetry. 585.

WILEY, C. C.

Transition spiral. 992.

WINTER, GEORGE

Column formulas. 173.

WITT, J. C.

Alkali-aggregate reaction. 780.

WITZIG, BERARD J.

Future of reservoirs. 1300.

Suspended sediment. 111.

WOOD, DETHIC HEWITT

Memoir of. 1567.

WOOD, WILLIAM HOWELL

Memoir of. 1608.

WOODS, K. B.

Design of roadbeds. 730.

YOUNG, ARTHUR A.

Evaporation. 43.

ZIESING, AUGUST

Memoir of. 1569.
